Nest-Building Fish.—The habits of those few fishes which build nests for their progeny are very curious, and indicate a highly-developed instinct. One of these, the Gourami (*Asphronemus olfax*), has lately been studied by M. Carbonnier in his private aquarium. The male animal constructs a nest of froth of considerable size, 15 to 18 centimetres horizontal diameter and 10 to 12 centimetres height. He prepares the bubbles in the air (which he sucks in and then expels), strengthening them with mucous matter from his mouth, and brings them into the nest. Sometimes the buccal secretion will fail him, whereupon he goes to the bottom in search of some confervæ, which he sucks and bites for a little, in order to stimulate the act of secretion. The nest got ready, the female is nduced to enter. Not less curious is the way in which the male brings the eggs from the bottom into the nest. He seems unable to bring them up in his mouth; instead of this, he first akes in an abundant supply of air, then descending, he places himself under the eggs, and all at once, by a violent contraction of the muscles in the interior of the mouth and pharynx, he forces out the air he had accumulated, by his gills. This air, finely divided or pulverised, in some sort, by the lamellæ and fringes of the gills, escapes in the form of two jets of veritable gaseous powder, which envelops the eggs and raises them to the surface. In this manœuvre, M. Carbonnier says, the Gourami quite disappeared in a kind of air-mist, and when this had dissipated, he reappeared with a multitude of air-bubbles like little pearls, clinging all over his body.

Beaver in Siberia.—The beaver which, some centuries ago, was so numerous in Russia and Western Siberia, and which was upposed to have totally disappeared from both countries, continues to exist on the rivulet Pelyin. M. Poliakoff has procured rom an ostyack on the Obi five skins of these animals killed ast year, and he has engaged a hunter to procure this winter omplete specimens for the Museum of the St. Petersburg Academy. No farther back than a century ago the beaver was ommon on one of the affluents of the Irtysh, Bobrofka, but it as now totally disappeared from the locality, the last colony xisting probably on the Pelyin.

NOTES

The first volume of "China," by the well-known geologist Baron von Richthofen, has just appeared. The Berlin Academy f Sciences has granted a generous sum to defray the expense of ublishing this costly work.

We have pleasure in announcing that a new Natural History ournal is about to be started, which is intended to form a bond f union among the various schools belonging to the Society of Friends in this country, both those for boys and girls. Some of he oldest societies of the kind in the country are in connection ith these schools, especially the one at York, to which reference has more than once been made in these columns. The journal is intended to be specially devoted to young beginners; he main object being to awaken a personal interest in natural istory pursuits, and to induce tyros to make and *record* observations. By this means it is hoped to promote a genuine study in lace of the indiscriminate collecting now so much in vogue. Other cognate subjects will also be taken up as space permits, uch as chemistry, carpentry, &c. It is intended to publish the rst number on February 15; communications, which are warmly nvited, should be addressed to J. E. Clark, B.Sc., 20, Bootham, York.

Under the title of the "Indian Miscellany," a work is announced by Mr. J. Munsell, of Albany, New York, on the history, rts, inventions, languages, religions, traditions, and superstitions of the American aborigines; with descriptions of their omestic life, manners, customs, traits, governments, wars, treaties, amusements, exploits, &c.; together with sketches of travel and exploration in the Indian country, incidents of border warfare, journals of military expeditions, narratives of captivity, anecdotes of pioneer adventure, missionary relations, &c.

M. Ed. Becquerel has been elected president of the French Physical Society, which seems, like its English sister society, to be doing excellent work.

The Council of the Geographical Society of Paris has appointed M. Levasseur president for 1877. MM. Daubrée and Quatrefages have been appointed vice-presidents, and M. Maunoir has been continued general secretary.

It is stated on good authority that the measurement of the photographs taken by the French parties during the transit of Venus is not progressing favourably. More than 1,000 plates are to be investigated micrographically, and at the present moment only forty-seven have been disposed of. Unforeseen difficulties are said to have arisen.

In 1828 M. Janson de Sailly, a French barrister who had married a sister of the celebrated Berryer, left by will his fortune to the French University, under the condition of creating a high school in the Quartier des Champs Elysées, to be named Janson College. The will was accepted by the Government, but the heirs tried to get it cancelled, and a law-suit was instituted, which was ended only in December, 1876. The Janson College will be inaugurated in 1878. The legacy is quite adequate to carry out the purpose of the testator, who was proprietor of the greatest part of a large estate.

German educational statistics show that in Saxony one out of 1,194 of the total male population is in actual attendance upon a university, while in Prussia the proportion is 1 io 1,328.

The next annual meeting of the *Deutsche geologische Gesellschaft* takes place at Vienna, in September of this year.

The Council of the Society of Arts have made arrangements for the delivery of six lectures on various scientific subjects, which will take the place of the usual papers and discussions, on six Wednesday evenings during the session. The following gentlemen have each consented to deliver one of the lectures:—Sir John Lubbock, Bart., F.R.S., Mr. E. J. Reed, C.B., M.P., Prof. W. K. Clifford, M.A., F.R.S., Prof. Alexander Kennedy, C.E., Dr. B. W. Richardson, F.R.S., Mr. James Baillie Hamilton.

The Bremen Geographical Society has received a report from Capt. Wiggins dated Jenissei, November 25, in which he gives more fully the results of his late voyage to Siberia. The Podaratta Bay was found to be exceedingly shallow, and the river itself could not be ascended by craft drawing over two feet of water. Special stress is laid upon the discovery of the channel for sea-going vessels up the picturesque Jenissei as far as Kureika. Numerous observations of the temperature of the air and water, the specific gravity of the latter, &c., were taken during the progress of the voyage. These all tend to show that the Gulf Stream and equatorial currents exert a decided influence much farther to the east than was hitherto supposed, as they pass through the straits of Jugor and Waigat into the Karian Sea.

The adherence of air round a current of some fluid or liquid when this is forced through the air, has been utilised in various ways, as in water bellows, the blast pipe of locomotives, Sprengel's air-pump, the Bunsen burner, &c. Prof. Teclu, of Vienna, has recently described, in *Poggendorff's Annalen*, a simple arrangement, in which a jet of steam is used to do the work of an air-pump. A small steam boiler containing 1·5 litres of water, and tested to something over one atmosphere, is heated over a gas furnace. It has a safety-valve, which also serves for admission of water when necessary. From above rises a brass steam pipe consisting of two similar parts, each of which is a tube narrowing upwards; the terminal aperture of the lower tube (*a*) is situated just where the contraction of the upper tube (*b*) terminates, leaving a small annular aperture. Two lateral tubes proceed from the wide portion of the upper tube, one to the vessel to be exhausted, the other to a manometer. It will be seen that the steam issuing from the boiler exerts suction on the air in the connected vessels.

AT a meeting of the Edinburgh Botanical Society, held on January 11, Mr. M'Nab made a second communication on the scarcity of holly berries at Christmas. He has learned from correspondents in various parts of the kingdom that the scarcity of holly berries has been very general. The only places where the supply of berries has been abundant are in the Highlands, in such districts as the Trossachs, and in the vicinity of Loch Katrine and Loch Ard. At Ranelagh, near Dublin, few berries were to be obtained, but several of the trees were covered with clusters of white and cream-coloured flowers, and it is of interest to note that all the flowers, both open and past, of the specimens received by Mr. M'Nab from Ranelagh, were hermaphrodite.

AT a meeting of the Glasgow Philosophical Society, held on Wednesday, January 10, it was agreed, on the motion of Sir William Thomson, to petition both houses of Parliament for the amendment of the Patent Laws, the objects aimed at being the reduction of the stamp duty on patents, an extension of the time for which patents were granted, and the abolition in connection with the notice to proceed.

AT the second meeting of the Edinburgh Naturalists' Field Club, which was held on Friday last, a lecture on "Foraminifera," copiously illustrated by diagrams and microscopical preparations, was delivered by Mr. D'Arcy W. Thompson, a pupil of the present seventh class of the Edinburgh Academy. Science lectures *by* schoolboys are a much rarer occurrence than science lectures *to* them.

IN a note to the Roman Academy on the rate of oratorial utterance, M. Mariotti recalls an observation made by Gibbon that a facile English orator pronounced 7,200 words in an hour, *i.e.*, 120 in a minute, and two in a second. Though it might seem possible to investigate the velocity of the Greek and Roman orators, knowing that the judicial orations in Athens were recited in a space of time determined by the clepsydra, yet their methods render conjecture somewhat vague. Thus, *e.g.*, it is said that Caius Gracchus, when speaking in the forum, had a servant concealed behind him, who, with an ivory instrument, signalled to him at the proper moments to raise or to lower his voice. Nowadays, when parliamentary discussions, as has been said, are little more than animated conversations, accurate observations may be made by means of stenography on the rate of speaking of various orators. M. Mariotti gives some such data from the Sub-Alpine and Italian Parliaments. De Foresta pronounced sixty words in a minute; Massimo d'Azaglio, 90; Gioberti, 100; Ratazzi, 150; Mameli, 180; Cordova, the quickest, was able to pronounce as many as 210. The very rapid orators, M. Mariotti says, are rather admired than effective, such as Macaulay in England, and Cordova in Italy. The mind of the hearer is not allowed sufficient time to take in the meaning. It is possible, speaking rapidly in the Italian tongue, to pronounce 300 words in a minute. Comparative observations on the subject in parliaments of different countries, would afford important data regarding various tongues, and suggest interesting psychological considerations. From observations in the Parliament of Athens, it might be possible to conjecture the velocity of the ancient Greek orators. In this way stenography might render valuable services to philology and philosophy.

WE notice in the January number of the *Geological Magazine* a paper by Mr. James Durham on "The 'Kames' in the Neighbourhood of Newport, Fife, N.B.," accompanied by a sketch-map of the locality. Unhappily, the paper is written much in the same style as too many papers on kames have already been written, and we find in it, as is too often the case, more generalisations than thorough descriptions of the interior structure of these interesting formations, and not even a single detailed section. It gives us an opportunity, however, of observing that only thorough explorations of the structure of those kames the interior of which is rendered accessible by adequate cuttings, together with detailed studies of the directions, positions, and forms of the kames, discussed in connection with the topography of the locality and its neighbourhood, can help us to settle the question as to the origin of kames, so much debated hitherto without arriving at any definitive result. As to the conclusions of the author, viz., that "the kames" owe their present forms to the same denuding agencies as are at present in operation, we must object that, even if the author had proved his statement with reference to the Newport kames, he was by no means entitled to generalise from it; there are hundreds of kames and thousands of totally identical gravelly mounds and ridges the shapes of which have nothing to do with denuding agencies.

THE first number of the *Veröffentlichungen des kaiserlichen deutschen Gesundheitsamtes*, appeared last week. It gives the mortality statistics of about 150 German cities and a large number of foreign cities, and supplies a most valuable picture of the progress of epidemics as well as the general statistics of disease, and the working of all sanitary regulations at home and abroad. A graphic representation of the meteorology of the past week is also added.

VERY high floods, second only to those of 1872, are reported, by Russian newspapers, from the shores of the Amoor. After unusually heavy rains, which fell almost without interruption from the middle of July until the end of August, the waters of the great river rose so as to menace even Blagovieshensk, built on a comparatively high bank, and overflowed the villages and fields of the Upper and Middle Amoor. A very heavy gale visited also the Lower Amoor on the night of September 18 and 19. Some barges were destroyed, a steamer was much damaged, and some houses on the shore at Khabarofka were washed away.

THE rain which fell at St. Jaen, in the Côtes-du-Nord, on the night of December 29-30, 1876, was observed to be tinged red. A bottle filled with the water has been sent to Dinant to be analysed microscopically and chemically.

THE French Government is selling by auction the last four balloons which were constructed during the siege for escaping from Paris. These balloons are considered unfit for service, and others will be constructed by the balloon committee, a credit of 200,000 francs having been placed in the budget of 1877 for military ballooning.

NEWS has been received from the *Frigorific*, which has arrived with its cargo of meat at La Plata, where experiments have been continued on the largest scale. The success is complete.

THE Paris-Lyons-Mediterranean Railway Company have ordered sixty locomotives to be constructed, which are intended to travel from Paris to Marseilles (1,820 kilometres) in twelve hours. The Northern Railway has established comparative experiments on the Westinghouse continuous brakes and electric brakes. The old hand-brakes are to be superseded at any co by the Northern Railway.

PROF. MACH, of the Vienna Academy, has recently made some experiments on the velocity of propagation of sound-waves from explosion. He finds that in course of the motion this velocity diminishes, and soon approximates to the ordinary velocity of sound. In one experiment, by means of a fall-apparatus with double hammers, two percussion caps were exploded (at a deerminate interval) at the two ends of a tube. From the displacement of the interference-band on the inner smoked surface of the tube, the velocities were found to be more than 700 metres over a stretch of 50 centimetres. With weaker explosions or longer stretches, the velocities were less. Again, a pistol-ball, whose velocity was determined, liberated at two tations, at a measurable interval of time, two electric discharges. From the displacement of the interference-band, the velocity appeared to be about 400 metres. Several other experiments are described in Prof. Mach's paper.

Mr. Frederick A. Ober has recently sailed from America or Martinique to commence an exploration of the West India Islands, under the patronage of the Smithsonian Institution. Mr. Ober proposes to begin at Martinique, and to collect the vertebrates on all the Leeward Islands, visiting each one in succession, and proceeding east and south by the Windward Islands to the Spanish Main. The work will probably occupy several years, and with it will be combined the taking of photographic views of the scenery and inhabitants. It is believed that, should Mr. Ober be as successful as he anticipates, a critical investigation of his collections by specialists will not only bring to light species long ago described and not met with for many years, but will include some new to science, and at the same time elucidate many interesting problems in physical and zoological geography.

Mr. John Murray has the following new works in the press:—"Scepticism in Geology, and the Reasons for it," by Verifier; "The Cradle of the Blue Nile," an account of a journey through the mountains of Abyssinia and the plains of Soudan, and a residence at the court of King John of Ethiopia, by E. A. De Cosson, F.R.G.S.; "Pioneering in South Brazil," a narrative of three years of forest and prairie life in Paranâ, by Th. P. Bigg Wither. These two last books will both be accompanied by maps and illustrations.

We have the following books on our table:—"Winds of Doctrine," by Ch. Elam (Smith, Elder, and Co.); "Thebes and its Five Greater Temples," by Capt. Abney, F.R.S. (Sampson Low and Co.); "Animal Physiology," by Prof. McKendrick (Chambers); "The Two Americas," by Sir R. Lambart Price Sampson Low and Co.); "The Discoveries of Prince Henry the Navigator," by R. H. Major (Sampson Low and Co.); "Darwiniana," by Prof. Asa Gray (Trübner); "Across the Vatna Jokull," by W. L. Watts (Longmans); Dr. Dobell's "Reports on Diseases of the Chest," vol. ii., 1876 (Smith, Elder, and Co.).

The additions to the Zoological Society's Gardens during the past week include two Secretary Vultures (*Serpentarius reptilivorus*) from South Africa, presented by Capt. Larmer, of s.s. *African*; two Crowned Partridges (*Rollulus cristatus*) from Malacca, presented by Mr. Barclay Field; three Chukar Partridges (*Caccabis chukar*) from North-West India, presented by Capt. Newton Pauli; two Caroline Conures (*Conurus carolinensis*) from North America, presented by Mr. L. Delves Broughton; a Wood Owl (*Syrnium aluco*), European, presented by Mrs. A. O. Faulkner.

SCIENTIFIC SERIALS

The *American Journal of Science and Arts*, December, 1876.—Experiments on the nature of the force involved in Crookes's radiometer, by O. N. Rood.—Experiments on the sympathetic resonance of tuning-forks, by Robert Spice.—Types of orographic structure, by J. W. Powell.—On the ethers of uric acid, by H. B. Hill.—Notice of a meteorite from Madison Co., N.C., by B. S. Burton.—On a recent discovery of carboniferous Batrachians in Nova Scotia, by J. W. Dawson.—On the association of crystals of quartz and calcite in parallel position, as observed on a specimen from the Yellowstone Park, by Edward E. Dana.—Principal characters of the American Pterodactyls, by O. C. Marsh.

SOCIETIES AND ACADEMIES

London

Mathematical Society, January 11.—Mr. S. Roberts, treasurer, in the chair.—Mr. G. W. von Tunzelmann was elected a member.—The following communications were made to the Society:—Determinant conditions for curves, or surfaces, of the same order, having all their intersections common, by Mr. J. Hammond.—Numerical values of the first twelve powers of π, of their reciprocals, and of certain other related quantities, by Mr. J. W. L. Glaisher, F.R.S.—On some general classes of multiple definite integrals, by Mr. E. B. Elliott.—On the partial differential $s + Pp + Qq + Z = 0$, by Prof. H. W. Lloyd Tanner.—Determination of the axes of a conic in tri-linear co-ordinates, by Mr. J. J. Walker.—On some elliptic-function properties, by Prof. H. J. S. Smith, F.R.S.

Linnean Society, December 21, 1876.—Prof. Allman, president, in the chair.—Mr. Thomas Christy and Mr. Robert Drane were balloted for and duly elected Fellows of the Society.—The butterflies of Malacca, formed the subject of a paper by Mr. A. G. Butler. Of 258 species now registered from Malacca thirty-six are endemic; of the remainder sixty-five also belong to Assam or Nepal, thirty-eight to Moulmein, thirty-three to Ceylon, ninety-four to Penang, forty-six to Singapore, 112 to Borneo, forty-one to Sumatra, eighty-seven to Java, thirty-nine to Siam, twenty-six to China, two to New Hebrides, and six to Australia. Thus the Malaccan butterflies preponderate towards those of the Indian region. For several reasons, however, the so-called Penang fauna must be accepted with considerable qualifications.—A communication was read from Mr. J. R. Jackson on the commercial uses of a species of cane termed "Whangee." This was shown to be a species of *Phyllostachys*, possibly *P. nigra*, and supposed to be from China. That common in the trade he considers not to be the stem proper but the rhizome; pale-coloured, as introduced, plants of the kind in question grown in England produce a black cane, hence bleaching must be resorted to with the commercial sort.—*Craniorrhinus waldeni* is the name of a new Hornbill from the Island of Panay (Philippines), described by Mr. R. B. Sharpe. It is allied to *C. cassidix*. The new species was found by Prof. Steere in a virgin forest in the mountainous range of the island.—An extract of a letter from Dr. J. Anderson, of Calcutta, was read. It mentioned some curious facts in connection with the Hornbills *Hydrocissa albirostris* and *Aceros subruficollis*. These birds greedily devour, head foremost, the smaller kinds of the feathered tribe, and before doing so break all the bones of the bodies and toss the bird about.—The Secretary read some morphological notes on certain species of *Thunbergia*, by Mr. Marcus Hartog. He states that microscopical sections of *T. laurifolia* reveal axillary buds inside the sixth and eighth pair of bracts, the basal elevations becoming pedicel and bractlets, and inside these, by repetition, sister buds arise. The flowers are thus axillary buds formed in succession from the axis outwards and are as independent as if they had arisen side by side.—Dr. Buchanan White brought forward a paper on the male genital armature in the European Rhopalocera. His researches yield evidence that as in some other orders of the Insecta the appreciable structural variations of the organs in question afford good characters whereby to distinguish not only genera, but species, of the above limited group of Lepidoptera.—Prof. Flower communicated a memoir on the morphology of mammalian *Ossicula auditus*, by Mr. A. G. H. Doran. While dealing with these diminutive bones *in extenso*, the author more particularly confined his summary to those of the Insectivora, Cheiroptera, Cetacea, Sirenia, Edentata, Marsupialia, and Monotremata. In the first of these groups the ossicula present no positive or marked characteristic. Among the bats there is a resemblance to what obtains in the shrews, except in the genus *Pteropus*, where the malleus is of a lower type. Of whales, *Balæna* has the most generalised type; the dolphins have relatively stout stapedial crura and other marked features; *Platanista* has slightly modified ossicula. Those of Sirenia are distinguished by weight and outline. Certain of the Edentata (armadillos) differ among themselves, and so do the sloths and ant-eaters, as far as concerns their internal ear-bones. Marsupials possess ossicula of a low grade still descending in the Monotremata. The general conclusion arrived at is that even by the so-to-say subsidiary differentiation of the auditory ossicles doubtful affinities in some cases receive a certain interpretation.—*Actæmorpha erosa* is the name given to a new genus and species of crustacean described by Mr. E. J. Miers. It was dredged at seven fathoms, and came up along with a number of *Cancroidea*, &c., and which it resembles much, though structurally undoubtedly belonging to the family Leucosiidæ.—Mr. H. N. Moseley tendered a paper descriptive of two new and remarkable forms of deep-sea Ascidians obtained by him during the *Challenger* expedition. The first of these aberrant forms was trawled in the North Pacific, from a depth of 2,900 fathoms. This *Hypobythius calycodes*, of cup-like shape, is probably allied to *Boltenia*, but differs, among other things, in possessing a series of cartilaginous plates developed with symmetrical arrangement on its otherwise soft test. The second Ascidian, named by the author, *Octacnemus bythius*, was got from 1,070 fathoms. Star-shaped or of eight-rayed form, its gill-sac is nearly horizontal, and gill-network absent; muscular prolongations of the tunic run into the curious conical protuberances of the test; nucleus contracted and small like that of *Salpa*. This unique specimen, so far as our present knowledge goes, is presumed to be without living allies.

Anthropological Institute, January 9.—Col. A. Lane Fox, president, in the chair.—Mr. Henry Hyde Clarke exhibited a handsome feather dress from the Amazon.—Mr. Moseley, naturalist to the *Challenger* expedition, then read a long and most interesting account of the inhabitants of the Admiralty Islands. He considered that in their arts, as shown in the ornamentation of their weapons, &c., they resembled the natives of New Guinea, while in a peculiar note in their chants or singing he noticed a strong Fijian resemblance; their manner of hafting the stone implements differed from that in other groups, the stone being fixed in a slot in the wood. Obsidian spear and knife heads were shown, the mounting of the obsidian flakes in the spear heads being effected with a strong gum and twine. The lecturer described most fully the customs, dress, and manners of the natives, and gave some thirty-five words of the language. The whole was illustrated with maps, sketches, and numerous objects. The president and Prof. Rolleston took part in the discussion.—Mr. J. P. [illegible]arrison then read the report on recent excavations at Cissbury Camp. The pit that has been excavated immediately adjoins the one cleared out by Mr. E. Willett in 1874, and is of nearly the same size. There are two platforms, one above the other, in a kind of apse on the highest, or eastern side of the pit. Galleries radiate in all directions, excepting towards the west, where, under a mass of chalk rock which projects into the pit some six feet, there is a small chamber. Outside of it a quantity of charcoal and smoked chalk indicated that a fire had been made on the floor of the pit. Lines in different combinations were found at the entrances of two of the galleries and also on loose blocks of chalk; some of them may, perhaps, possess a definite meaning, but the majority were most probably idle marks.

PARIS

Academy of Sciences, January 3.—M. Peligot in the chair. The following papers were read:—Observations on a reclamation recently presented by M. Faye, with regard to whirlwinds produced in the atmosphere, by P. Secchi. The supposition of descending currents in whirlwinds is very old; we find it in Lucretius and the ancient physicists. Besides trombes with descending pressure, there are many which exert suction. M. Faye replied, denying the latter fact, maintaining the novelty of his ideas, &c.—Practical processes for the destruction of Phylloxera, by M. Boiteau. He describes an apparatus, a perforator with automatic distribution, employed in applying the insecticide liquid.—The programme of a prize founded by the late Dr. Bressa, was announced from the President of the Turin Academy of Sciences. It is 12,000 francs, and to be awarded every two years to Italian and foreign *savants* alternately, for the most brilliant and useful discovery or most remarkable work in the physical and experimental sciences, natural history, pure and applied mathematics, physiology, and pathology, not excluding geology, history, geography, and statistics. First award, in 1879, to a *savant* of any nationality.—The cyclic or logarithmic periods of the quadratrix of an algebraic curve of degree m are the products by $2\pi\sqrt{-1}$ of the roots of an algebraic equation of degree m, which may always be obtained, and the coefficients of which are rational functions of those of the equation of the curve proposed. Theorem by M. Maximilien Marie.—On the cause of motion in the radiometer, by MM. Bertin and Garbe. In a suspended radiometer, according to the initial conditions, the movement of the vessel may be *nil*, positive, or negative, and thus may be explained various errors of observation. From the equation $I\omega + I'\omega' = \text{const.}$ (where I, I' are the moments of inertia of vessel and vane-system, $\omega\ \omega'$ their angular velocities), the authors draw several consequences which are verified by experiment.—On the flow of mercury by capillary tubes, by M. Villari. The quantity which flows in a second is proportional to the pressure under which the flow occurs, and to the fourth power of the radius of the tubes, and inversely proportional to the length of the tubes, if a certain minimum length have been passed which is smaller the narrower the tubes, and the less the pressure. For tubes with elliptic section, the minimum length under which these laws are no longer verified is smaller than for circular tubes whose radius is equal to the mean radius of the elliptical section. The quantity of flowing mercury, lastly, depends on a certain constant, which depends on the form of aperture of the tube and the nature of the sides.—On an experiment similar to that of singing flames, by M. Montenat. Into a long vertical metallic tube is lowered a metallic basket with glowing charcoal. When this has reached the lower part, the air-current produces a sound. On raising the charcoal towards the middle, the sounds increase, diminish, and cease; on continuing the movement they recur, but at the double octave of the first, and they cease as the charcoal nears the orifice. M. Jamin recalled M. Kastner's pyrophone.—On the rotatory power of mannite and its derivatives, by M. Bouchardat. Contrary to MM. Müntz and Aubin, who supposed mannite to be a substance with indifferent rotatory power, it is shown to possess a real levorotatory power near $-0° 15'$.—Researches on Melezitose, by M. Villiers.—Remarks on this communication and on the constitution of the isomerous sugars of cane sugar, by M. Berthelot. The unison of two molecules of the same glucose, regarded in turn as aldehyde and as alcohol, produces three distinct types of isomerous saccharoses. Of these three types, mixed ether, mixed aldehyde, and ether aldehyde, the first and third alone are capable of reproducing their generators by simple hydration, under the influence of acids or ferments.—Graphic study of the movements of the brain in man, by MM. Giacomini and Mosso.—On the alterations of quaternary deposits by atmospheric agents, by M. Vanden Broeck. Such alterations in the Paris valley permit of assimilating the red diluvium to the grey, a simple *facies* of modification of the same layer.—M. Virlet d'Aoust described a lunar halo observed by him at Paris on the 30th ult.

THURSDAY, JANUARY 25, 1877

THE ENCYCLOPÆDIA BRITANNICA

Encyclopædia Britannica. Ninth Edition. Vol. V. (Edinburgh: A. and C. Black, 1876.)

THE article of greatest scientific interest in this volume is, of course, that on Chemistry. We can conceive of few literary tasks more trying to a duly qualified and conscientious writer than to attempt to give a comprehensive and well-balanced account of the rise, progress, and present position of a science like chemistry within an encyclopædia article of such compass as even the most compliant of editors would tolerate. And we must confess at the outset that it was with some feeling of sympathy for its authors, engendered by this reflection, that we commenced the examination of their essay—a feeling, however, which quickly altered its complexion as the consciousness grew upon us that in everything which is essential it may fairly compare with any one of its predecessors. And than this, no higher praise, we think, is possible.

The article divides itself, naturally, into three parts. In the first part, which we owe to Mr. F. H. Butler, is traced the origin and growth of chemistry. Its only fault is its exceeding brevity; it is hardly to be expected that within the space of some six or seven pages we can have a picture as lively or as complete as we find in the works of Hoefer or of Hermann Kopp. Of the birth of chemistry very little is said, and only the slightest reference is made to its association with the Greeks, Arabians, and Egyptians. With the rise of the Spagyrists with Paracelsus, who taught that the true use of chemistry is not to make gold but medicines, we seem to perceive the first attempts at a rational pursuit of the study, but the crooked manner in which the sect sought to advance its doctrine of the threefold constitution of matter was too much for the patience even of the gentle Robert Boyle, who had scant mercy for "the sooty empiricks, having their eyes darkened and their brains troubled with the smoke of their furnaces," who were "wont to endeavour to evince their salt, sulphur, and mercury (to which they gave the canting title of hypostatical principles) to be the true principles of things." The growth of Iatro-Chemistry until its final overthrow by Hoffmann so late as the beginning of the eighteenth century is concisely and carefully worked out, and the relations of its doctrines to those of Becher and Stahl are made apparent. Indeed the largest portion of this section of the article is devoted to the Phlogistic period, and the theory itself is set in a proper light. It has been too much the fashion to decry the services of Stahl's great conception, and people have marvelled that men of insight and logical minds—such men as Bergmann, Macquer, Scheele, or Cavendish—could have been hoodwinked by such a doctrine. But the theory was perfectly consistent in the outset, and it was only by the very excellence with which it served the purpose of a great theory that it fell. We are glad to find, too, that the services of Black and Cavendish as the real founders of quantitative chemistry meet with a just appreciation. The labours of Lavoisier are estimated with equal impartiality. For, as Liebig declares, although "Lavoisier discovered no new body, no new property, no natural phenomenon previously unknown . . . his immortal glory consisted in this—that he infused into the body of the science a new spirit; but"—he is careful to add—"the members of that body were already in existence and rightly joined together." It may be worth while noting that the date of Lavoisier's famous memoir "On the Nature of the Principle which Combines with the Metals during their Calcination and which Augments their Weight," is given as 1755, at which time if, as some authorities declare, he was born in 1745 (our author says 1743), the great chemist would be of the tender age of ten years; the careful reader would doubtless marvel at so remarkable an instance of precocity did he not discover from the context that the memoir must be antedated by at least twenty years. That *clarté* which was the distinguishing feature of Lavoisier's mind is reflected in his "Traité de Chimie," with an outline of which Mr. Butler fitly closes his account of this stirring epoch. It is instructive to trace the progress of our knowledge of the elementary bodies from the date of the publication of that work. Excluding light and caloric, Lavoisier recognised some thirty simple substances; since his time the number of the elements has doubled itself, but it is remarkable to observe how slow, with all our appliances, is the rate of discovery in these degenerate days. Gallium, the latest on the list, was brought to light in 1875. If we divide the lapsed portion of the present century into periods of twenty-five years, we find that the times of discovery distribute themselves as follows:—

1800–1825	22	New elements.
1825–1850	10	,, ,,
1850–1875	5	,, ,,

And yet, if we may credit M. Mendelejeff and his Laws of Periodicity, we have nothing like our proper complement of elements. Obviously, therefore, if the present rate of increase is to be maintained, the occupation of the chemist will not be gone for some time to come; ages must elapse before even the alphabet of his science is constructed; and by the time that Macaulay's Richard Quongti goes to complete his studies at the University of Tombuctoo, attracted by the high scientific character of Prof. Quashaboo, the learned professor will doubtless be engaged on the article "Chemistry," to occupy an entire volume of the 101st edition of the "Britannica," which will still be published by the eminent firm of Black.

Mr. Butler repeats the common statement, that the atomic theory first suggested itself to Dalton during his investigations on light carburetted hydrogen, and olefiant gas; the matter is probably of little moment, but as an historical fact it may be noted that the germ of his great work is to be found in his "Experimental Inquiry into the Proportion of the Several Gases Contained in the Atmosphere," read before the Literary and Philosophical Society of Manchester in November, 1802. In this paper Dalton states that one of the component gases—the oxygen—has the power of combining chemically, in two different proportions, with nitric oxide, to form two distinct compounds; and that the quantities by weight of oxygen which thus combine are in the ratio of one to two. It was this circumstance which first aroused Dalton's attention to the fact that one chemical element can combine with another in two different but definite proportions by weight. The study of the hydrocarbons and of carbon monoxide and dioxide was not taken up until two years later. (See Roscoe's "John Dalton and his Atomic Theory," Science Lectures, 1874.)

It has probably been from considerations of space that Mr. Butler has been unable to do more than glance, in the briefest possible manner, at the progress of modern theory, and we fear that in one or two instances, his reader may complain that in the effort to be concise he has become obscure. The idea of the polyatomicity of the elements is dismissed in a single line. The doctrine of *materia prima* has played such an important part in the past, and if we may judge from the signs of the times, is destined to play a still more important part in the future, that it is surely an omission of some moment to neglect all mention of Prout's hypothesis, of Dumas's extension of it, of its unquestionable influence upon the French school, and of the labours of Stas in connection with it. It is to be regretted too that so little is said of the rise of what may be termed the physical side of chemistry; of, for example, the influence of Dulong and Petit's law, of the law of Avogadro, of Mitscherlich's law of isomorphism, and that no direct reference is made to modern notions of the constitution of matter. It is true that certain of these matters are mentioned in subsequent sections of the general article, but they have their proper place in a historical account of the growth of the science. Lastly, the value of this portion of the article would have been greatly augmented by some reference to the bibliography of chemical history; Mr. Butler will excite the interest and curiosity of many students by his well-written and thoroughly readable sketch; he would have increased their gratitude by informing them how they might satisfy their craving for further knowledge.

The second, and by far the largest, portion of the article (it occupies nearly two-thirds of the whole) treats of Inorganic Chemistry, and is the work of Prof. Armstrong. In its main features it differs considerably from the ordinary run of descriptive treatises, although we question whether any one of them exhibits a more complete *coup d'œil* of the present position of this branch of the science. No space is wasted on mere *technics* (if we may employ a word which is sanctioned by Worcester), and it would be almost impossible for one ignorant of the science to employ it as a *vade mecum.* It is characterised by the manner in which broad and comprehensive principles are grasped and illustrated; entire groups are contrasted or compared, marched up and down as it were, like the skilful handling of battalions. Nevertheless, whilst we cannot but admire the fearless manner of his evolutions, we are afraid that Dr. Armstrong's love and zeal for system and generalisation occasionally allure him upon tender ground. The article is, presumably, not specially written for chemists, although we have no hesitation in affirming that every chemist who reads it will do so with pleasure, and therefore hypotheses such as that Epsom salts may be regarded as the normal magnesium salt of dihydrated sulphuric acid, H_6SO_6, crystallised with five molecules of water; or that the true formula of potassium perchlorate is $K_2Cl_2O_8$; or that the molecule of selenium dioxide is probably not represented by the formula SeO_2; or that the so-called hydrogen disulphide has presumably the composition H_2S_3; which are not the common property of the science, however ingenious and suggestive they may be, as these undoubtedly are, do not, we submit, come within the scope of a treatise which should primarily be a register of facts for the use of general readers. We allow that Dr. Armstrong is generally very cautious in his mode of stating these and similar conjectures, and possibly a very careful reader, whilst admitting their relevancy, would regard them in their proper light of tentative hypotheses; but all readers are not careful; the beaten path, we are told, is the safe path; and although scientific preachers, unlike other preachers, may with impunity be as heterodox as they please among themselves, it may be doubted how far it is expedient to preach any other than perfectly safe doctrine to the laity. This is really the only piece of adverse criticism we have to offer. When facts are known they are stated, and with remarkable perspicacity. As instances of careful and judicious compilation we may refer to the sections on ozone, hydrogen dioxide, and the organo-silicon compounds. A commendable feature is the recognition of the great importance of what we have before termed the physical side of chemistry; and in this respect Dr. Armstrong's treatise is unique: we have no hesitation in asserting that everything of value which recent investigation in the domain of chemical physics has brought to light is carefully interwoven in the proper place. The results of the thermo-chemical work of Thomsen and others; of the work of Troost and Hautefeuille and Brodie on dissociation phenomena; of the researches of Berthelot and others on the state of salts in solution; and of numerous other works scarcely less important, are duly set forth, and in such relation as to enforce their value and applicability. Indeed, in one or two cases we have the results of work which has not yet been fully published, as in the account of the action of nitric acid upon the various metals. It appears that with the exception of silver all the metals give with this acid a mixture, in varying proportions, of free nitrogen and nitrogen dioxide and monoxide. If, however, we compare the behaviour of the acid in the case of the three closely-related metals, magnesium, zinc, and cadmium, the reducing action of the evolved hydrogen is found to be greatest with the magnesium, and least with the cadmium, which result Dr. Armstrong connects with the fact that in the solution of these metals, the greatest amount of heat is evolved by magnesium and the least by cadmium. But that the comparative reducing power of the hydrogen evolved by the action of the three metals stands in no direct relation to the heat developed on solution, appears to be evident from the circumstance that in the case of the deoxidation of solutions of vanadium pentoxide by the action of these metals, the very reverse obtains: magnesium added to the solution of the pentoxide forms the trioxide, and the liquid becomes green; under no conditions, apparently, is this metal able to bring about a lower degree of oxidation; on the other hand, zinc and cadmium carry the deoxidation a stage further, and a lavender-coloured solution of the dioxide is obtained. And it would further appear from experiments which are in progress by the writer of this notice, that the amount of hydrogen which is effective in the work of reduction, as measured by its power of deoxidising ferric sulphate, amounts, in the case of zinc, to about twenty-two per cent. of that which is evolved; whereas in the case of magnesium, under circumstances as similar as possible, it is only about eight per cent. This, indeed, is but a portion of the broad problem of the connection between the conditions of a chemical change and its amount, one side of which, as Dr. Armstrong shows us, has already been attacked by Messrs. Harcourt and Esson. We may add, in this connection, that it would have conduced to clearness if, in the concise account of the work of these chemists, the term "thiosulphate" had been substituted for that of "hyposulphite," since we have the existence of Schützenberger's acid duly stated a few pages further on, and it, in accordance with Henry Watts's suggestion, is called hyposulphurous acid.

Of the remaining portion of the article, namely, that on organic chemistry, we have but little space to speak. In one respect Mr. Meldola has had the most difficult share of the work, for it is no light task to be obliged to concentrate the essence of modern organic chemistry within less than forty pages. The general arrangement of this section bears considerable resemblance to that of Prof. Schorlemmer's excellent Manual of the Carbon Compounds, and although it, of necessity, cannot be attractive to the general reader, we can congratulate Mr. Meldola on having produced a compilation which will be highly serviceable to chemists. PACKARD'S LIFE-HISTORIES OF ANIMALS

Life-Histories of Animals, including Man; or, Outlines of Comparative Embryology. By A. S. Packard, jun. (New York: Holt and Co.)

IN the rapidly-shifting condition of our knowledge of the development of all kinds of animals, it is a most difficult thing to produce a satisfactory treatise on Comparative Embryology. None the less such a work is much needed by our university students, and the little book which Dr. Packard has put together may be recommended to them as containing a great deal of the latest information on the subject, well illustrated by diagrams derived from a number of widely-scattered German, French, English, and American periodicals.

At first sight Dr. Packard's book appears considerably better than it really is. The student needs to be cautioned in using it, since it combines with much that is excellent a surprising amount of inaccuracy, and is sadly deficient in critical power. Dr. Packard is a student of German zoological journals, and is too ready to attach a large measure of importance to German work because it is German. Moreover, though he has himself engaged in researches on the embryology of the King Crab and of Insects, he has clearly not worked over a wide field in the subject, and consequently is not able to bring a trained experience to bear on the discrimination of the sound and the unsound observations and speculations of recent writers.

Amongst the good points of the book (to take some of these to begin with) we have a figure supplied by Dr. Bessels of his *Protobathybius Robesonii*; the account and figures of various Monads from James Clark, Dallinger, and Drysdale; the text and figures relating to the [illegible] figures of developing *Dentalium*; figures relating to the development of Arthropods from the works of Bobretzky, Kowalewsky, and Ganin; Morse's figures of developing Terebratulina; Agassiz's Tornaria and Balanoglossus; Wyman's embryonic skates; whilst good figures of larval Ascidians are also given.

Whilst insisting on the service which the book will render to the young student, we shall now point to some of its shortcomings. In the first place it is somewhat misleading to call attention in the title of the book to the two pages which are devoted to man. The Vertebrata altogether, are not treated with the same proportion of attention, relatively to our knowledge of them, as are the lower groups of animals.

It may be pointed out that whilst giving a large number of very useful citations of recent embryological works, Dr. Packard is not uniformly careful to ascribe the use of the terms and genealogical hypotheses which he employs to their rightful authors. In his chapter on the life-history of the Mollusca, he makes use of the terms Trochosphere and Veliger which I introduced into embryological nomenclature in my paper on the Development of the Pond Snail (*Quart. Journ. Micros. Science*, 1874), which he cites at the end of the chapter; he does not, however, ascribe either the terms or the views connected with them to their author. I am induced to mention this omission specially, since Prof. Semper of Würzburg, in his last publication—a heavy octavo discussing the relationship between Vertebrates and Annelids—has made a leading feature of the Trochosphere, appropriating the name as applied by me and the doctrine connected with it, without the slightest acknowledgment. The impropriety of Semper's proceeding is the greater since he makes no mere passing allusion to the Trochosphere, but puts forward a "Trochosphere-theory" which is intended to eclipse the "Gastrula-theory" of Haeckel.

A few points amongst those which we have noted as blemishes may be conveniently cited in order of pages.

Page 3.—We read "Bathybius was first discovered by Prof. Wyville Thomson in 1869, in dredging at a depth of 2,435 fathoms at the mouth of the Bay of Biscay." It was not, but was described and named by Huxley in 1868. Thomson appears to have seen it in 1869, in a living state under the microscope, to judge from his description quoted by Packard. Presumably this was not the sulphate of lime with which Bathybius has since been identified by the same authority.

Pages 24 and 25.—Urella should be Uvella.

Page 54.—"We have by tearing apart a species of Sycandra (or Sycon) perhaps *S. ciliata*, which grows on a Ptilota, found the planula much as figured by Haeckel, Metschnikoff, and Carter, and anyone can with patience and care observe the life-history of the marine sponges." It would have been more satisfactory if Dr. Packard had told us whether the planulæ he saw were like the figures of Haeckel or those of Metschnikoff; they certainly could not have been like both. It is a mistake to dismiss one of the most difficult problems which is now baffling embryologists with the assurance that "anyone can with patience and care" solve it.

Page 96.—"Sprat" for young oysters should be "spat." Salensky's observation on the young oyster, and his erroneous interpretations, are quoted with simple faith by Dr. Packard; so, too, are the same author's observations on Gasteropod development.

Page 105.—A serious error is here revived as to the identity of the velum of the Gasteropod larva, and the wings of such Pteropods as Styliola. The older observations of Gegenbaur, and the later ones of Fol, have shown that the velum co-exists with, and is quite distinct from, the expanded wing-like foot-lobes of the Pteropods.

Page 117.—The mode of development of Grenacher's Cephalopod is not, as stated by Dr. Packard, "totally different" from that of the common cuttle-fishes. It differs only in the somewhat smaller size of the nutritive yelk. The marginal cilia have no significance.

Page 120.—"Peripatus has been proved by the researches of Mr. Moseley to be a tracheate insect, for in the young genuine tracheæ exist, though they disappear in the adult, or at least have not been discovered." We should have expected to find Dr. Packard less inaccurate in what relates to the Arthropods. The above is altogether misleading; what Mr. Moseley found was that the adult Peripatus is richly supplied with tracheæ. He did not find tracheæ in the embryos, but he found still more important evidence of Arthropod character, namely, the presence of a pair of foot-jaws, the first post-oral pair of appendages becoming modified in the course of development, so as to function as mandibles.

Page 207.—Amphioxus is said to possess "primitive kidneys like the segmental organs of Worms." Of all the varied attempts to fix upon renal organs in Amphioxus there are none which quite warrant this statement. The fact is that nothing corresponding to the segmental organs of Worms has ever been described in Amphioxus, excepting the "pigmented canals." Though sometimes one epithelial area and sometimes another is declared for the time to be "renal," functionally if not morphiologically, the truth is that no renal organs at all are known to exist in Amphioxus.

Notes like the preceding might be multiplied were it worth while. Though such inaccuracy of statement does somewhat lessen the value of Dr. Packard's book, it is nevertheless one which is really welcome, and serves very well the main purpose for which it was designed, viz., that of conducting the commencing student over the recent literature of that young giant, Comparative Embryology.

OUR BOOK SHELF

Descriptive Catalogue of a Collection of the Economic Minerals of Canada, and Notes on a Stratigraphical Collection of Rocks. Exhibited at the Philadelphia International Exhibition. (Montreal, 1876.)

THE geological survey of Canada, under the direction of Mr. Selwyn, F.R.S., has placed in the Philadelphia Exhibition a collection of minerals and rock specimens of much interest, as they very fairly represent the geological productions of the Dominion, as far as the operations of the survey have extended. The descriptive catalogue of these "exhibits" (we regret the use of this new-fangled Americanism in a Canadian work) has been ably drawn up by the Geological Corps of Canada under the following heads:—1. Metals and their ores. 2. Materials used in the production of heat and light. 3. Minerals applicable to certain chemical manufactures, and their products. 4. Mineral manures. 5. Mineral pigments and detergents. 6. Salt, brines, and mineral waters. 7. Materials applicable to common and decorative construction. 8. Refractory materials, pottery-clays, and pottery. 9. Materials for grinding and polishing. 10. Minerals applicable to the fine arts and to jewellery. 11. Miscellaneous minerals. This catalogue is sufficiently comprehensive, while the arrangement is well adapted for easy reference.

Along with the descriptions of the specimens under each head we frequently find a condensed account of the origin and progress of various industrial pursuits. Thus under the head of Class 2, "Materials used in the production of heat and light," we have short notices of the more important collieries in the eastern provinces of Canada, together with observations on the origin of the petroleum springs of Ontario. The region in which the petroleum beds occur is situated in the western part of Ontario, around the town of Petrolia, occupying about eleven square miles of level ground, covered to a depth of about 100 feet with bluish clay. The oil is tapped by borings, which penetrate a series of bluish dolomites, shales, and marls to a depth of 380 feet under the clay, when a productive stratum is struck, and the oil, accompanied by sulphurous saline water, flows into the borehole, or well. The strata penetrated in boring the oil-wells, belong apparently to the "Hamilton," "Chemung," and "Portage" groups, representing according to Sir W. Logan, the upper portion of our Devonian beds,[1] but the petroleum itself is believed to originate in the lime-stones of the "Corniferous" formation which lie underneath; the strata occur in the form of a flattened dome. Another source of petroleum is the "Trenton" group, much lower down in the geological series, and referable to the Lower Silurian period. The geological position of the petroleum beds, as well as cases of actual observation, all go to show that the source of the mineral oil is animal, not vegetable. The limestones of the Corniferous, Gaspé, and Trenton groups are more or less coralline, and from the observations which Sir W. Logan records, it would appear that the oil is derived from the decomposition of the animal matter which originally filled the cells of the coral-rock. In such a position the oil has been observed, where these palæozoic limestones crop out at the surface, and where the limestone is overlaid by sandstone, as in the United States, or by shales or other materials, as in Canada. The animal oil has saturated these latter to such a degree that they have become underground reservoirs which can be made available by artificial means.

The notes by Mr. Selwyn on the collection of rock-specimens suggest several points on which we should like to dwell, did space permit. We shall only, however, refer to the remarkable case of metamorphic action to which he calls attention; namely, that to the south-east of the Valley of the St. Lawrence the formations are highly metamorphosed, their representatives to the north of that river being in their unaltered condition. This change takes place along a great line of dislocation ranging from Lake Champlain to Quebec and Gaspé, as described by Dr. Sterry Hunt. The change in the condition of these beds, none of which are probably older than the Devonian period, is so great, that the hand-specimens are undistinguishable from others collected in Eastern Canada or Ontario of undoubted Laurentian age. That metamorphic rocks may be of any geological period is a fact of which students of geology should be reminded; for we have recently had evidence before us, that some of the rising generation of geologists are still instructed in the exceedingly erroneous view that there is a "metamorphic system" of rocks forming the base of the general series.

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.]

Holly Berries and Rare Birds

WITH reference to the statement which has been made by Mr. McNab of the Botanic Gardens in Edinburgh, corroborated by Mr. Darwin and others in England, that holly berries are, this season, extremely scarce, it may be interesting to note that so far as this district is concerned, the holly is, on the contrary, unusually rich in fruit. For many years I have never seen so abundant a crop, and I suspect this will be found to be the case all over the West Highlands.

We have had a most unusual winter, from its extreme mildness, skies almost continually densely overcast, and the persistence of east wind. The rainfall for 1876 was not much in excess of our average—fifty-three inches. We have had little snow, and only one severe gale of wind. But the barometer has been frequently very low, in sympathy with the destructive gales both to the north and to the south of us.

I don't know whether it is due to any of those circumstances of climate that we have had two very rare birds—the great grey shrike, and the greater spotted woodpecker.

The shrike was seen here about twelve years ago, on one occasion; and a specimen of the woodpecker was killed about fifty years ago. About the time when the shrike was seen here on the last occasion, several specimens were shot in different parts of the low country; but this winter I have seen no case mentioned of the bird being observed. ARGYLL

Inveraray, January 20

On the Southern Tendency of Peninsulas

THE attention of those interested in physical geography has long been attracted to the remarkable fact that almost all the great peninsulas of the earth trend southwards, and that the majority, at any rate, have an island, or group of islands, at their southern extremity. Thus Mrs. Somerville, calling attention to this, says:—"The tendency of the land to assume a peninsular form is very remarkable, and it is still more so that almost all the peninsulas trend to the south, circumstances that depend on some unknown cause which seems to have acted very extensively. The continents of South America, Africa, and Greenland, are peninsulas on a gigantic scale, all directed to the south; the peninsula of India, the Indo-Chinese peninsula; those of Korea, Kamtchatka, Florida, California, and Aliaska, in North America; as well as the European peninsulas of Norway and Sweden, Spain and Portugal, Italy and Greece, observe the same direction. . . .

"Many of the peninsulas have an island, or group of islands at their extremity, as South America, which is terminated by the group of Tierra del Fuego; India has Ceylon; Malacca has Sumatra and Banca; the southern extremity of Australia ends in Tasmania, or Van Diemen's Land; a chain of islands runs from the end of the peninsula of Aliaska; Greenland has a group of islands at its extremity; and Sicily lies close to the southern termination of Italy."

Now may we not correlate this with the remarkable preponderance of ocean in the southern hemisphere, which M. Adhémar has suggested to be due to the alteration of the centre of gravity of the earth, caused by the great southern cupola of ice? However that may be, the preponderance of water in the south is very remarkable. Taking each parallel as unity, the proportion of sea is as follows:—

60° North	0·353	10° South	0·786
50° ,, ...	0·407	20° ,, ...	0·777
40° ,, ...	0·527	30° ,, ...	0·791
30° ,, ...	0·536	40° ,, ...	0·951
20° ,, ...	0·677	50° ,, ...	0·972
10° ,, ...	0·710	60° ,, ...	1·000
0° ,, ...	0·771		

Without at the present moment entering upon any discussion as to the cause which has produced this remarkable result, the fact at any rate seems to throw some light on the southern direction of promontories, for which, as far as I am aware, no cause has yet been suggested. For let us suppose three tracts of land, each trending north and south, each with a central backbone, but one with a general slope southwards, one with a northward slope, and the third without any. The first will, of course, form a peninsula pointing southwards, because as we proceed southwards, less and less of the surface will project above the water, until nothing but the central ridge remains. The second tract, however, would also assume the same form, because, though by the hypothesis the land does not sink, still the gradual preponderance of water would produce the same effect.

If, moreover, the central mountain ridge, as is so generally the case, presents a series of detached summits, the last of such elevations which rises above the water level will necessarily form an island, situated, with reference to the land, like those mentioned by Mrs. Somerville.

Lastly, in the third case, the gradual diminution of water would tend to neutralise the effect of the slope, and if the two were equal, the land would form, not a pointed peninsula, but an oblong tract.

If there is anything in the above suggestions it will throw some light on the southern trend of peninsulas by bringing them under the general law to which is due the remarkable preponderance of ocean in the southern hemisphere. JOHN LUBBOCK

Down, Kent

Basking Shark

IN looking over some old numbers of NATURE, which I had not been able to read, owing to my absence from Florence, I came across Dr. E. Perceval Wright's interesting article on the basking shark, *Selache maxima* (NATURE, vol. xiv. p. 313), which I read with much pleasure, and on which I would beg to offer a few observations, which I hope will not be considered as coming too late.

First and foremost, Dr. Wright in justly lamenting the absence of information on a most strange and singular form of Elasmobranch fish, far from being rare on the British coasts, entirely omits to mention the exhaustive and most important memoir on the genus *Selache*, published by Prof. P. Pavesi, of Pavia, in the *Annali del Museo Civico di Storia Naturale di Genova*, edited with so much ability, and mostly at his own private expense, by my friend, the Marquis G. Doria. In Italy we usually take much pains to be *au jour* of foreign scientific literature, and we are striving to do our best to form a good scientific literature of our own, therefore we may be excused if we feel anxious that it should be more generally known and appreciated abroad. Doria's *Annali* include most important zoological papers, and form already eight big volumes, which have cost the editor no small amount of pains and money; and it is most desirable that they should not escape the notice of working zoologists out of Italy. Indeed I may refer to some of the leading English zoologists, and more especially to my friend Dr. P. L. Sclater, to corroborate my assertion.

Prof. Pavesi's paper, "Contribuzione alla Storia Naturale del genere Selache," is continued in the sixth volume of Doria's *Annali*, published in 1874; and had Prof. Wright read it, he would have discovered that the very conflicting opinions on *Selache*, *Polyprosopus*, and *Pseudotriacis* had been most carefully examined, discussed, and sifted, that all the anatomical and zoological labours of well known and little known *savants* on the subject had been carefully analysed and critically studied by Prof. Pavesi, who in illustrating in a very lucid and minute manner the zoological affinities and anatomical peculiarities of a fine specimen of *Selache* captured at Lerici, near Spezia, on April 25, 1871, has succeeded in solving the Gordian knot which confused the true relations of the three genera above cited, and refers those strange Selacoids to two forms: *Selache maxima* (Gunn) and *S. rostrata* (Macri). To the latter species, characterised by a most singular snout, is to be referred the Lerici specimens, now in the Museum of the University of Genoa; one captured near Reggio (Calabria) in May, 1795, and described by Macri as *Squalus rostratus;* and lastly, the basking sharks, captured on the Western British coasts, and described in an incomplete manner as *Polypresopus* by Couch, and as *Squalus* or *Celorhinus rostratus* by Cornish.

Prof. Pavesi has largely illustrated the anatomy of *S. rostrata* in his memoir, especially the skeleton of the Lerici specimen which is preserved entire in the Genoa Museum; he also describes and figures the strange baleen-like fringes which adorn the branchial arches. HENRY J. GIGLIOLI

Florence

[We have also received a communication from Rev. M. Harvey, of St. John's, Newfoundland, mentioning that a specimen of the basking shark had been captured entangled in some salmon nets off the south shore of Conception Bay in August, 1876. Mr. Harvey thinks that the shark was probably feeding on caplin, as the Bay was full of shoals of this little fish. The teeth in his dried specimen were about a quarter of an inch in length, though probably in the fresh state they hardly projected beyond the gums. For other details we would refer Mr. Harvey to Prof. Pavesi's memoir quoted above, with the hope that he may still further continue his interesting investigation of the fauna of Newfoundland.—ED.]

The "Challenger" Collections

IT is a rather remarkable proof of the increased interest taken in natural science, that no one worth listening to has ventured to make a remark in disparagement of the *Challenger* expedition, or to utter a growl at the liberal support accorded to it from the national fund. This goes far to show that extensive classes of the community are able in various degrees to appreciate the objects and results of the expedition. One of these results is the collection of specimens in natural history. It is on the final destination of this collection that I wish to offer a suggestion. Within my own recollection it would have been difficult to name half-a-dozen public museums in Great Britain and Ireland where a series of objects, such as could be formed out of the duplicates in the *Challenger* collection, would be sure of meeting with a suitable reception. The number now would probably exceed a score, exclusive of museums in public colleges and schools; at a rough estimate the total number may be put down as at least forty. The supporters of these museums, as public tax-payers, have willingly contributed towards the expenses of the late noble and successful expedition; but it is not alone on this ground that I would respectfully urge a recognition of their claim to share in the treasure trove, but rather on the ground of the impulse that might be given to the study of natural science, and to the cordial support of plans for further expeditions of a like character.

For reasons which will be obvious on reflection, it would be a great saving of time and trouble to those engaged in the arrangement of the specimens if public museums were invited to send in, on or before a certain fixed day, to some central board, an expression of their desire to participate in the benefit of the *Challenger* collections, at the same time stating the grounds of their claim, and the department in natural science in which they would prefer to receive contributions. The examination and determination of these applications must be a work of time, therefore the sooner the plan is set on foot the better. Monographs will probably be published, and museums will purchase them; but they cannot buy the specimens, and the value of the monographs to any institution will be increased tenfold by the possession of authenticated specimens of some of the species described. Of course there are universities and other centres of scientific teaching which must come first; but I respectfully and earnestly protest against drawing the line of exclusion too stringently. There is now a great national opportunity for encouraging in a substantial way the instruction given in lectures and science classes, which often languishes for want of illustrations. I know of stores of natural history treasures. If only they had been dispensed in wisely apportioned nuclei, how valuable, by this time, might have been the collections accumulated round them. If selection amongst the claimants be impossible, might not series be made up for loan or sale? It will be unworthy of the way in which the *Challenger* work has been done, if even a single Rhizopod shall find its resting-place in a dust-hole.

HENRY H. HIGGINS

Traces of Pre-Glacial Man in America

IN NATURE, vol. xv. p. 87, you have given an outline of a paper by Prof. Hughes, read before the Cambridge Philosophical Society, "in which he criticised the evidence offered to support the view that man existed on the earth during or before the glacial period." As concerning the question of the antiquity of man in North America, I would first call attention to the remarks on this subject by the late Prof. Jeffries Wyman, the most cautious and careful of archæologists, who writes:[1] "The ancient remains found in California, brought to the notice of the scientific world by Prof. J. D. Whitney, and referred by him to *the Tertiary period*, &c," to which is added a footnote, that "*the ample evidence collected by Prof. Whitney, but not yet published, substantiates the opinion given above with regard to age. The omission of the Calaveras skull would not weaken the evidence as to the existence of man in the Tertiary period in California.*" Inasmuch as the Glacial period occurred at the close of the Tertiary period, if Prof. Whitney's discoveries are conclusive, as to this side of the Atlantic, does it not follow that man must have existed, certainly in Asia, prior to the glacial epoch? We are assured by all ethnologists, that man migrated from Asia to America, and now we are offered proofs of his American sojourn, of a date preceding the occurrence of glacial conditions. Speaking of the Eskimo, Dr. Peschel remarks[1]: "The identity of their language with that of the Namollo, their skill on the sea, their domestication of the dog, their use of the sledge, the Mongolian type of their faces, their capability for higher civilisation, are sufficient reasons for answering the question, whether a migration took place from Asia to America, or conversely from America to Asia, in favour of the former alternative; yet such a migration from Asia, by way of Behring's Straits, must have occurred at a much later period *than the first colonisation of the New World from the Old one.*" Again, in speaking of the Red Indians, he remarks[2]: "It is not impossible that the first migrations took place at a time when what is now the channel of Behring's Straits was occupied by an isthmus. The climate of those northern shores must then have been much milder than at the present day, for no currents from the Frozen Ocean could have penetrated into the Pacific." This reference to a milder climate must necessarily refer to the genial warmth of Pliocene times; for scarcely under other circumstances can we find time enough to explain the various phases of lost civilisations, especially in South America. Whether or not the supposed traces of glacial and pre-glacial man in Europe be really such—if the archæology of North America has, so far, been correctly interpreted—then, unless they have been totally destroyed, unquestionable traces of such early man will be ultimately discovered; but if such "finds" should never gladden English archæologists, the earnest workers in America have rendered it certainly true that in Asia, and doubtless in Europe, man did exist during the closing epoch of the Tertiary period, if there is, indeed, no error in the supposition that our American aborigines migrated from the Old World.

CHAS. C. ABBOTT

Trenton, N.J., U.S.A., December 16, 1876

Glacial Drift in California

IN a recent letter from my brother residing in California, he describes a curious moraine or drift formation, which may, perhaps, be as new to some of your readers as it was to myself. His description, with a few verbal alterations, is as follows:—

"The plains for a distance of from five to twenty miles from the foot of the Sierra Nevada are covered with what are locally termed 'hog-wallows.' The surface thus designated may be represented on a small scale by covering the bottom of a large flat dish with eggs distributed so that their longer axes shall lie at various angles with one another, and then filling the dish with fine sand to a little more than half the height of the eggs. The surface of the sand and of those parts of the eggs which rise above it, gives a fair representation of the 'hog-wallow' land. The mounds, which are represented by the eggs, vary from two to five feet in height, and from ten to thirty feet in diameter, some being nearly circular, some oval, while others are more irregular in shape. Those nearest the foot-hills are the largest, and they gradually diminish in size as they extend out into the plain. They are composed of gravel and boulders of irregular sizes, generally covered with a surface-soil, but sometimes bare. These tracts, which are very extensive in some parts of the State, have been till lately unexplained; but it is now generally admitted that they are due to the retreat of the broad foot of the glacier, leaving behind it a layer of *débris* or moraine-matter, which has become arranged in its present form by the innumerable rills that issued from the retiring sheet of ice. A living glacier has lately been discovered far up in the Sierra Nevada, near the head waters of the San Joaquim River."

Perhaps some of your geological readers may know if any similar formations occur elsewhere; and may favour us with their views as to whether so extensive and uniform a deposit could be due to a retreating glacier alone, or would not rather require the agency of a temporary submergence to spread out the *débris* with such uniformity. During the retreat of the waters, pluvial action might perhaps wash away the softened soil in the regular manner described.

ALFRED R. WALLACE

The Number of Species of Insects

PROF. HUXLEY is very much within the mark when he estimates the species of insects at "about 100,000, if not more." Were I to estimate the number of described species at 200,000, I believe the figures would also fall short of the truth, even allowing a liberal margin for synonyms. In one order alone (*Coleoptera*) it is estimated that 80,000 species have been described.

I could enlarge upon the bearing these figures have upon theories on the geographical distribution of animals, but content myself with the remark that the groups of insects selected by writers on the subject are those in which colour is most prominent and structure least differentiated.

Lewisham, January 12 R. MCLACHLAN

[WE sent the above to Prof. Huxley, who has appended the following note.—"It was not my object to give an accurate estimate of the total number of species of insects. Gerstaecker, in the new edition of Broun's 'Thier-reich,' gives 200,000 as the total number of species of *Arthropoda*; but I dare say that Mr. McLachlan has good grounds for the claim he puts in for insects alone. "T. H. HUXLEY"—ED.]

Meteor

PRECISELY at 6 P.M., on the 19th inst., I saw a splendid meteor traverse the sky from a point about midway between Orion's belt and the Pleiades to a point directly under the moon, and about 10° above the horizon. It was pure white and dazzling, lasted about five seconds, emitted no sparks, except at the moment of disappearance, and was about half the size of the moon at the time.

R. M. BARRINGTON

Bray, Co. Wicklow, January 21

Diurnal Barometric Range at Low and High Levels

YOUR notice under this head (vol. xv. p. 187) of my paper on the daily inequalities of the barometer at Mount Washington and Portland, Maine, has hit a blot of which I was unconscious until now. Had I been more than a student writing one of his first essays in meteorology, I should probably, like yourself, have suspected something wrong in the Portland curve. The morning maximum and the afternoon minimum, as you point out, occur very much earlier than is usual.

Differences varying from + 0·027 inch to − 0·004 inch between your averages of General Myer's figures and those given in my paper did not surprise me, as mine were intended to represent the temperature of 60° F., while you have probably taken the observations either as already reduced to 32°, or have yourself reduced them to this temperature. My own impression is and was that the printed observations are not corrected for temperature, and in order to make the comparison with as little change as possible in the original figures for the three stations I brought each to something near a mean temperature for the three attached thermometers. Unfortunately, and here comes the blot, I now find that, by some mischance, in taking out the differences for Portland the external temperatures were taken instead of those by the attached thermometer. I exceedingly regret this, and shall as early as practicable make the required correction.

Fortunately this error does not affect the purport of my paper or the suggestions which I offer in it towards the explanation of the long-vexed question of the cause or causes of the daily inequality of the barometer.

An acquaintance with the variations of the daily barometric curves, which depend on change of season and difference of locality, would undoubtedly be of assistance in drawing these curves when the observations for only a few hours are given, but the six hours for which the Portland figures are given are so well distributed as to leave little uncertainty as to the general form of the curve in this case. I should not, however, be satisfied with any curve for the Portland observations which, when analysed by the usual formula and reconstructed from the co-efficients thus obtained, did not reproduce the original observations, and also the interpolated values for the other hours, within a limit of error of 0·001 inch. Unless your curve can stand this test I shall not be satisfied with your deductions as to the epochs of maximum and minimum values. Having had much experience in drawing such curves, I venture to assert that the Portland observations, whether taken as they are printed or after a correction for temperature, will still give the morning maximum and afternoon minimum of the barometer much earlier than is usually the case in this country. If my paper draws attention to any singularity of this kind it will mitigate the disappointment caused by the mistake in the temperature correction.

I append the times of maxima and minima for Portland, May, 1872, as corrected; also similar data for five years at the Naval Observatory, Washington, U.S., and for Oxford, England.

Times of Daily Maxima and Minima of the Barometer for the Month of May.

Former Climates

IT appears to be established that a climate favourable to the growth of coal plants and coral builders has prevailed in latitudes where the sun now shines for about seven months out of twelve.

Without inquiring how it came about that a warm sea once washed polar coasts, it would be interesting to learn whether the plants and animals concerned in the production of coal forests and coral reefs can flourish under these conditions of light supply.

Holmwood, Putney Hill D. PIDGEON

Tape-worms of Rabbits

HAVING had occasion to dissect a number of wild rabbits, I have been surprised to find that the majority of them are infested with a large species of tape-worm. Can any of your readers inform me whether the life-history of this parasite has ever been made out? The case appears to be a remarkable one, because the host cannot here be suspected of ever taking animal food. Unless, therefore, we suppose that the tape-worm of a rabbit differs from other tape-worms in not passing through a hydatid stage, it becomes difficult to explain the very general occurrence of this species.

GEORGE J. ROMANES

POLARISCOPE OBJECTS

THE following is an interesting combination :—When the polariser and analyser are crossed, insert a concave plate of quartz cut parallel to the axis, with its axis inclined at 45° to that of the polariser, add to this a quartz wedge cut also parallel to the axis, having its axis placed perpendicular to that of the concave plate. The coloured circles, shown by the concave plate alone, will be seen to be displaced in the direction of the thicker edge, to a distance dependent upon the angle of the wedge. Also, as the wedge is made to slide in or out, the circles will be seen to expand or contract, according as the thicker or thinner part of it is presented to the field of view.

The explanation of this is to be found in the fact that a combination of two crystalline plates is optically equivalent to a single plate, whenever the axes of the plates are either parallel or perpendicular to one another. This follows immediately from a comparison of the mathematical expressions for the intensity of the light at any part of the field in the two cases. The expressions will be found in Verdet (Oeuvres, tome vi. p. 110), who further remarks that, if the two sections are parallel, the addition of the second is equivalent to an augmentation, or a diminution of the thickness, according as the two plates are both positive or both negative, or are one attractive and one repulsive. If the principal axes of the plates are perpendicular, the addition of the second plate is equivalent to a diminution of the thickness when the plates are of the same sign, and to an augmentation of thickness when they are of opposite signs.

When, as in the case proposed, the second plate is a wedge, the effect of the combination will be the same as if the flat side of the concave plate were cut away wedgewise, but in direction opposite to that of the actual wedge. Optically, then, the bottom of the concavity will be thrown towards the side on which the combination is optically thinnest; *i.e.*, on which the actual wedge is thinnest.

The sliding of the wedge will not alter the displacement of the centre, which is dependent on the angle, and not on the thickness of the wedge, but it will alter the total thickness of the compound plate, and consequently the diameter of the circles.

In addition to the above, I may mention another piece devised and constructed for me by Mr. C. D. Ahrens. This consists of two quartz cones, one hollow, the other solid, fitting into one another; one cone is of right-handed, the other of left-handed, quartz, and the axis of each is parallel to that of the crystal. The polarisation figure due to this combination is of course a series of concentric circles, which expand or contract when the analyser is turned in one direction or in the other.

If the field of view be examined at various distances from the centre, it will be found that there is a distance, viz., where the right and left-handed cones compensate one another, at which there is no colour, but only an alternation of light and darkness. In the immediate neighbourhood of this the red and orange assume the brown and drab hues due to low illumination, in accordance with Helmholtz's experiments; beyond this the colours are more brilliant; while at still greater distances, where the thickness of one cone much exceeds that of the other, the colours become more pale.

MUSEUMS

THE subject of Museum management and arrangement having lately been commented upon by Prof. Flower in a lecture delivered at South Kensington Museum, and printed in NATURE of December 14, 28, *et seq.*, and also by Prof. Boyd Dawkins in an address to the Manchester Literary and Philosophical Society, noticed in NATURE of December 7, it may not be an inopportune time to suggest to those who have the management of these institutions the desirability of their mutual co-operation in order to develop them to their fullest extent. The great progress which has been made during the past few years in the establishment of museums in the various provincial towns of this country is highly creditable to those who have assisted in the movement, and the influence which they might have, if properly utilised and developed, on the education and intellectual progression of the people, gives them a forcible claim to national and individual support.

There is no doubt that the present financial support given to museums is totally inadequate to maintain them in an efficient state, and we hope to see this remedied to some extent in the next session of Parliament, by the adoption of Mr. A. J. Mundella's Bill for Increasing the Library and Museum Rate, the penny rate not realising sufficient money, except in large and wealthy towns, to serve the purpose for which it is intended. Mr. Mundella's Bill gives the power to levy a rate, not exceeding 2*d.* in the pound, for the purpose of establishing and maintaining free libraries and museums, and in those towns where there is no museum, but only a library or libraries, the rate not to exceed 1½*d.* in the pound. This slight increase would not press heavily on any section of the ratepayers, while it would enable many of our libraries and museums which are now languishing for want of funds to go on in their wide sphere of usefulness with increased vigour and zeal.

The important conference of the mayors of towns and chairmen of museum committees, which was held in Birmingham on the 5th instant, to discuss and urge the claims of museums and galleries of art to some of the surplus funds remaining from the International Exhibition of 1851, and also to the duplicates which are stored away in Government collections, is a step in the right direction, and we hope that it will be productive of good results.

With the more general diffusion of education among the great masses of the people which it is hoped will result from the passing of the recent elementary education acts, the class of readers and students will be greatly enlarged, and we might naturally look for something being done by the Government to meet the increased demand for books and objects of study which is likely to follow; and we see no reason why museums themselves should not be occasionally converted into schoolrooms where teachers could bring their zoological, geological, and other natural science classes, and find well-arranged material for illustrating their lessons. Of course we take it for granted that these sciences will eventually be taught in all elementary schools under Government control.

With regard to the preservation and arrangement of specimens in museums, those who had the pleasure of listening to Prof. Flower's lecture cannot have failed to carry away some useful suggestions, and his remarks, together with those of Prof. Boyd Dawkins on the neglected and unsatisfactory state of many of our museum collections, are well worth the consideration of those in charge of them. What ought fairly to be the aim and scope of a provincial museum is a question which each town must to a great extent answer for itself, as it must depend on the resources of the neighbourhood and on the facilities possessed for obtaining certain classes of objects; and curators would do wisely to content themselves with doing only what can be done thoroughly and well, be it ever so little, and not to accept objects simply with the view of filling empty cases. We are well aware that curators are not always responsible for the incongruities which get into a museum, and if the refusal of objects were always left with them, we should not have museums sinking into advertising establishments or mere curiosity shops. We do not, however, intend now to go into this subject, but in order that all the important matters connected with the work of museums may receive full and careful consideration, we would suggest that an association be formed, to consist of curators and others engaged in the arrangement of museums. Such an association need not in any way interfere with those now existing, as there is a sufficiently wide field for discussion and action included in the work and development of museums without treading on the ground occupied by other associations. By holding periodical meetings and constantly changing the place of meeting from town to town, the various museums of the kingdom could be inspected, and their contents and plan of arrangement discussed and criticised. Friendly communications would thus be opened among all museums, and exchanges could be arranged to their general advantage. Much might be said as to the necessity and work for such an association, but we content ourselves, for the present, with suggesting it, and now leave the matter to be taken up by those most intimately concerned.

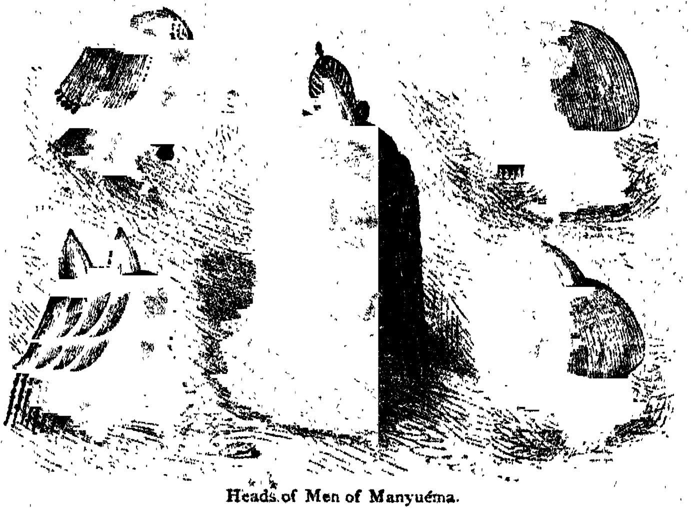
E. H.

ACROSS AFRICA[1]

OUR readers are no doubt already familiar with the main results of Commander Cameron's remarkable march across the continent of Africa; many details concerning it have appeared through various channels. These, however, have only been sufficient to whet the appetite of all who take an interest in African exploration for the complete narrative; this we find quite as interesting and informing as we had reason to believe it would be. Commander Cameron has not attempted to produce a highly polished summary of the copious notes he seems to have taken by the way; he takes the reader along with him step by step and day by day over the long and to him often tedious route he had to travel, and in the end the reader finds he has become possessed of a substantial amount of new information concerning one of the most important sections of one of the most interesting continents.

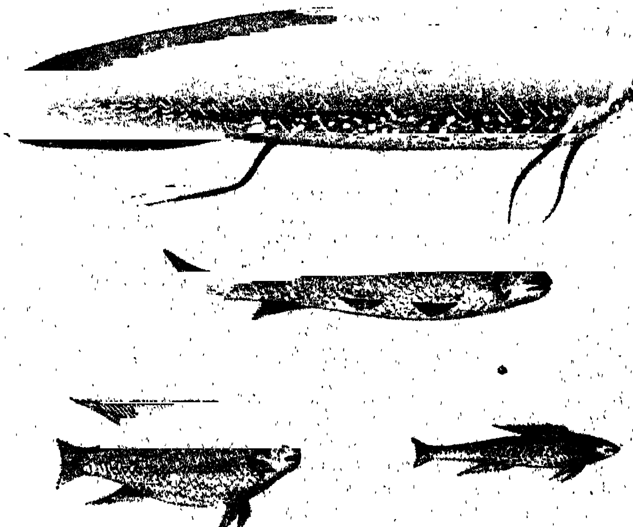
Commander Cameron's story is so well known that to summarise it here would merely be to repeat what we have already given on various occasions. The primary object of the expedition which he commanded, it will be remembered, was to seek and succour the great Livingstone, whom Stanley had just discovered, after the explorer had been hidden in the centre of Africa for five or six years. Cameron as leader, with Dr. Dillon, Lieut. Murphy, and poor young Moffat, who had sold his all to enable him to find and help his uncle, set out from Bagamoyo with a large following, early in 1873. They had only got as far as Unyanyembé in October when they were sadly surprised by the bearers of Livingstone's remains, the great traveller having died in the previous May on the south of Lake Bangweolo, almost on the same day as his enthusiastic nephew perished on the threshold of his search for his uncle. Under the new circumstances Lieut. Murphy decided to return, Dillon was compelled by the state of his health to accompany him, and Cameron resolved to proceed alone to take up and continue the work of his immortal predecessor. By doing so, he rightly believed he was carrying out the spirit of his instructions. Dillon's sad end, a few days after he left Cameron, is already known to all.

Cameron's route may be divided into four sections. First, from the coast to Ujiji; second, the survey of Lake Tanganyika; third, his journey to Nyangwé, on the banks of the broad Lualaba; and fourth, from Nyangwé, south and west, to the west coast. The first part of this route is already to a considerable extent familiar to those who have read the narratives of Burton, Speke, and Stanley. Nevertheless, it will be found that Commander Cameron has added considerably to our knowledge of its appearance, its products, and its people. The admirable series of levels which he was able to take from first to last, and the results of which are condensed in the section that accompanies his interesting map, shows that the ground rises till about the thirty-fourth degree west, when it slowly slopes to the centre of the continent, which is a wide hollow or basin, rising very gradually towards the western coast, on which side the descent is very steep. The country between the coast is varied in character, sometimes level, and sometimes very hilly, frequently swampy and liable to be inundated by the overflow of the numerous rivers which water it, but very often well wooded, thickly populated, and fertile. It is cut up into a number of states inhabited by various small tribes independent of each other, the appearance, manners, and customs of which are frequently referred to by Commander Cameron. Of the Wanyamwesi, especially, he has much to say, for at Unyanyembé, in their territory, he was detained for many weeks by fever, and indeed did not reach Ujiji till February, 1874, after innumerable troubles caused by his scratch lot of followers, and being fleeced at every hand by the chiefs through whose villages he had to pass.



Heads of Men of Manyuéma.

Cameron was well-received and well-treated by the Arab traders at Kawelé, the capital of Ujiji, and here he fortunately secured Livingstone's papers. After measuring a short base-line, he set out on March 13 to circumnavigate the southern half of Lake Tanganyika. Our readers will remember that Burton and Speke were able to survey a comparatively small portion of the lake in the neighbourhood of Ujiji, while Livingstone and Stanley coasted the east side of the northern part, and a portion of the north-west coast. Cameron has, therefore, by his survey been able to add considerably to our knowledge of this interesting lake. He sailed along the eastern side of the southern half, crossed to the west just before reach-



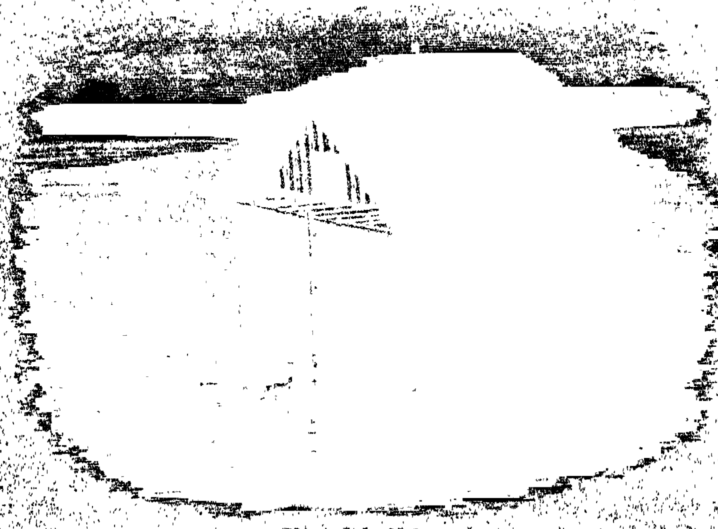
Tanganyika Fishes.

---

[1] "Across Africa." By Verney Lovett Cameron, C.B., D.C.L., Commander R.N. 2 vols. (London: Daldy, Isbister, and Co., 1877.)

ing the end of the lake, passed up the west side, examined the Lukuga, and returned to Ujiji on May 9. His work contains a great deal of information as to the result of this survey, and he has been able to lay down, we have no doubt with considerable accuracy, the contour of the shores. These are mostly high and rocky, covered with trees and other vegetation, often fringed with dense reeds, and cut up by a multitude of streams. Animal life of all kinds, quadrupeds, birds, insects, fishes, abounds around and in the lake, the scenery of which Cameron describes as of surpassing beauty. The western shores are well peopled by a fairly industrious population, but many portions of the east coast have been devastated by slave-hunters, evidences of whose destructive raids were seen all along Cameron's route. With regard to the river Lukugu, which Cameron believes to be the outlet of Lake Tanganyika, and an affluent of the Lualaba, he has some interesting notes. He believes he traced a distinct current westwards, and sailed up several miles until stopped by a dense barrier of vegetation which crossed from side to side. As we said when referring to this point previously, we do not think much is to be gained by discussing the question in its present shape. It is not as if no further data were to be obtained, the question is one capable of demonstration by the attainment of additional information, and we hope that Mr. Stanley will be able to set it at rest as satisfactorily as he has settled the contour of the Victoria Nyanza. To Cameron geographers are greatly indebted for the large additions he has made to a knowledge of Lake Tanganyika.

Nyangwé from the River.



Hut in Lake Mohrya.

About a fortnight after his return from this survey—which, we ought to say, was carried out amidst innumerable difficulties caused by the timidity and inefficiency of his crews—Cameron crossed the lake to make for Nyangwé in the hope of obtaining boats to take him down the Lualaba. He passed over pretty much the same route as did Livingstone, whose memory he still found alive among the people. The two main districts in this route are Uguhha and Manyuema, and the people are among the most interesting with whom Cameron came in contact. In Uguhha copper is largely worked, and shaped into curious cross-bars, and in Manyuema iron ore is found and largely smelted in elaborately and ingeniously-constructed furnaces. The people of Manyuema are in many respects peculiar, and although undoubted cannibals, superior to the tribes around them. Cameron believes them to be a superior intrusive race, the lower classes being aborigines. They live in well-built houses, arranged in neat villages, and are of fine physique. They seem well deserving of further study.

At Nyangwé Cameron was well treated by an old Arab who had been kind to Livingstone but to his great disappointment he failed in obtaining boats to carry out his cherished purpose. He was assured by many people, both here and in his journey southwards, that the Lualaba a fine broad stream at Nyangwé, flowed westwards into a large lake, Sankorra, to which men came in large boats capable of holding 200 people, for the purpose of trading From the interesting data collected by Cameron we must say that he has good reason for connecting the Lualaba with the Congo, and regarding the latter as the great drainer of all the region to the west and north-west of Tanganyika. The Lualaba is in the very lowest part of the great Central African basin, is a river of very large volume, which, in the upper part of its course receives various affluents, and it is difficult to conceive what other south-west African river except the Congo could carry of all this drainage. Still there is an extensive region, from about 5° N. to 10° S. waiting to be explored, and until this is done we think it premature and unnecessary to maintain any positive theory on the subject. The solution cannot now be far off with so many expeditions either on the field or about to be sent out. The data obtained by Commander Cameron are of great value, and will form an important guide to subsequent explorers.

In company with an Arab trader, Cameron proceeded southwards in the hope of being able to work his way north to Lake Sankorra. In this, too, alas, he was grievously disappointed, his designs being thwarted on every hand by the caprices of besotted chiefs and brutal slave-hunters, and the cowardly fears of his own men. The greater part of the ground from Nyangwé to the coast region, south and west, over which Cameron now travelled, is quite new, never having been before explored by an European, so far as is known. Much of the second volume, on this account, possesses novel interest. Most of the country is fertile, well watered, and well wooded Innumerable streams were crossed, and so level is the watershed between the streams going east and those going west, that during floods, which seem to be frequent, their courses must sometimes be changed. About 200 mil south of Nyangwé, Cameron came to Kilemba, the head-quarters of Kasongo, the chief of the extensive district of Urua, and where is the principal station of the remarkable Arab trader, Jumah Amerikani. This individual has extensive trading connections over Central Africa, is a man of considerable intelligence, and was able to give Cameron much geographical information which he had gathered during his widespread journeys. Cameron was compelled to remain at Kilemba for about eight months, and had it not been for the ever-to-be-remembered kindness of this humane and generous Arab trader, his life must have been intolerable, even if he had been able to preserve it. The treatment of Cameron by this remarkable man is beyond all praise. Cameron found at Kilemba a black slave-hunter from the Portuguese settlements, than whom probably a more barbarous blackguard does not exist. The cruelties practised by this man and the chief Kasongo are almost incredible and painful to read of. The whole country here is being rapidly devastated by these slave-hunters from the west coast, and until their fiendish practices are put a stop to, the country can never be opened up either to exploration or legitimate traffic.

While staying here Cameron visited an interesting little lake, Mohrya, studded with houses built on high piles. He also heard of a people who dwell in caves in this region; we believe that Livingstone refers to this in his "Last Journals." Cameron also paid a visit to a Lake Kassali, a short distance south of Kilemba, and which contains many floating islands; but he was not permitted to reach the shores. He has collected much interesting information about the people among whom he was compelled to sojourn, and collected many notes from various sources concerning the geography of the region. But the capricious restrictions under which he was placed compelled him to lead a life of comparative idleness, so that when Kendele, the brutal slave-hunter, whose pleasure he was compelled to await, was ready to march with his ill-gotten human booty, the wearied traveller was heartily glad. This was in June, 1875, and starved and nearly dead with scurvy he reached Benguella in November.

Village in Manyuema.

Of the value of Commander Cameron's work we think there can be but one opinion. Every page is interesting, and he has been able to add materially to our knowledge of the hydrography, the geology, the people, and products of the important part of Africa he traversed. The general results he discusses in two concluding chapters, and botanists will be pleased to find in an appendix an enumeration of the plants collected in the region about Lake Tanganyika, drawn up by Mr. Oliver. The flora of the region, Mr. Oliver states, may be taken as belonging to the basin of the Congo.

THE TROPICAL FORESTS OF HAMPSHIRE[1]

III.

WE have in the series of beds, the aspect and formation of which I have endeavoured to describe, a total thickness of perhaps somewhere about 1,000 feet. We read in Lyell's "Geology" and other works that river and delta deposits are accumulated with comparatively great rapidity, as in the case of the Rhone delta above Geneva, which has advanced one-and-a-half miles in historical times. Throughout the Bournemouth district we have in the great and sudden deposits of coarse grit evidence of quick deposition. We also find leaves folded over with half an inch of sediment between the folds, and leaves sun-cracked

---

[1] Continued from p. 261. This concluding article is the substance of a paper read by Mr. J. S. Gardner, F.G.S., at the Geologists' Association, January 4.

and divided with that or more difference in level between the segments, which also shows extreme rapidity of deposition; and although we have proof that we in some cases see the actual soil in which some of the smaller plants grew, still penetrated by their roots, there is no evidence of its having been long occupied, or that it indicates more than a rapid fern growth between recurring floods. We have further, in the fine state of preservation of some of the leaves, which have been doubtless buried before decay set in, and in the breaking up and redeposition of beds, evidence of rapid accumulation; yet we must not hastily conclude that the time required for the formation of these deposits was, even geologically speaking, short. We over and over again see beds, one above another, which have been cut through and carried away after they had become consolidated, that is, after the muds had become so hard that they have resisted the dissolving power of water and been rolled and redeposited as pebbles and boulders.

The same spots may have been again and again silted up and denuded before the beds finally remaining were covered up, the same material has been rearranged by different currents perhaps a great number of times, whilst the constant unconformability of the strata may indicate periods of rest or great lapses of time. All our facts as to the depression of areas tend to show that it is an extremely slow and imperceptible process—slower still when the general depression is intermittent. We have further a totally different kind of evidence, which to my mind is still stronger, of the vast ages that rolled away during the deposition of these beds. This is the significant fact that the entire marine fauna was completely changed. By this I mean that we have in the London clay a fauna that migrated away, a fauna familiar to us and characterised by great nautili and other shells, crustacea, &c., peculiar to it. In the succeeding Bracklesham beds we have another totally distinct fauna, so that the duration of the land period was sufficiently long for the fauna of the London clay sea to be entirely changed before the return of the sea whose fauna we have recorded in the Bracklesham beds. In the Barton beds which overlie the Bournemouth deposits, we have again an extensive fauna, most distinctly characterised and widely separated from that of either of the preceding beds just mentioned.

In many cases it is recognised that variations in fauna are dependent upon the depth of the sea, but such cannot be the case in this instance since we get species belonging to the same genera, so closely resembling each other, that we cannot but infer that they lived under similar conditions. And when we come to see, as we do, that this applies to all the groups, the inference drawn from one individual group accumulates to an evidence which presents itself as at any rate approaching certainty. The well known case of the difference in the fauna of the Red Sea and the Mediterranean, which are separated by so narrow a strip of land, has been often referred to as a possible explanation of how different fossil faunas occurring close together may have existed contemporaneously, and do not imply any lapse of time during which changes of climate occurred; but although in many cases it is impossible when a purely hypothetical theory is brought forward to bring an argument to disprove it, yet in this case there is no evidence whatever in its favour, and what little evidence there is bearing on the question, is directly opposed to it; therefore the other seems the more reasonable explanation. The great changes in the flora which I shall mention to you, although principally due perhaps to the great change of level of which we have other indications, may also indicate long lapse of time, long enough as I have said for the marine fauna of Bracklesham to develop, to disappear, and to give place to that of Barton.

These deposits, which have been neglected by geologists, are of extreme importance as being one of the few records we have of land surface. The rocks in which organic remains are found are aqueous rocks, principally marine; the remains of aquatic animals are more numerous than are those of terrestrial animals, and are, for the same reason, far more numerous than those of plants. Such facts as these give great interest to series of land remains of so complete a nature. We can form an idea of how incomplete our terrestrial records are when we consider that whilst upwards of 4,400 plants are growing in Great Britain, about 700 only are known fossil, whilst 513 testaceous mollusca now inhabit Great Britain, and 4,590 were known fossil as far back as 1862.

The Bournemouth flora seems to consist principally of trees or hard-wooded shrubs, comparatively few remains of the herbaceous vegetation being preserved.

Parasitic fungi are abundant. Ferns, extremely rare in the lower part of the series, become abundant, as far as the remains go, almost to the exclusion of other vegetation, towards the close of the middle period. The prevailing group seems that of Acrostichum, of which several species are present. We can also determine, with almost certainty, the presence of Angiopteris, Anemia, Nephrodium, Gleichenia, Lygodium, and there are, besides these, several undetermined forms.

Of Conifers we have Cupressus and Taxodium, determined by De la Harpe, with the addition of Dacridium and indications of Pinus; Cycads have disappeared.

Of Monocotyledons we have indications of reeds and rushes; Pandanus is represented by its fruit, Nipadites; palms are very abundant, especially in the lowermost beds of Corfe, the middle beds of Studland, and the upper middle beds of Bournemouth. Massolongho has determined Chamoecyparites, in addition to which many fan and feather palms exist, belonging to Flabellaria, Sabal, Phœnicites, and a genus new to the Eocene, Iriartea. A gigantic aroid is also very abundant, and the Smilaceæ occur in all the fossiliferous beds throughout, and are represented by five or six species.

The Dicotyledons are, however, most abundant, and it is probable that a vast number of species will be determined from these beds. De la Harpe's list included in 1856:—

Apetalæ.—Populus, Ulmus, Laurus, Quercus, and Artocarpidium, to which Massolongho added Daphnogene. To these we may now add Carpinus, Fagus, Castanea, Salix, Platanus, Ficus, Celtis, numerous Proteaceæ, Cinnamomum.

Polypetalæ.—Elæodendron, Rhamnus, Prunus, Juglans, Cluytia, have been already noticed by De la Harpe. We will add, *fide* Massolongho, Ceratopetalum, and as new to the Bournemouth flora, Acer, Dodonæa, Celastrus, Eucalyptus, and a number of Leguminosæ.

Monopetalæ.—De la Harpe has determined Diospyros; to this may perhaps be added Porana.

Cactus and Stenocarpus have been previously mentioned, and have never previously been found fossil.

In addition to these we have probably represented almost every genus described from continental Eocene floras, but it is premature, for the reasons already stated, to go further into this question at present. The forms I have mentioned will, however, give you a general idea of the composition of the flora.

It will have been gathered from the anniversary addresses of our president, Mr. Carruthers, that the remains of plants are, if possible, of more interest and importance than those of marine animals, as whilst we have already some idea of the succession and development of animal life, especially of the more purely marine orders of crustacea, mollusca, echinodermata, &c., we know very little of the history and development of plant life. Mr. Carruthers laid stress on the somewhat sudden occurrence of dicotyledons as being unfavourable to the hypothesis of evolution in descent. I concur with him fully that it is difficult to realise that the absence of dicotyledons can be due to any cause but their absence from the then existing vegetation, yet there are certain causes ending to make their preservation difficult, which may erhaps be taken into account.

Some kinds of coniferous plants resist decay, when im-mersed in water, more completely than do almost any icotyledons, and this resistance may, owing to their esinous nature, be very greatly increased when the im-mersion is in sea-water. This supposition is borne out y a fact I have noticed, that in some Eocene beds, such s the marine beds at Bournemouth, the Bembridge marls, he Bracklesham beds, coniferous remains preponderate, hilst from the two latter places I have never seen re-mains of dicotyledons at all, although there is evidence in hese cases that dicotyledons were abundant on all urrounding land areas. This may partly account for heir complete absence in marine cretaceous rocks in England, where, as in the gault, &c., foliage, fruit, resinous ums in the form of amber, remains of coniferæ, are reserved. The foreign cretaceous rocks, in which an bundance of dicotyledons is met with, are principally of resh-water origin.

It should be borne in mind that our Chalk period con-ains a deep sea fauna, and we have no record in England s to what were the prevailing contemporaneous shallow ater forms of life in other regions. I have great doubts, owever, as to the correct position of many of the foreign o-called cretaceous beds. Those of America, from which ost of the list of dicotyledons of this period is derived, ppear to me, from the character of their fauna, to be ither Lower Eocene, or at most filling in the gap between ur chalk and London clay. Most of the shells have a arvellously Eocene-like aspect, and I take it that the resence of an ammonite, and some few other forms of hells, which in England do not range above the Chalk, hould not be taken as conclusive evidence of the anti-uity of the bed, as although migrated from our seas, they ay very well have lived on in other regions. It is incon-istent to assume that no ammonite lived on in any part f the world to a more recent period than that of our halk; the finding of pleurotomaria and other supposed xtinct cretaceous shells in Australian waters, should not e forgotten. The same doubts apply to many of the uropean leaf deposits; many of these are isolated atches, and their age has been inferred rather from he character of the leaves than from their strati-raphical position. The age of many of the so-called iocene leaf-beds is admitted now to be extremely oubtful.

What little evidence we may expect to find in these eds seems to me likely to be in favour of the theory of volution by descent, although until the flora has been orked out, it is premature to offer an opinion. By far e greater number of the plants belong to the lowest ivision of the dicotyledons, the *apetalæ*, a minority are *olypetalous*, whilst none can, as far as I know, with cer-inty be assigned to the highest (according to Haeckel) roup, the *monopetalæ*.

Prof. Ettingshausen has traced the gradual develop-ent of some of the Miocene forms into existing species, otably that of *Castanea atava* to *Castanea vesca*; when e was here last summer and saw my collection, he espe-ially picked out the castanea from Bournemouth as arrying the history of this genus a step further back, and nking it with the oak—as it possesses an oak-like haracter of venation. I would merely add that many otanists who have studied fossil plants, as Unger, chimper, and others, are profoundly impressed with the mount of botanical evidence that has already been rought forward in support of the theory of evolution.

OUR ASTRONOMICAL COLUMN

RED STAR IN CETUS.—No. 4 of Sir John Herschel's list of d stars at p. 448 of his Cape Observations is placed by him in A. 1h. 19m. 8·7s., N.P.D. 123° 26′ 1″ for 1830, with the remark "most beautiful orange red. Two observations," and he estimated it 6m. Dunlop in his catalogue of 253 double and triple stars in vol. iii. of the *Memoirs of the Royal Astronomical Society*, gives the position of a highly-coloured object thus: for 1827, R.A. 1h. 19m. 43s., N.P.D. 123° 31′, and calls it "a very singular star of the seventh magnitude, of an uncommon red purple colour, very dusky, and ill-defined;" he made three observations upon it, and notes that it had a small star preceding and another following it. We may presume that these stars are identical, with an error of position on the part of one or other observer, most probably on Dunlop's, whose catalogue contains a number of errors; and it may also be supposed that this is the star spectroscopically examined by Secchi, which he calls No. 11 of Schellerup's catalogue of red stars, but places in 35° 17′ S. declination (A.N. 1737), perhaps through a misprint. In this state of uncertainty as to the star's true place, meridional observation appears very desirable. So far we believe it is not to be found in any catalogue, founded on such observations; it does not occur in the zones published in the Washington volumes 1869-71, a most valuable series, nor in those of Prof. Ragona in the *Giornale Astronomico e Meteorologico del R. Osservatorio di Palermo*, vols. i. and ii., neither is it found in the southern catalogues of the Cape, Madras, or Melbourne Observatories. Sir John Herschel's place reduced to 1877·0 is R.A. 1h. 21m. 19·0s., N.P.D. 123° 11′ 16″. Secchi says of the star he examined, "couleur rose; spectre à zones discontinues."

VARIABLE STARS.—There is considerable probability that Lalande 12863-5 should be added to the list of variable stars. His estimates of magnitude are 6½ and 8½; it is 6 on Harding's Atlas and in Argelander, 6·7 in Heis, 7·3 in the *Durchmusterung*, but does not occur in Piazzi, Bessel, or Santini. Piazzi has a star of the ninth magnitude about 1¼° distant (VI. 190), which, oddly enough, he places in the Lynx. The position of Lalande's star for the beginning of 1877 is in R.A. 6h. 35m. 23s., N.P.D. 83° 32·3′.

Will some one of our southern readers record the actual magnitude of μ Doradus? At present we have the following estimates indicating a long period of variation. La Caille 5m. about 1751, Brisbane 6m. about 1825, Jacob 9·5m. in 1850 and 9·2m. in 1855; while Moesta states that between February, 1860, and January, 1861, he had always found it 8¼m. or 9m. The law of variation may be similar to that of 34 Cygni, P Cygni of Schönfeld, the so-called Nova of 1600.

A FIFTH COMET IN 1851.—In a small tract entitled "Ragguagli Popolari sulle Comete Periodiche," by Prof. Ragona, published at Palermo, in 1855, there is reference to a comet stated to have been discovered at Rome by Prof. Calandrelli, director of the Pontifical Observatory, in the morning twilight on November 30, 1851, which both the discoverer and the writer of the tract considered to be the short-period comet of Brorsen, due in perihelion in the autumn of that year. By comparison with B.A.C. 4798, the following position resulted:—

1851, November 29, at 17h. 32m., M.T. at Rome.

Right Ascension, 14h. 21m. 38s. Declination, + 1° 47′ 2″. This position Prof. Ragona compares with the elements of Brorsen's comet according to Dr. van Galen, and found the differences between calculation and observation + 35′ 27″ in R.A., and + 11′ 1″ in declination. But notwithstanding this approximation, it is certain it was not the periodical comet of Brorsen that was observed by Calandrelli, Dr. van Galen's prediction having been vitiated by a serious error of calculation, so that, instead of arriving at perihelion on November 10, the date assigned by him in *Ast. Nach.*, No. 782, the comet passed that point in its orbit about September 25, and consequently on November 30 was far removed from the position of the body observed by Calandrelli, which was therefore a new comet.

It is stated that Calandrelli published an account of his observations in the Roman journals in December, which was transferred to the official journal of Palermo on the 11th of the same month. Perhaps a reference to the Italian journals might bring to light a further observation or observations; the comet is said to have been bright, but the weather about the date of discovery was unsettled, and for several days previously had prevented observations of any kind.

Belts on Jupiter.—In connection with the supposed periodicity in the appearance of marked colour on the belts of this planet, the observations of Gruithuisen, of Munich, in the years 1836-40 possess interest. They are found in his *Astronomische Jahrbuch*, 1839, p. 76, 1840, p. 99, and 1841, p. 101. He first noticed the colour on April 23, 1836, at 9½h., when, observing with a 30-inch refractor of 2½ inches aperture, and power 150, the single central belt then visible had a brown tint throughout, and he states that, hardly believing his own vision, he called a person who was at hand, and on asking him what colour the belts presented, he replied "the colour of rust." With a 5-feet telescope, power 120, the brown tint was not distinguished. On subsequent occasions he found that with the highest powers of the telescope the belt appeared of a bright reddish brown, while with the lower powers it was merely of a dark shade, and hence concluded that the intensity of light was disadvantageous to discerning the colour. In addition to the brown tint of the central belt, it was remarked that the planet near its north pole had a bluish-grey tint in May, 1836; a few months later Dr. Albert, a pupil of Bessel, observing with a 30-inch telescope, found the polar region "quite blue." The length of Gruithuisen's descriptive remarks prevents their being transferred to this column, but we refer to the observations, as his annual volumes are not often met with here, and the fact of such observations having been made forty years since may not be generally known. That these tints should have been conspicuous with such small optical aid is worthy of note.

The Intra-Mercurial Planet.—In M. Leverrier's last communication to the Paris Academy on the planet assumed to exist within the orbit of Mercury, it was mentioned that, with the elements adopted, or very similar ones, a solar conjunction would occur on March 22, and a transit over the sun's disc was possible, though uncertain. A close examination of the disc is therefore to be recommended on March 22 and 23, and there is reason to believe that observers in widely-differing longitudes are prepared to undertake it. If no transit should then occur, eight or nine years may elapse before one is possible at the spring node.

CHEMICAL NOTES

Atomic Weights of Caesium and Rubidium.—M. Godeffroy gives an account in Liebig's *Annalen* of some determinations he has made on the above subject. To obtain pure material he employs Redtenbacher's method for the separation of the caesium, rubidium, and potassium, by preparing their respective alums, separating these by fractional crystallisation, and finally converting them into pure chlorides of the metals. The determination of chlorine in the non-diliquescent caesium chloride, gave, as the mean of four closely-agreeing experiments, the atomic weight of caesium as equal to 132·557, the atomic weights of chlorine and silver being taken as 35·46 and 107·94 respectively; from analogous experiments the author finds the atomic weight of rubidium to be equal to 85·476.

the Specific Heat of Gases.—
vii., E. Wiedemann gives a most
munication on this matter, in which he criticises the
of Regnault on the same subject, and describes a new method of

the specific heats of gases introduced by
ng the author's results with those of Regnault it is found that the method employed by the former is not inferior in accuracy to that of Regnault, and also that a great economy of material may be effected by using Wiedemann's process; this economy giving the experiments greater range in a comparatively shorter time. The following tables give a synopsis of the
bers and numerous tables given in Wiedemann's paper:—

Specific Heats of Equal

		II.	III.	IV.
Air	0·2389			
	3·410			
Carbon monoxide	0·2426			
Carbon dioxide	0·1952			
Ethylene	0·3364		0·5015	49·08
Nitrous oxide ...	0·1983	0·2212	0·2442	23·15
Ammonia ...	0·5009	0·5317	0·5629	12·38

Heats of Equal Volumes.

	V.	VI.	VII.	VIII.	
		100°	200°	Specific weight.	$\frac{PV}{P'V'}$
Air	0·2389	—	—	1	1·00215
Hydrogen	0·2359	—	—	0·0692	—
Carbon monoxide...	0·2346	—	—	0·967	1·00293
Carbon dioxide ...	0·2985	0·3316	0·3650	1·529	1·00722
Ethylene	0·3254	0·4052	0·4851	0·9677	
Nitrous oxide ...	0·3014	0·3362	0·3712	1·5241	1·00651
Ammonia	0·2952	0·3134	0·3318	0·5894	1·01881

Columns I., II., III., contain the true specific heats at the temperatures indicated; column IV. the difference of specific heat at 0° and 200° expressed in percentage of the specific heat at 0°. Columns V., VI., VII., represent the true specific heats in reference to the unit of volume, the specific heat of the unit volume of air being taken as 0·2389; column IX. gives Regnault's proportions of the products of the volumes V and V', and the pressures P and P', when P is at the pressure of one, and P' at the pressure of two atmospheres. Herr Wiedemann thinks that the specific heat determined in these experiments seems to be composed of two parts, the heat caused by work expended on the expansion of the gases in overcoming outside pressure, and secondly, the heat employed in the internal work of the gas itself. He also thinks that attempts to determine the separate parts of the heat of molecular motion, of which the specific heat is composed in constant volumes—of the heat of atoms according to Naumann—and also the attempt to establish simple relations between the two to be still premature, as the alteration of the specific heat with the temperature would cause these effects to have different relations between different temperatures. The author thinks that the alteration of specific heat of the gases with the temperature cannot be explained by the deviation of such gases from the perfect gaseous condition. As an illustration of this he cites the case of ammonia gas, which, although more remote from the state of a perfect gas than nitrous oxide or carbon dioxide, still possesses smaller variations of its
heat with change of temperature than either of these latter gases.

Antimony Pentachloride on certain Or-
Substances.—The action of this re-agent on some organic substances has lately been investigated by C. W.
who
obtained. When chloroform and antimony pentachloride are

chloroform becomes converted into carbon tetrachloride. Ethyle omide is attacked by antimony pentachloride, the whole of the bromine being liberated and ethyle chloride formed. The action of antimony pentachloride on ethene bromide differs according to the quantities employed. With the same number of molecules of the two substances the chief product is ethylene chlorobromide, whilst with two molecules of pentachloride to one of ethene bromide the product is ethene chloride. Ethene bromide is not acted on when similarly heated with phosphorous pentachloride. The product of the reaction of acetic acid with antimony pentachloride is monochloracetic acid, accompanied by another substance with a higher boiling point. When salicylic acid is gradually added to antimony pentachloride, monochloro- and dichloro-salicylic acids are produced along with other products; monochloro-salicylic acid is found in small quantities only. Dichloro-salicylic acid on being boiled with potash for a considerable length of time exchanges its chlorine for hydroxyl, yielding gallic acid accompanied with pyro-gallic and oxy-salicylic acids. When para-oxybenzoic acid is acted on by two or four molecules of antimony pentachloride the mono- and dichlorinated acids are found respectively. From these reactions it is evident that the action of antimony pentachloride differs from that of its analogue, phosphorous pentachloride, since it simply parts with its chlorine, which replaces hydrogen in the acid radical, instead of replacing the hydroxyl group by chlorine, as is generally the case when phosphorous pentachloride acts upon organic substances.

ACTION OF CHLORINE ON PEROXYDES.—MM. Spring and Arisqueta continue (*Bull. Acad. de Belg.*, xlii p. 565) their researches into the action of chlorine on peroxydes of metals, for the purpose of elucidating the very important question whether the atomicity of certain bodies is variable (as supposed by Kolbe and Blomstrand), *i.e.*, whether whilst one atom of a body in a molecule is, say, tri-atomic and possesses basic properties, another atom of the same body may be pent-atomic and partake of the properties of an acid, or whether the atomicity remains invariable, as supposed by Kékulé and the authors of the paper. Former researches induced M. Spring to conclude that the atoms of chlorine possess constantly the same properties in all their compounds with oxygen, which would be contrary to the alleged varying atomicity. Now, studying the action of chlorine upon the peroxyde of silver, the authors prove, by a very delicate experiment, that its result is the formation of a peroxyde of chlorine, a body prevised by the theory, but unknown until now, and they conclude, therefore, that the structure of peroxydes of silver and of chlorine is identical, which identity gives a new argument in support of the invariability of the atomicity of chlorine and silver.

BORON AND ITS SPECIFIC HEAT.—Boron occurs, it is known, in two different forms, in the amorphous state, and in crystals. M. Hampe has recently found (*Liebig's Annalen der Chemie*) that both the black and the honey-yellow crystals are not pure boron, but compounds of the element; the black crystals consisting of albuminium and bromine in the proportions AlB_{12}, and the yellow crystals of aluminium, carbon, and boron, $C_2Al_3B_{48}$. Boron has hitherto been numbered among the few elements which show a departure from Dulong and Petit's general law of the constancy of specific heat into atomic weight, and M. Weber sought the reason for this departure in the case of boron, as in those of carbon and silicon, in the fact that the specific heat varies with the temperatures, but at high temperatures reaches a value which establishes an agreement with Dulong and Petit's law. The determination of the specific heat of boron, however, as also M. Weber's experiments, were made with crystals of boron. Now, since, according to M. Hampe, these crystals are not pure boron, but compounds of it, the whole question as to the validity of Dulong and Petit's law for the pure element boron remains an open one. All the attempts made by M. Hampe to produce pure crystallised boron had been without success. He is engaged in further investigating whether the amorphous boron can be produced in absolute purity.

HEATED AIR.—Dr. Kayser, of Nuremberg, has lately conducted a number of experiments upon the effects of heating ordinary air, with especial reference to the warming of dwellings. The results appear in the last report of the Munich Industrial Museum, and may briefly be summed up as follows:—Air previously free from carbon monoxide was invariably found to contain this gas after heating. The tests were performed with chromic acid, and also with cuprous chloride. In order to test the products of the decomposition of the dust present in the air, about sixty litres of air, which had been heated, were drawn through an ordinary apparatus for determining carbonic acid, which contained absolute alcohol. The liquid assumed a yellowish brown colour, and flakey masses were suspended in it. The flakes were found to consist chiefly of carbon. After filtration and evaporation of the solution, a brown residue was obtained. This was insoluble in water, intensely acrid, and possessed a resinous, empyreumatic odour. The estimations of carbonic acid and water before and after heating showed no difference worthy of mention.

NOTES

CONTRIBUTIONS are being collected in Stockholm for the establishment of a scientific college. The *Dagblatt* states that steps will be taken at once to fill the chairs in philology, the natural sciences, history, &c.

BARON VON RICHTHOFEN, for a long series of years president of the Berlin Geographical Society, has accepted a call to the Chair of Geography in the University of Bonn.

THE large collections brought back by the German exploring expedition in the *Gazelle* under the command of Baron v. Schleinitz have been formed into a separate museum in Berlin. The ethnographical section is especially rich and valuable, embracing many objects brought from islands where the natives are rapidly disappearing.

THE Society for African Exploration at Berlin has been amalgamated with the newly-formed German branch of the international societies, under the leadership of the King of Belgium. During the three years of its existence it has been exceedingly active, and has expended the following sums:—Dr. Güssfeldt's Loango expedition, 9,200*l.*; expedition of Homeyer, Lux, and Pogge to the Cassandje, 1,000*l.*; Dr. Lenz's journey to the Ogowe, 1,000*l.*; various stations and shorter excursions, 2,500*l.* It has at present over 5,000*l.* in its treasury. The first session of the newly-formed *Deutsche afrikanische Gesellschaft*, was held in Berlin on January 16. The society confines its field of operations to Central Africa, proposing to open up this region "to civilisation, travel, and commerce, by the establishment of permanent stations and the maintenance of exploring parties." The energies of the society will also be directed to the repression of slavery. A letter was read from the Crown Prince of Germany, expressing his desire to take an active part in furthering the objects of the Society. A request for pecuniary assistance from the Government has already been presented to the Chancellor of the Empire.

THE Berlin *Afrikanische Gesellschaft* has received telegraphic news from Dr. v. Pogge, the African explorer, who landed last week in Lisbon, stating that he had succeeded in penetrating to the long-sought-for country of King Muata Yambo in Central Africa. A detailed report is awaited with interest in geographical circles.

DR. O. LENZ, the African traveller, has been forced to return to Europe with a shattered constitution. For a number of years he has indefatigably pursued his researches in equatorial Africa, having led, during this period, the three German exploring expeditions into the Ogowe and Gaboon region.

THE Council of the Italian Geographical Society have agreed to present Sir George Nares with its gold medal.

AT the last meeting of the Paris Geographical Society the Abbé Durand gave an address, the object of which was to prove that the Portuguese crossed Central Africa in the fifteenth and sixteenth centuries, from the Congo to Mozambique.

THE Norwegian geologist, K. Pettersen, is planning a new expedition to Spitzbergen during the coming summer, which shall aim at a thorough geological survey of the island. A petition has been presented to the Norwegian Government requesting a grant for the undertaking.

AT the meeting of the Royal Geographical Society on Monday, Dr. Mullens read a paper on "Later Explorations in Madagascar," giving an account of five journeys of unusual importance, and over entirely new ground, by English missionaries in Madagascar during the last two years.

ON January 13 the Sumatra Expedition of the Dutch Geographical Society embarked at Nieuwediep for the east. A corps of leading scientific men have been gathered together for this expedition, and interesting as well as valuable results are expected from their researches. A great portion of their time will be devoted to the exploration of the as yet unvisited Diambi region, which is represented by the natives as abounding in useful woods and minerals. The Dutch Government has displayed a lively interest in the undertaking, and has placed at the service of the expedition a steamer completely fitted out for a two years' cruise. If favourable reports are brought back it is intended to send colonies to the above-mentioned district.

ON January 10 the St. Petersburg Academy of Sciences celebrated its 150th annual anniversary in an extraordinary gathering, at which the Emperor and royal family were present. Count Lütke, the president, reviewed the past activity of the Academy in a short address. The great medals of merit were assigned this year to Profs. Beilstein and von Bunge. The Emperor of Germany and M. Lesseps were among the list of those elected as honorary members. Among the fourteen leading scientific men elected as corresponding members, were Profs. Frankland, Newton, and Wright, England; Prof. Kirchhoff, of Berlin; Prof. Fiorelli, of Naples; Profs. Berthelot, Egger, and Decaisne, of Paris.

ON January 12, Prof. Wilhelm F. B. Hofmeister, one of the leading German botanists, died at the age of fifty-two. Although a self-taught botanist, he attracted attention at an early age by his publications on embryology and the physiology of plants, and was elected member of several royal academies. In 1863 he was called to the ordinary professorship of botany in Heidelberg, and in 1873 accepted a call to Tübingen, where he was active until the time of his death. But a short time since he received from Holland the great medal of Boerhaave—worth 75*l*.—in recognition of his botanical investigations. Among Prof. Hofmeister's principal works are "Die Entwickelung des Embryo der Phanerogamen. Eine Reihe mikroscopischer Untersuchungen," "Vergleichen der Untersuchung der Keimung, Entfaltung und Fruchtbildung höheren Kryptogamen, und der Samerbildung der Coniferen," and an extensive handbook of physiological botany, published in conjunction with de Bary, Irmisch, and Sachs.

WE regret to record the death, on the 11th inst., of Mr. Alfred Smee, F.R.S., F.C.S., F.R.C.S., F.L.S., &c. Mr. Smee was born June 18, 1818. He was educated at St. Paul's School, and afterwards at King's College and St. Bartholomew's Hospital, and was elected Fellow of the Royal Society at the early age of twenty-one. As an eminent and well-qualified medical man he held many offices, including that of Surgeon to the Bank of England. To scientific men he is best known as the inventor of the battery known as Smee's Battery, and which for certain purposes is still more useful than any other form of battery. For this he got the Gold Medal of the Society of Arts in 1840. He was author of numerous works, of which we note the following:—"Elements of Electro-Metallurgy," "Sources of Physical Science," "Elements of Electro-Biology," "On the Monogenesis of Physical Forces," "Lecture on Electro-Metallurgy," "My Garden," "The Mind of Man."

THE French *Officiel* publishes the regulations for the appointment of professors of hydrography by the Government. There are to be three classes of them. The third class is to be recruited by competitive examination from officers of the national navy and captains of the mercantile navy. They are to be appointed by the President of the Republic, according to the award given by the jury of admission. The jury is to be composed of an admiral or vice-admiral president, two examiners from the marine department, a hydrographical engineer, and a professor of hydrography.

THE credit asked by the French Government for public instruction in 1878 is 52,000,000 francs. In 1877 it was 49,000,000, and in 1876 only 39,000,000.

THE electric light is becoming common in Paris in connection with works that have to be carried on during the night. A large lamp fed by a six-horse power has been established in the Avenue de l'Opéra, and others are employed in the Trocadero in connection with the building of the Exhibition Palace. The gramme machine and screw regulator are employed.

THE first number is issued of an important publication, *The Wild Flowers of America*, by Dr. G. L. Goodale, Professor in Harvard University, with coloured illustrations by Isaac Sprague. The present number consists of figures of five species, in four plates, and the plates are accompanied by a botanical description together with some gossip about folk-lore, popular names, &c. The paucity of figures of even the commoner American plants will render the work very welcome to botanists. The name of the artist is a sufficient guarantee of the faithfulness of the drawing, and the colouring appears to us to be successful.

CAPT. H. W. HOWGATE, Acting Signal Officer, U.S.N., suggests the following method of attaining the North Pole:—To be able to take advantage of the occasional breaking-up of the ice-barrier with the greatest certainty and with the least expenditure of time, money, and human life, it is essential that the exploring party be on the ground at the very time the ice gives way and opens the gateway to the long-sought prize. This can only be done by colonising a few hardy, resolute, and experienced men at some point near the borders of the Polar Sea, and the most favourable one for the purpose appears to be that where the *Discovery* wintered last year. Such a party should consist of at least twenty men, and should be provided with provisions and other necessary supplies for three years, at the end of which period they should be visited, and, if still unsuccessful in accomplishing the object, revictualled and again left to their work. It is stated that an effort will be made to induce the U.S. Government to adopt this plan.

BEHM'S last *Geographischer Jahresbericht* shows a total of thirty-six geographical societies in existence at present.

DURING the middle of January the South of Norway has been visited with the severest snowstorm experienced since 1818. In some of the villages snow covers the roofs of the houses to the depth of sixteen feet, and dwellings have been unable to support the overlying weight. Communication is dependent upon the use of snow-shoes.

THE Prussian Universities granted during the past year 500 doctor's diplomas upon the basis of a thesis and oral examination. Göttingen bestowed 139, Berlin, 90. Twenty honorary degrees were granted during the same period.

M. FIZEAU has been elected Vice-President of the French Academy of Sciences for the coming year, from the section of the mathematical sciences; the President is M. Peligot. Of the Academy's *Mémoires*, tome xxxix., in course of publication, is reserved for works of M. Chevreul, on dyeing, on an error of reasoning frequent in sciences which are concerned with the concrete, science in relation to grammar, history of opinions on the chemical nature of bodies of chemical and living species, &c. The Academy is also publishing a number of documents on the Transit of Venus. Tomes xxiii., xxiv., and xxv. of *Mémoires des Savants Étrangers* contain memoirs on the theory of running waters, a system of irrigation, the succinic series, the carboniferous flora of the department of the Loire, the transformation and equivalence of chemical forces, the transparence of flames, vision of scintillating lights and nocturnal transparence of the atmosphere, the Phylloxera, &c.

THE *Bulletin de la Fédération des Sociétés d'Horticulture de Belgique* for 1875 is just published, and illustrates the great activity with which this branch of science is pursued in the little kingdom. Besides the official papers connected with the federation, and reports from twenty-five associated societies, the volume contains the "Correspondance botanique" for that year, a list of botanists and horticulturists holding official positions throughout the world, a sketch of the life of Mathias de l'Obel (Lobelius), by E. Morren, and several other papers by the same writer.

MR. THOMAS COMBER reprints from the *Transactions* of the Historic Society of Lancashire and Cheshire, a useful paper entitled "Geographical Statistics of the Extra-British European Flora," containing a considerable mass of information which will be valuable to anyone interested in the subject of the distribution of continental species, and the causes of the range which they now enjoy.

HUNGARY is developing no small degree of activity in matters of scientific interest. The president of the Royal Society for Natural Sciences at Pesth reported in the annual Session of January 17, that the present membership amounts to 4,650. Five subjects for prize treatises were announced, one of which was on the chemical resources and industries of the kingdom.

THE phenomenon of the "black drop" has recently been made the subject of experimental study by M. Ch. André, who has communicated his results to the French Academy. Without stopping to describe his artificial transit, we may state that he had a battery communicating with the planet Venus, the other with the limb of the sun; and at the moment of geometrical contact a current was produced, which was registered on a Brequet chronograph. On the same instrument was inscribed parallelly the hour given by a Winnerl pendulum, and the mark produced by the observer pressing down a Morse key. The conclusions of M. André are, shortly, as follows: The black drop is not an accidental fact, but one that is necessary and characteristic of the phenomenon. With sufficiently strong light, the bridge is always produced at the moment of geometric contact, however perfect the telescope. It may be made to disappear entirely in the retinal image, either by increasing sufficiently the absorbent power of the dark glass used, or by placing before the objective a screen formed of a large number of very narrow rings separated by dark rings of the same width, also by diminishing the intensity of the luminous source. In each case the transit is produced in a geometric manner. All these facts accord with the theory of diffraction rightly interpreted. The ligament is not a real obstacle to observation of the transit. There is a *simultaneous phase* for all telescopes, whatever their apertures, which corresponds to geometric contact, and after a suitable education one may observe with an error equal at the most to 0·75s. for internal contact of ingress, and 1·50s. for internal contact of egress. The total error, then, may be reduced to 2·5s. Now to have the solar parallax to a hundredth of second of arc, it is sufficient not to commit, in the duration of transit, an error above five seconds of time; hence the observation of the transit of Venus may furnish this parallax to nearly five-thousandths of a second of arc.

A PAIR of Kœnig Ut^4 forks will show the phenomenon of sympathetic resonance at much greater distance than a pair of Ut^3 forks. The common explanation is that as double the number of impulses are delivered in a second, double the energy is conveyed to the distant fork. This is questioned by Mr Robert Spice (*American Journal of Science and Arts*), in view of the law of forces radiating from a centre. At twenty feet, in fact, the intensity of resonance of Ut^4 forks is undoubtedly greater than the intensity of Ut^3 forks at six feet. With Ut^3 forks of bell-metal he got, at forty feet, a greater result than that obtained with the steel Ut^4 forks of Kœnig. The hypothesis he offers is this: *The intensity of sympathetic resonance of forks on their cases increases with the angular deviation or motion of the prongs.* By means of an electro-chemical registering apparatus Mr. Spice finds that when a fork (between Ut^3 and Ut^4) is in vibration, its stem or handle alternately rises and falls in accord with the period of the fork, through about $\frac{1}{80}$ inch. In sympathetic resonance the case gives the stem this up-and-down motion, which is conveyed to the prongs and sets them in motion, as a hand might start a pendulum suspended from it (by moving laterally, say, one inch each way). This motion of $\frac{1}{80}$ inch may be looked on as a constant. If we decrease the length of the fork without altering the constant, we thereby allow of a greater initial angle, the result of which is the same as shortening the pendulum cord. Thus we are in a position to explain the deportment of the bell-metal forks. The velocity of sound in bell-metal is much less than in steel; hence, retaining similar thicknesses in both cases, an Ut^3 fork in bell-metal would be shorter than an Ut^3 fork in steel. Therefore, though we retain the vibration number, we gain advantage from the shortness of the fork, and hence from the increase of angular motion of the prongs.

THE applicability to liquids of Kirchoff's law as to the subdivision of galvanic currents in bifurcating metallic conductors having been doubted, Prof. Lenz has recently (*Bull. de l'Ac. de St. Pétersb.*, vol. xxii., No. 3) made a series of experiments with solutions of sulphates of copper and zinc and of nitrate of silver. He arrives at the conclusion that the subdivision of galvanic currents in liquids follows exactly the same laws as their subdivision in metallic conductors.

IN a paper "On Evolution in Geology," in the January number of the *Geological Magazine*, Mr. W. J. Sollas, starting from the ground that the energy of the earth and the sun is a continually diminishing quantity, and must at the beginning of geological history have been far in excess of its present amount, briefly discusses the influence of this greater quantity of energy on geological changes. He arrives at the conclusion that all main factors of geological changes, viz., the denudation, reproduction, and the elevation and depression of strata, must have notably and rapidly decreased in intensity; and, alluding to the opposition met with from geologists by Sir W. Thomson's views, he insists on the mistake of attempting to check the results as to the age of the world obtained by the physicist with these deduced by the geologist," which last are based on the rate of changes produced now, during a period of diminished energy of all main geological factors.

THE Chair of Botany at Aberdeen, we learn from the *Gardener's Chronicle*, is likely to be vacant shortly. Among the candidates are mentioned the names of Dr. J. B. Balfour, Rev. Dr. Brown, Dr. W. R. M'Nab, and Dr. Traill.

MR. C. P. OGILVIE, who has been studying the art of aquarium management at the Royal Aquarium, Westminster, has been appointed Curator and Resident Naturalist to the aquarium recently completed at Great Yarmouth, Norfolk.

THE distance between Paris and Marseilles is 863 kilometres, not 1,820, as stated in our note on p. 266 last week.

THE additions to the Zoological Society's Gardens during the past week include a Malbrouck Monkey (*Cercopithecus cynosurus*) from East Africa, presented by Mr. L. C. Brown; a Macaque Monkey (*Macacus cynomolgus*) from India, presented by Mrs. Cecil Long; a Pig-tailed Monkey (*Macacus nemestrinus*) from Java, presented by the crew of H.M.S. *Dwarf;* a Bay Lynx (*Felis rufa*) from North America, presented by Mr. W. Otho N. Shaw; two Teguexin Lizards (*Teius teguexin*) from South America, presented by Mr. A. Stradling; an Ocelot (*Felis pardalis*), an Azara's Fox (*Canis azaræ*) from South America, a Tataupa Tinamou (*Crypturus tataupa*), two Talpacoti Ground Doves (*Chamæpelia talpacoti*), two Scaly Doves (*Scardafella squamosa*) from Brazil, a Chopi Starling (*Aphobus chopi*), a Chilian Sea Eagle (*Geranoaëtus aguia*) from Pernambuco, deposited; two Ring-tailed Lemurs (*Lemur catta*) from Madagascar, purchased.

SCIENTIFIC SERIALS

THE *American Journal of Science and Arts*, January.—Contributions to meteorology, being results derived from an examination of the observations of the United States Signal Service, and from other sources, by Elias Loomis.—On some points in connection with vegetation, by J. H. Gilbert.—Observations on a property of the retina first noticed by Tait, by Ogden N. Rood.—On grains of metallic iron in Dolerytes from New Hampshire, by George W. Hawes.—On certain phenomena of binocular vision, by Francis E. Nipher.—Notes on the Vespertine strata of Virginia and West Virginia, by William M. Fontaine.—On the production of transparent metallic films by the electrical discharge in exhausted tubes, by Arthur W. Wright.

THE *Verhandlungen des naturhistorischen Vereins der preussischen Rheinlande und Westfalens* (Jahrg. 33, Part 1.) contain the following papers of interest:—Geological, Mineralogical, and Anthropological Section: On some new discoveries in the Jurassic formation west of the river Weser, by W. Treukner.—On a diseased ox's rib from the calcareous tuff-stone in the vicinity of the Toenisstein saline spring (Rhenish Prussia), by Prof. Schaaffhausen.—On some bronze implements found near the Weser river, by the same.—On a petrified piece of wood with the image of a human face, by the same.—On the so-called periclinic combinations of Albite by Prof. vom Rath.—On Skorodite-crystals, on plagioclase, and on Brookite crystals, by the same.—On a pine cone found near Dormagen, on the Rhine, together with Roman coins and antiquities, by Prof. Schaaffhausen.—On Capellini's researches on pliocene man in Tuscany, by the same.—On some stone implements recently found, by the same.—On geological researches made at Nagyag and Vöröspatak, in Transylvania, by Prof. vom Rath.—On olivine from Dockweiler and on crystallised slakes, by Dr. Mohr.—Physical Section: On Mallet's theory of volcanic force, by Prof. A. von Lasaulx.—On a further simplification of the electrodynamic fundamental law, by Prof. Clausius.—On anomalous dispersion of light, by Prof. Ketteler.—On the effects of a stroke of lightning, by Herr Gieseler.—Zoological and Anatomical Section: Synoptical review of the genera and species of *Stilpnoida*, by A. Förster.—On the respiration of *Limnaca*, by Prof. Troschel On a specimen of *Pediculus capitis* with extremely large system of tracheæ, by Dr. Bertkau.—On Dareste's investigations on the reproduction of eels, by Prof. Troschel.—On the *Cephalopoda* of the German upper chalk, by Dr. Schlüter.—On the spermatogenesis of *Amphibia*, by Prof. von la Valette St. George.—Botanical Section: On the influence of interior and exterior causes upon new formations in plants, by Prof. Vöchting.—On the fruit of *Raphia taedigera*, by the same.—On some phenomena observed in the botanical garden of Poppelsdorf, near Bonn, during the summer of 1875, by Herr Körnicke.

SOCIETIES AND ACADEMIES

LONDON

Royal Astronomical Society, January 12.—Mr. William Huggins, D.C.L., president, in the chair.—Mr. Robert John Baillie, Mr. Henry Vere Barclay, the Rev. Daniel Dutton, Mr. Samuel Haywood, Dr. Louis Stomeyer Little, Mr. Richard Pearce, Commander William James Lloyd Wharton, R.N., H.M. surveying ship *Fawn*, and Mr. Jesse Young, were elected Fellows of the Society.—A paper by Mr. Marth giving an ephemeris for the satellites of Uranus for the year 1877, was read. This is one of a series of papers which Mr. Marth has presented to the Society giving ephemerides useful for physical observations of the major planets and their satellites. It was remarked by the president that these ephemerides involve much labour in their construction, and the astronomical world is greatly indebted to Mr. Marth for their production.—A paper by Prof. Harkness on the theory of the horizontal photoheliograph was read. The instrument consists of a heliostat and a long focussed object-glass, in the principal focus of which the negatives are taken; the distortion produced by secondary magnifiers is thus avoided, and very accurate means are adopted for determining the shrinkage of the collodion film upon the plate and the accurate orientation of the photograph.—Mr. Wentworth Erck read a paper on an improved eye-piece for viewing the sun. His method is to use a small glass prism as a reflector which is placed within the image of the sun, so that only a portion of the rays from a part of the disc are reflected into the eye-piece at any one time; the effects of heating are thus reduced to a minimum, and for viewing small areas of the sun the eye-piece is preferable to that suggested by Mr. Dawes in which the light of the whole image is reflected and the small area to be observed is viewed through a diaphragm which is exposed to the heating effects of the reflected rays.—A paper by Mr. Knott was presented to the society; it contains a catalogue which he has been some years in preparing, and gives a very large number of micrometrical measures of double stars which have been made with a very fine eight-inch refracting telescope formerly the property of Mr. Dawes.

Chemical Society, January 18.—Prof. Odling, F.R.S., vice-president, in the chair.—The secretary read a paper by Dr. Jäger on some derivatives of dithymyltricloroethane, a substance produced on adding a mixture of sulphuric and acetic acids to a mixture of thymol and chloral. By heating this compound with zinc dust it yields dithymylethane and dithymylethene.—Mr. Kingsett then read a preliminary notice by Dr. Heike and himself on some new reactions in organic chemistry and their ultimate bearings, showing that the colour reaction known as the "Pettenkofer reaction" produced by the action of sulphuric acid on sugar and cholic acid extended to many other substances, some of which did not require the admixture of sugar to produce the colour. This was followed by a paper on dinitroso-orcin and dinitro-orcin, by Dr. J. Stenhouse and Mr. C. E. Groves, in which the methods of preparation and properties of these compounds were fully described.—The last communication, by Mr. T. Carnelley, was on high melting points with special reference to those of metallic salts, Part 3.—The meeting was then adjourned until Thursday, February 1.

Zoological Society, January 16.—Prof. Newton, F.R.S., vice-president, in the chair.—Capt. H. W. Feilden, exhibited and made remarks on some of the birds collected by him in the Arctic regions during the recent North Polar Expedition. Sixteen species were enumerated as having been met with on the shores of the Polar Basin, and north of 82° N. lat., but some of these only occurred as stragglers.—The Rev. Canon Tristram exhibited and made remarks on a specimen of a rare terrestrial Dormouse (*Eliomys melanurus*), obtained by him in Southern Palestine, where it is found in desert places.—Mr. P. L. Sclater, F.R.S., exhibited and called attention to a collection of mammals, birds, reptiles, fishes, and insects, which had been made by the Rev. George Brown during his recent residence in Duke of York Island, and during excursions to the neighbouring islands of New Britain and New Ireland.—Prof. A. H. Garrod read a note on a variety of the domestic swine in the Society's collection, and pointed out that the presence of rudiments of a supplementary digit between the third and fourth digit might be the cause of the consolidation of the hoof, observable in this variety.—A communication was read from Mr. Henry Durnford containing notices of the habits of some small mammals obtained in the neighbourhood of Buenos Ayres.—A communication was read from Mr. Gerard Krefft, containing notes on a young living Cassowary (*Casuarius australis*), which had been obtained from North Australia, and was destined for the Society's collection.—A communication was read from Mr. G. French Angas, containing a description of a new species of *Helix*, from South Australia, which he proposed to call *Helix* (*Rhagada*) *kooringensis*.—A second paper by Mr. Angas contained the description of two genera and twenty species of marine shells, from different localities on the coast of New South Wales.

Geological Society, December 20.—Prof. P. Martin Duncan, F.R.S., president, in the chair.—Bartholomew Parker Bidder, Robert William Cheadle, David Grieve, Player Isaac, James Love, Kerry Nicholls, William Ridley, William Joseph Spratling, and George Blake Walker were elected Fellows of the Society.—The President announced that the late Dr. Barlow had left to the Society by will the sum of 500*l.*, to be invested and to constitute a fund under the title of the Jameson-Barlow Fund," the proceeds to be applied annually, or at intervals of two or more years, at the discretion of the Council, in such manner as shall seem to them best for the advancement of the study of geology. Dr. Barlow also left to the Society, under certain restrictions, his collections of geological specimens, and a selection of books from his library. The President further announced the donation to the Society, by the Earl of Enniskillen, of the drawings made by Mr. Dinkel, from Sir Philip de Malpas Grey-Egerton's collection, for the illustration of Prof. Agassiz's great work on Fossil Fishes, presented in accordance with the promise made by his Lordship at the meeting of May 24.—The following communications were read:—On *Pharetrospongia strahani*, a fossil Holorhaphidote Sponge from the Cambridge Coprolite Bed, by W. J. Sollas, F.G.S.—On the remains of a large Crustacean, probably indicative of a new species of *Eurypterus*, or allied genus (*Eurypterus ? stevensoni*) from the Lower Carboniferous series (Cement-stone group) of Berwickshire, by Robert Etheridge, jun., F.G.S., Palæontologist to the Geological Survey of Scotland. The fragmentary Crustacean remains described in this paper are referred by the author to a large species of *Eurypterus*. They are from a rather lower horizon in the Lower Carboniferous than that from which *Eurypterus scouleri*, Hibbert, was obtained. The animal was probably twice the size of *E. scouleri*. The remains consist of large scale-like markings and marginal spines which once covered the surface and bordered the head and the hinder edges of the body segments of a gigantic Crustacean, agreeing in general characters with the same parts in *E. scouleri*, but differing in points of detail. For the species, supposing it to be distinct, the author proposes the name of *E. stevensoni*.—On the Silurian Grits near Corwen, North Wales, by Prof. T. McKenny Hughes, F.G.S. The author commenced with a description of sections near Corwen, in North Wales, from which he made out that the grits close to Corwen were not the Denbigh grits, but a lower variable series, passing in places into conglomerate and sandstone with subordinate limestone and shale. The series, under the name of "*The Corwen Beds*," he described in detail, having traced them round the hills south of Corwen, also near Bryngorlan, south of the Vale of Clwyd, on Cyrnybrain, and south of Llangollen. He had noticed in places a kind of double cleavage affecting the lower series, but not the upper, and also fragments of cleaved mudstone included in the upper, from which he inferred a disturbance of the older rocks previous to the deposition of the newer. He exhibited a selection of fossils, and said that immediately below the Corwen beds there were none but Bala fossils. In the Corwen beds all the few fossils found were common to the Llandovery rocks, some of them, as *Meristella crassa* and *Petraia crenulata*, being peculiar to that formation. In the flaggy slates above the Pale Slates he had found Graptolites and Orthoceratites of the same species as those found in the Denbigh Flags. He considered that the Corwen Beds were on the horizon of the May Hill or Llandovery group, and should be taken as the base of the Silurian, thus including in the Pale Slates or Tarannon Shale a thick series which intervened between the Corwen Beds and the flaggy slates of Penyglog.—On mineral veins, by W. Morgan, communicated by Warington W. Smyth, F.R.S.

Meteorological Society, January 17.—Annual General Meeting.—Mr. H. S. Eaton, president, in the chair.—The Council in their Report to the Fellows expressed their satisfaction at the progress that had been made by the Society during the year. The first point on which they thought there was reason for congratulation was the publication in their journal of the daily observations taken at Hawes and Strathfield Turgiss and of the monthly abstracts of the observations at thirteen other stations. The increase in the number of Fellows was considered worthy of special reference, as it is an indication not only of the vitality of the Society but also of the advance which meteorology is now making amongst the professional and general public. They also referred with much satisfaction to the enlargement of the Quarterly Journal as well as to the printing of the Catalogue of the Library and of the List of Fellows, which have both been issued during the year. They drew special attention to the report of Mr. Symons on the new stations which have been inspected and brought into relation with the Society. The financial position, notwithstanding the large outlays during the year, was very good. The report also contained the very interesting discussion by the Rev. T. A. Preston, of the observations on natural periodical phenomena.—The following gentlemen were elected Officers and Council for the ensuing year:—President, Henry Storks Eaton, M.A. Vice-Presidents: James Park Harrison, M.A., John Knox Laughton, F.R.A.S., Robert James Mann, F.R.A.S., Charles Vincent Walkci, F.R.S. Treasurer, Henry Perigal, F.R.A.S. Trustees: Sir Antonio Brady, F.G.S., Stephen William Silver, F.R.G.S. Secretaries: George James Symons, John W. Tripe, M.D. Foreign Secretary. Robert H. Scott, F.R.S. Council: Percy Bicknell, Arthur Brewin, F.R.A.S., Charles Brooke, F.R.S., Edward Ernest Dymond, John Evans, F.R.S., Rogers Field, Assoc. Inst. C.E., Charles Greaves, M. Inst. C.E., William Carpenter Nash, Rev. Thomas Arthur Preston, M.A., William Sowerby, F.L.S., Capt. Henry Toynbee, F.R.A.S., George Mathews Whipple, F.R.A.S.

PARIS

Academy of Sciences, January 8.—M. Peligot in the chair.—The following papers were read:—Exploration of the Gulf of the two Syrtes, between Sfax and Benghazi, by M. Mouchez. This was in the early part of last year. The author sketches the character of the coast, and refers to difficulties he had with the natives, who are very hostile to Frenchmen, but receive Englishmen with ovation, for defending the Sultan. They had some curious very old arms. The great recent development of the Alfa trade on the Algerian coast is notable, and the fact that while 75 per cent. comes to England and 18 per cent. to Spain, only 4 per cent. comes to France. M. Mouchez regrets this small consumption by his country.—Theorems relating to series of triangles of the same perimeter satisfying four other conditions, by M. Chasles.—Does ozone combine with free nitrogen in presence of alkalies to form nitrous compounds and nitrates? by M. Berthelot. He verifies Schönbein's observations on the formation of nitrous compounds during slow oxidation of phosphorus in contact with air, but he had not observed oxidation of free nitrogen by ozone in presence of alkalies. He points out some sources of error in Schönbein's experiments.—Note on the alteration of urine, *à propos* of recent communications of Dr. Bastian, by MM. Pasteur and Joubert. Dr. Bastian had said that M. Pasteur in repeating his experiment had exceeded the point of saturation of the urine (with solid potash). MM. Pasteur and Joubert have re-examined the point, in careful experiment, and produced exact neutralisation; though they consider this not indispensable for fertilisation. Dr. Bastian would have got quite different results from what he described, had he used KO, HO, which alone can properly be called *potash*.—Observations on the interior structure of one of the masses of native iron of Ovifak, by M. Daubrée. In its section it presented the aspect of a loop of iron from a refining hearth, the scoriæ of which had been very incompletely expelled by compression with the hammer or rolling mill.—Note on the fall of a meteorite which took place on August 16, 1875, at Feid Chair, in the circle of La Calle, province of Constantine, by M. Daubrée. It fell about midday; a noise was heard like a thunderpeal, and there was a train of blackish smoke with brilliant light in the middle of it. The mass, which weighed 380 grammes, rebounded to about 30 metres further on, making a hole. It is of the most common type of sporadosiderites.—M. van Tieghem was elected member in the section of Botany, in place of the late M. Brongniart.—Report on a memoir of M. Haton de la Goupillière, entitled "Researches on the Brachistochrone of a Heavy Body with regard to Passive Resistances."—Determination of the polar distance in magnets, by M. Benoit.—Experiments on the coagulation of fibrine, by M. Schmidt. This is essentially a process of fermentation; soluble albuminoid substances are changed by the action of a specific ferment and in presence of a small quantity of neutral salts of alkaline metals, into insoluble bodies. The ferment does not pre-exist; it is formed when the liquids are brought into abnormal conditions. The places of its formation are the white corpuscles of the blood, the lymph, chyle, and pus, and the cells of certain tissues, which undergo decomposition, the liquid then receiving from them a new quantity of fibrinoplastic substance. Meanwhile all the fibrinogen substance disappears as such, while the fibrinoplastic substance in excess, with the ferment becomes a constituent part of the serum. A temperature of zero retards considerably the formation of the ferment; concentrated neutral salts of alkaline metals hinder it almost entirely. They also paralyse the action of the ferment in the liquids.—On the spontaneous disappearance of a disease which for seven years attacked the vines in the island of Cyprus, by M. Dubreuil. It seems to have been öidium; its disappearance is attributed to the growing of abundance of sumach among the vines.—On the construction of open manometers, for measuring high pressures, by M. Cailletet. In his apparatus a metallic tube (70m. long 2mm. inner diameter) is soldered into a reservoir of mercury at the foot of a hill side. At the free end above is adapted a wide glass tube. When the mercury is compressed in the reservoir it rises to the glass tube. This upper part is movable by reason of the flexibility of the metallic tube, and may be shifted between stakes fixed on the slope. The pressure developed is measured by the difference of levels of the mercury in the glass tube and the reservoir.—Effects of heat on voltaic circuits completed by an electrolyte, by M. Hellesen. In one arrangement two test tubes are connected by a tube near the top and fitted with saturated solution of sulphate of copper; a copper plate is inserted in the upper part in one, another in the lower part in the other; and the former is heated with a spirit lamp. A considerable current is had.—Action of sulphate of lime on alkaline sulphates, by M. Ditte.—On the camphor of patchouli, by M. de Montgolfier.—Note on the life and survival of spermatozoids within the mammalian egg, by M. Campana.

January 15.—M. Fizeau in the chair.—The following papers were read:—Exploration of the Great Syrtes, by M. Mouchez. He describes this coast as in great part an utter desert of sand, without tree or dwelling; and the beach strewed with wreck of vessels whose surviving crews were probably massacred. Careful survey was made of some 250 leagues of coast line, also observation of the tide (total amplitude at Syzygies about 1·5m.), the strange atmospheric refractions preceding and following the sirocco, the declination of the needle, and natural history.—Note on the question of the nature and the contagion of the disease called typhoid fever, by M. Bouillaud. M. Pasteur referred to his researches in which he had proved the disease of silkworms to be both contagious and infectious in the highest degree and not at all epidemic, in the ordinary sense. The same would probably hold good for typhoid fever. M. Chevreul also made some remarks.—Spectroscopic study of the new star observed by M. Schmidt, by P. Secchi. His observations chiefly confirm those by M. Cornu.—On the application of photography to observation of the transit of Venus, by M. Angot. This treats of the measurement of direct parallactic effect; which can be measured (1) by the angle of position; and (2) by the distance of the centres of the two stars. In the former it is difficult in practice to get with sufficient exactness a fixed direction as origin for the angles of position. The American expeditions have come nearest solving the problem, and their results will aid to a judgment on the method. In the second method, the determination of the angular value of the images is a difficulty; M. Angot shows how it may be met. A third method, based on the fact, that for objects uniformly illuminated, with straight borders and dimensions far above the zone of diffraction, the increase of the image of a luminous object is equal to the diminution of that of a dark object in like circumstances, seems at first irreproachable, but, in practice, leads to much error, because (1) the diameter of Venus is far from being large with reference to the extent of the diffracted zone; and (2) the luminous intensity of different parts of the sun is not uniform.—Experiments on the coagulation of fibrine, by M. Schmidt. He distinguishes *proplastic* liquids, which do not contain ferments but contain substances generative of coagulation; *plastic* liquids, which coagulate spontaneously and contain ferment and which are generators of fibrine; and *fibrinogenous* liquids, serosities which contain the substance fibrinogen.—Second note relative to the effects produced by Phylloxera on the roots of various American and indigenous stocks, by M. Foey.—Effects of dilute sulphocarbonates on vines, by M. Maistre.—On the simultaneous determination of annual constants of aberration and of parallax, by M. Trepied. Observations of declination will give at once and with the same weight, the special constants of aberration and parallax for each of the stars, and these determinations, made at two stations suitably chosen will enable us to appreciate the influence of the absolute movement of translation of the solar system on the phenomenon of aberration.—On the relations which necessarily exist between the periods of the quadratrix of the most general algebraic curve of degree *m*, and, *à fortiori*, of a particular curve in its degree, by M. Marie.—The phenomena of the radiometer explained by means of pyro-electricity, by M. de Fonvielle. Pyro-electric phenomena occur not only at the surface of certain crystals when subjected to a variation of temperature, but any non-conducting body submitted to the action of luminous rays is heated, then electrified more or less according to its nature and the intensity of the action. M. Fonvielle thinks all the phenomena hitherto observed in the radiometer may be thus explained.—Note on a new derivative of albuminoid matter, by M. Schützenberger—On the optical properties of Mannite, by MM. Müntz and Aubin.—Action of chlorochromic acid on organic matters, by M. Etard.—Chemical studies on mistletoe (*Viscum album*, Linn.), by MM. Grandeau and Bouton: 1. The composition of the stem differs essentially from that of the species of trees on which it grows. 2. The composition varies with the species. 3. Mistletoe contains much more potash and phosphoric acid than its supporting trees, and much less lime. 4. It seems to live on the tree like a plant on the soil; it takes from the yellow parts gorged with nutritive juices, the incombustible matters necessary for its organisation.—On testing of wines for fuchsine and other similar colouring matters, by M. Béchamp.—On the passage of plasma through living unperforated membranes, by M. Cornu. It passes in a manner contrary apparently to the laws of endosmose.—On the winter of 1877, by M. Renou.—M. Archereau presented prepared carbons for the electric light, said to increase the stability and illuminating power. They consist of carbon agglomerated and compressed, mixed with magnesia.

DARWIN'S "GEOLOGICAL OBSERVATIONS"

Geological Observations on the Volcanic Islands and Parts of South America visited during the Voyage of H.M.S. "Beagle." By Charles Darwin, M.A., F.R.S. Second Edition, with Maps and Illustrations. (London: Smith, Elder, and Co., 1876.)

MR. DARWIN'S important contributions to biological observation and theory have during the last seventeen years attracted so much public attention, that there is some danger—one from which, however, all geologists will claim exemption—of his valuable labours in almost every department of geological research being to some extent lost sight of. Long, however, before the publication of the "Origin of Species," its author had achieved a foremost place in the ranks of the cultivators of geological science; nor must it be forgotten that the great work itself is as much a contribution to geology as to biology. Students of Mr. Darwin's earlier geological writings must all have been impressed by the powers of minute observation, the acumen in testing, and the skill in grouping data, and the boldness and originality in generalisation which distinguish their author; for these characteristics are no less conspicuously displayed in the theory of Coral Reefs than in that of Natural Selection.

In December, 1831, Mr. Darwin sailed from England in H.M. surveying vessel the *Beagle*, having accepted an invitation from the late Capt. FitzRoy to act as volunteer naturalist to the expedition then being despatched to complete the survey of the coast of South America. After an absence of nearly five years—during which many of the islands in the Atlantic were examined, large portions of both the east and west coasts of South America fully explored, several inland traverses of that continent made, the Falkland and Galapagos Islands carefully studied, and more rapid visits paid to Tahiti, New Zealand, Australia, Tasmania, the Cape of Good Hope, and a number of the coral islands in the Indian Ocean—the expedition returned to this country in August, 1836. Not a few important scientific discoveries will be associated with the names of the vessels of the United States Exploring Expedition, with the *Novara*, the *Challenger*, and many another surveying ship that might be mentioned; but it will be long indeed, we suspect, ere any vessel attains such a proud position in the annals of science as was won by the little ten-gun brig which bore our naturalist in his now famous "Voyage Round the World." Wherever in future the sciences of biology and geology shall be cultivated, there will the name of the *Beagle* become a household word.

The ten years which followed his return to England would appear to have been mainly devoted by Mr. Darwin to the publication of the numerous and important results obtained during the voyage. Besides editing the treatises of Prof. Owen, Mr. Waterhouse, Mr. Gould, the Rev. L. Jenyns, and Mr. Bell on the different groups of vertebrate animals, of which specimens were brought home, he wrote two very important works, one addressed to general readers—the "Naturalist's Voyage Round the World"—and the other of a more purely scientific character—the "Geology of the Voyage of the *Beagle*."

Before the publication of the "Origin of Species" had made the author's name so widely famous as it is at present, the works which we have named above, with the several memoirs communicated by their author to the *Transactions* and *Journal* of the Geological Society, had become universal favourites with the students of various branches of natural science; and this, no less on account of the rich store of novel observations which they contained, than for the originality and suggestiveness of their deductions from those observations. And since the appearance of their author's *magnum opus*, we confess that these earlier writings have for ourselves acquired a strange fascination. Again and again have we perused them, only to detect valuable observations and striking suggestions before missed, and to encounter fresh traces of the germs of ideas, that, after twenty-eight years of earnest thought and study, were developed into the theory of descent with modification, which is now exercising so important an influence on the progress of the natural sciences. At the commencement of the present notice we ventured to claim for geology at least a moiety of the advantages which have flowed from the publication of the "Origin of Species;" and, on the other hand, we feel that we are putting forward no undue demands on behalf of the same science, in declaring that the theory of Natural Selection must be regarded in at least as great a degree the prize of geological observation as the reward of biological research.

Such being the case, these "Geological Observations" are well worthy to take their place in the long series of the author's contributions to the doctrine of descent, side by side with those more widely known works on different departments of zoology and botany which have been published subsequently to the "Origin of Species." Two years ago the first part of the "Geology of the Voyage of the *Beagle*"—a work which has long been out of print, and has become extremely scarce—was republished; and naturalists and geologists were alike gratified by the appearance of this revised and enlarged edition of the well-known memoir on Coral Reefs. The work now before us is a re-issue of the remaining portions of the "Geology of the Voyage of the *Beagle*," and will be equally welcome to a large section of the scientific public.

The districts described in the present work, as Mr. Darwin justly observes in his preface to the new edition, "have been so rarely visited by men of science" that very little "could be corrected or added from observations subsequently made." And on the other hand attempts to modernize the terminology could scarcely fail to detract from the minute accuracy of observations, which were clearly either recorded upon the actual spot where they were made, or at all events while the memory of them was still fresh and vivid in the mind of the author. We think, therefore, that a wise discretion has been exercised in allowing the descriptions and discussions of phenomena to remain in precisely the same form as when they were originally drawn up; though we must confess to a feeling of disappointment at the absence of notes from the author's pen, indicating how far in his own view some of these original conclusions have been strengthened or modified by his later studies and researches.

We can only permit ourselves to recall a few of the more important among the valuable contents of this book to the memories of our readers—and in doing so we shall dwell more particularly on such as, through recent discoveries or controversies, have acquired especial interest at the present day.

Every explorer who, since the publication of the "Observations on Volcanic Islands," has been called upon to investigate districts containing extinct volcanos, has been greatly aided by the valuable store of facts and suggestions contained in that work. We very much doubt, however, whether some of the interesting questions discussed in it—and we more especially refer to those relating to the nature and origin of the banded structure in lavas, with the light which these are calculated to throw on the difficult problem of the cause of foliation in rocks—have received that amount of attention from geologists, of which they are certainly deserving.

The proofs of the long-continued elevation of the shores of South America for thousands of miles, and to the height of many hundreds of feet, yet unattended with marked disturbances of the strata, the gradual disappearance of every trace of organism in rocks which once abounded with them, the survival of a most remarkable fauna of gigantic vertebrates to post-tertiary times, and its seemingly sudden extinction at a very recent period—these are some among the many interesting facts described in the second part of the work which are of especial value to geologists seeking to interpret the records of the past. Mr. Darwin's observation of an admixture of Jurassic and Cretaceous types of life in the same deposits in South America have acquired fresh significance now that the United States geologists have shown that ammonites range up into the tertiary strata, and that Dr. Waagen has described ammonites, goniatites, and ceratites, occurring in India, in the same bed with several carboniferous species of brachiopods. Now, too, that so much has been done by Dana, Le Conte, and others, in determining the mode of origin of the Rocky Mountains, and the part played by the volcanic outbursts which occurred simultaneously with the mountain-forming movements, Mr. Darwin's clear descriptions of the sections noticed by him in his traverses of the chain of the Andes will be referred to with fresh interest by geologists: and the comparison of phenomena displayed in distant parts of the same great chain is highly suggestive. But space fails us to refer to even a tithe of the points of interest which we have noted in our reperusal of this valuable work.

A striking characteristic of all Mr. Darwin's writings, and one which is very eminently displayed in the work before us, is his scientific candour. Like his teacher and friend, the late Sir Charles Lyell, he never forgets in his discussions to look at all sides of the questions before him, and to give the fullest expression and weight, alike to the difficulties which he himself detects, and to arguments which opponents may have advanced. With superficial readers this peculiarity in the writings of Lyell and Darwin has apparently very unjustly detracted from their merits; and we are sometimes amused by finding critics boldly parading as their own, objections which it is perfectly clear that only the candour of the authors has permitted them to rehearse, but which their own knowledge has not sufficed to enable them to understand or to make adequate use of.

Perhaps at no period in the history of the science have the great facts of geology suffered so much distortion from the works of pseudo-scientific writers—through which media alone science is too often, alas! transmitted to the general public—than at present. These writers selecting a few isolated and imperfectly understood facts, in bold defiance or lamentable ignorance of a thousand unmistakable and clearly established principles, proceed to build up the most elaborate hypotheses. We cannot therefore help regarding the republication of Mr. Darwin's "Geological Observations" as a most opportune event. The able geologist, De la Beche, many years ago wrote a charming little book entitled "How to Observe in Geology." To those anxious to learn this most important art at the present time, we would recommend as a model—since example is better than precept—the work now before us. The careful study of the clear and minute descriptions of geological phenomena, and the following step by step of the fair and cautious discussion of facts and arguments contained in this book can scarcely fail indeed to teach the reader something which is even more valuable than "how to observe," namely, how to *reason* in geology.

JOHN W. JUDD

TWO "CHALLENGER" BOOKS

Log Letters from the "Challenger." By Lord George Campbell. (London: Macmillan and Co., 1876.)

The Cruise of Her Majesty's Ship "Challenger." By W. J. J. Spry, R.N. With Map and Illustrations. (London: Sampson Low and Co., 1876.)

IT was to be expected that with so carefully-selected and intelligent a staff, both naval and civilian, on board, the cruise of the *Challenger* would be productive of something more than the official literature. It will have been seen from the "Preamble" which we recently published (*antea*, p. 254) that it must necessarily take a long time to arrange the abundant scientific results that have been obtained, and the complete official accounts may not be in the hands of the public for years. The Report on the Austrian *Novara* Expedition has taken seventeen years' serious labour to complete; but we hope to be in possession of the *Challenger* Reports in a much less space of time. Meantime many readers will be glad to have in a handy form a general account of the work which the expedition has done, and some details concerning the incidents of the long cruise and the many places which the ship visited. From either of the books before us such information may be obtained.

There is a wide difference, however, between the characters of the two works. Lord Campbell's is by no means an attractive book at first sight. It is a big, plain, heavy-looking volume, with a large page well filled with type, enormous paragraphs of sometimes half-a-dozen pages in length, and with not a single picture. One is apt to sigh at first at being compelled to read it, but after perusing a few sentences the reader "puts on the garment of praise for the spirit of heaviness," and finds the real difficulty to be to stop. Lord Campbell's pages bear all the marks of being genuine letters, written with no thought of a public before him, and only for the entertainment of those to whom they were sent. He has evidently not "got up" his subject at all, the information he conveys being almost entirely the results of his own observation. And a thoroughly good and most original observer he is, with a faculty of telling what he has seen in such a way as keeps the reader in a constant state of exhilaration. Lord Campbell makes no pretence at instruction, nevertheless in his own characteristic and irresistibly amusing way, he conveys a vast amount of information concerning all the places visited by the *Challenger*, and tells not a little of the results of the soundings and dredgings carried out by the "scientifics," as he calls the civilian staff. But apart from the genuine entertainment to be had from the work, its great value will be the observations made by the author on the various peoples among whom he sojourned for a longer or shorter period. Even well-informed ethnologists, we should think, will be able to obtain not a little important information from the work on the present condition, for example, of the inhabitants of many of the Pacific islands, such as those of the Friendly, Fiji, and Sandwich Islands, New Guinea, Admiralty Islands, &c. A very large space is devoted to Japan, and many shrewd remarks made on the present condition and future prospects of the Japanese. There are many interesting notes besides, on the physical aspect and natural history of most of the places visited, and in almost all cases it will be found that some new feature has been brought out. Even of such well-worn subjects as Teneriffe, the Azores, Cape de Verde Islands, Australia, New Zealand, Tahiti, the South American littoral, Lord Campbell manages to say something unexpectedly original. In a concluding chapter he gives an instructive summary of the *Challenger's* work and how she did it. We can only, in our space, speak in the most general way of the nature of the contents of this work. A more entertaining, a more genuinely bracing book, it would be difficult to find, and the reader who goes carefully to the end of it will have added considerably to his knowledge of the earth's surface. It is a great pity that a work so full of varied information should have been published without either an analytical table of contents or an index. A map would also have been a great help to the reader.

Mr. Spry professes simply to give a plain, straightforward narrative of the cruise, of some of the chief results obtained by sounding and dredging, with notes on the places and people visited, partly the result of his own observation and partly of reading. The book is nicely got-up, well printed, and contains a large number of interesting and well-executed illustrations, not only of people and places, but of the implements used in carrying out the work of the *Challenger*. He gives a very clear account of the various apparatus used, their construction and uses, which we commend to the perusal of the uninitiated reader who wants to know how such work as that of the *Challenger* is performed. Mr. Spry gives the curious story of the brothers Stoltenhoff, who were found living alone on Inaccessible Island, at considerable length, in the words of the elder brother. The work contains a really large amount of valuable information, and as no two men observe alike, we commend those who desire to have complete information about the cruise of the *Challenger*, to read both books. While Mr. Spry sometimes unnecessarily introduces information obtained from books, his work is, on the whole, thoroughly readable, and certainly instructive. Altogether, these preliminary "snacks" augur well for the great official feast which is being prepared for us.

OUR BOOK SHELF

The Year-Book of Facts in Science and Arts for 1876. Edited by James Mason. (London: Ward, Lock, and Tyler, 1877.)

THE "Year-Book of Facts" so long associated with the name of the late indefatigable Mr. Timbs seems to have taken a new lease of life under the present editor, who begins his duties with the volume before us. Some useful changes have been made; thus, there is a marked improvement in the arrangement and character of the contents, and the period covered by this year-book now extends from the autumn of one year to the autumn of the following, and not January to December as heretofore. The longer time thus given for preparation has been well used by Mr. Mason, who certainly has produced a volume far in advance of any of its predecessors. It is hardly necessary for us to say much about this well-known year-book, which does not pretend to be more than a popular digest of scientific scraps; and in no sense supplies the need, to which we have alluded in previous notices, of a carefully-prepared record of scientific progress—the nearest approach to which in the English language is the American "Annual Record of Science and Industry," edited by Mr. Baird. The present editor of the book before us has done his work, so far as it goes, in a comprehensive and careful manner. One or two serious omissions we notice, notably the important discovery made by Dr. Ker, and announced at the last meeting of the British Association, of the rotation of the plane of polarisation by reflection from a polished magnetic pole, certainly one of the most novel physical facts of the past year.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*]

Just Intonation

YOUR esteemed correspondent, Col. A. R. Clarke, declines to admit any error or oversight in his communication to NATURE under the signature of "A. R. C.," on December 21, 1876. I regret to be of a different opinion. The first error which I pointed out ought to be palpable enough to a mathematician who is acquainted with the ratios of a scale, and therefore I treated it as an oversight. Col. Clarke gives 27 to 16, instead of 5 to 3, as the ratio for A in our present diatonic scale. By his enlargement of the interval he would unknowingly convert the well-known consonance of a major Third between F and A into a Pythagorean ditone. Evidently the Colonel is not aware that F and A are notes *interposed* in the scale of C, that harmonically they belong to F, and require F as a consonant bass. All this has been explained in a pamphlet in print. I would therefore suggest to Col. Clarke an investment of sixpence in the purchase of a "Review of Helmholtz's New Musical Theories," published by Novello, Ewer, and Co., No. 1, Berners Street. To prove all the unadmitted charges would be too long for NATURE, and Col. Clarke will find most of them touched upon in that pamphlet as well as other current errors. In the meantime it is not difficult to tell that Col. Clarke derived his ratio from the harmonic scale of C, and not from that of F (which would have been right), or from the work of any modern mathematician.

It is because F and A are harmonically derived from F that our scale cannot be reduced to a common denominator. The F string exceeds the length of the C string by half, the ratio being 3 to 2, and one of the first rules of proportion is that "ratio can exist only between quantities of the same kind." When mathematicians employ the figures of 4 to 3 in the scale of C, the interval they really obtain is from C down to G (not from F down to C, as they have supposed), and when 5 to 3, they have the major Sixth from E down to G, and not the one from A down to C.

Music is a much more simple science than most men suppose. All that a mathematician requires is a set of harmonic scales, with powers of 2 and 3, before him. The scales include all ratios, and all consonances with their proportions of accompanying dissonances. They are scales of aliquot parts, and those aliquot parts are the corresponding multiples of vibrations. Time spent upon calculating temperament is but thrown away, because no mathematician's figures will be adopted in practice. Practical musicians will continue to tune by listening to the beats, as they have ever done, and perhaps all other musicians before them. The recommendation to eschew temperament may be even worthy of consideration in another point of view. Mathematicians have not given sufficient attention to the musical side of the question. Have we not, of late years, heard much of proposals to divide the octave into "twelve equal semitones"? Are we to imagine that this is a mathematician's idea of "*equal* temperament"? If music were but geometry, it would be an admirable arrangement: twelve equal semitones, like twelve equal inches in a foot. But, unfortunately, a musical scale is the very reverse of a geometrical one, and there are no two intervals alike in it. As it rises, the dimensions become less at every step, in ratio and in length. For instance, the ratio of C to C sharp is 16 to 17, that of G to G sharp (G being the half-way in point of vibrations) is 24 to 25, and from B to octave C is 30 to 32, but only because we omit B sharp, otherwise it would be 31 to 32. Fancy two such extremes "tempered" to the middle note! Only one of the twelve would fit into a musical scale, and there would be eleven discordant semitones out of the twelve. The discord would not be confined to one key only, but would be the same in every key. The so-called "diatonic semitones" are really tones. E is the seventh to F, which requires F as a bass, and B is the seventh to C in the scale of C. Are these to be changed into chromatic semitones?

The diminished attraction of music, some persons even disliking it, is mainly, if not wholly due to tempered tones. The first point to be considered by mathematicians who temper scales is the meaning of the two words, "consonance" and "dissonance." The charm of music depends upon "coincident," and "non-coincident" vibration.

In justice to Col. A. R. Clarke, let me add that I find only the first error to be his own, and am still disposed to attribute it to oversight in referring to a wrong scale. All the others are after precedent, and every source might be pointed out, although he is disposed chivalrously enough to defend those upon whom he relied. My excuse for writing at all is that NATURE is a purely scientific journal, and that I share with others an earnest wish to uphold it as a fair representative of English thought. Articles such as those of Col. Clarke and my own would be distasteful to any but scientific readers. As to the "comma of Pythagoras," it is not worth discussing. In spite of his chivalry, Col. Clarke knows as well as I do, that such an array of figures, representing vibrations, as 524, 288, cannot arise in less than nineteen octaves.

WM. CHAPPELL

Strafford Lodge, Oatlands Park, Surrey

The Nebula of Orion

IN NATURE, vol. xv. p. 201, in an account of the American Cambridge Observatory, it is stated that the nebula of Orion had not shown the slightest trace of resolvability under Lord Rosse's 3-feet reflector.

The authority for this statement is, I suppose, Nichol's "Thoughts on the System of the World," where, p. 52, it is said that in 1844-5, the 3-feet did not contain the vestige of a star in the nebula.

On the occasion there referred to the speculum must have been in bad order, for the resolution of parts of the nebula is quite within the reach of the instrument in its normal condition. In proof of this I may refer to Lord Oxmantown's paper on the Nebula of Orion, *Phil. Trans.*, 1861, and to an extract from my own note-books of an earlier date, February, 1848:—"With the 3-feet saw the nebula of Orion resolved as far up as the little bay and C 1 Orionis—powers 351 and 320—best with the latter which is a single lens."

I may add that Nichol also states, p. 55, that he had received from Lord Rosse, March 19, 1846 intelligence "that all about the trapezium is a mass of stars (in the six feet); the rest of the nebula also abounding with stars, and exhibiting the characteristics of resolvability strongly marked."

Observatory, Armagh, January 19 T. R. ROBINSON

Basking Shark

MY notice of Prof. Steenstrup's paper was written in the autumn of 1875, to accompany an electrotype of the woodcut in that paper of the baleen-like fringes of the basking shark, sent to me for NATURE from Copenhagen.

At the time I was quite ignorant that my friend and former master, Dr. Allman, had written on the subject, nor could the keenest bibliographer have known much of the contents of his memoir, as the only reference to it in the Fourth Annual Report of the Dublin Natural History Society for 1841-42, is "Two [papers] have been read on Icthyology; that on the basking shark (*Selachus maximus*) by Mr. Allman, caused him to notice the value of the fisheries of our southern coasts, abounding in large fishes and cetacea, whose capture would prove highly profitable to our fishermen from the quantity of oil they would yield." In June, 1876, on the arrival of the specimen in Dublin from Bofin, I had a woodcut made of a branchial arch with the fringe attached, and added a brief account of the specimen now in the Dublin Museum. About that time Dr. Allman told me that notes of his paper had been published in the *Saunders's News Letter*, but that he had forgotten the date. Guided by the notice in the Dublin Natural History Society's Report, I searched the files of that paper for the years 1841 and 1842 without success, but I fully purposed to mention what Dr. Allman had told me, from memory, of his researches, when I should get a proof of my manuscript. Unfortunately, from press of matter, my notes were not published until many weeks after they were sent, and the proof reached me during long vacation, when I completely forgot to do as I had intended. I regret this exceedingly, and hope Dr. Allman will accept my apology. I cannot, however regret, that it has induced Dr. Allman to publish an abstract of his paper (NATURE, vol. xiv. p. 368), and perhaps he may still further furnish us with the date of its original publication.

In answer to the note of Prof. Enrico Giglioli, which has called my attention again to this subject, I have simply to state that finding no notice in the Zoological Records for 1873 or for 1874 (this latter published May, 1876) of any papers on Selache, I concluded, as it now appears wrongly, that nothing had been written during these years on the subject. This was my misfortune, perhaps my fault; but regarding Italy as the mother country of all the sciences, being well aware of the advances she has made in biological researches during the last twenty years, and having gone each year, while one of the zoological recorders, to Florence to work out the Italian literature of the preceding year, I cannot accuse myself of any intentional neglect of the labours of Italian biologists. It is to be hoped that Prof. Giglioli will favour us with an abstract of Prof. Pavesi's memoir, especially of the reasons that induce Prof. Pavesi to assert that our Bofin shark is *S. rostrata* and not *S. maxima*, for to me it appears that our seas may possess both these species.

It may also be mentioned that no reference to Prof. Pavesi's memoir will be found in the account of the Pelerin appended to Prof. Lütken's "Fishes of Greenland," prepared for the use of the British North Polar Expedition, 1875.

E. PERCIVAL WRIGHT

Sense of Hearing in Insects and Birds. "Towering" of Birds

I AM glad to learn from Mr. M'Lachlan that stridulation is known to occur in several species of *Lepidoptera*; for this shows that the sense of hearing in these insects is probably of general occurrence. With regard to the sense of hearing in birds, I did not say in my previous letter that thrushes, &c., were guided to their food *exclusively* by this sense; indeed it would be a very anomalous thing if animals which possess so keen a sense of sight are not in the habit of using it, as Mr. McLachlan suggests, in any profitable way they can. But that thrushes trust *very largely* to their sense of hearing in their search for food—especially in certain conditions of the ground—no one, I think, who has observed the process can doubt. The bird runs rapidly some twelve to twenty feet in a straight line; it then stops suddenly, elevates its head, and remains motionless in a listening attitude; after pausing thus for a few seconds, it again runs to about the same distance as before, again stops to listen, and so on. These successive excursions are usually made in the same direction; but every now and then, during the process of listening, the thrush apparently hears a sound proceeding from some point within the circle which it has last entered; immediately the course of progression is deflected at an angle from the continuous straight line in which all the previous excursions were made, and, either with a single rush or after one or two brief pauses to make quite sure of the exact spot, the bird may nearly always be seen to find a worm.

I may take this opportunity of thanking your various correspondents for the information which they have supplied with regard to the towering of birds. Some of the letters mention ducks, teals, and widgeons as birds which occasionally tower. May I ask the writers of these letters whether the action in these cases resembled that of *true* towering in the case of partridges and grouse? I ask this because one of the numerous letters by which my communication to NATURE has been answered in the *Field*, states that birds of this build never tower; and on this supposed fact the writer constructs a theory as to the mechanism of towering in general. All the correspondence taken together cannot leave any doubt that there are at least *two* kinds of towering:—viz. (1) The common kind which I described, and the cause of which is certainly pulmonary hæmorrhage; and (2) a very rare kind which I have never myself witnessed, and the immediate cause of which appears to be cerebral injury. In the case of the second, or rare kind of towering, all the correspondents are agreed that the bird is not dead when found, and that it may even fly away again when disturbed. Never having had an opportunity of observing such a case, of course any hypothesis by which I may try to explain the cause of the rare kind of towering is of no further value than a conjecture; but I may remark that both kinds of towering may possibly be due to the same cause, if the parts of the brain which are injured when the second kind of towering ensues, are the parts whose injury Brown-Sequard found to be attended in the case of mammals, with bleeding of the lungs. At any rate, it would be worth while for any sportsman who may have the opportunity, to dissect a bird which he has seen to exhibit the second kind of towering, in order to ascertain whether, in such cases also, some degree of pulmonary hæmorrhage may not have taken place.

GEORGE J. ROMANES

IN Mr. G. J. Romanes' interesting remarks (NATURE, vol. xv., p. 177) on the sense of hearing in insects, he says:—"In the case of moths, however, I believe that sounds are never emitted, except of course the Death's-head."

As I trust that insects will continue to have a place in his observations, may I be allowed to call Mr. Romanes' attention to the following species of Lepidoptera which are known to produce sounds:—

1. *Vanessa*, several species.—The sound produced—which has been compared to the friction of sand-paper—has been noticed by several observers, viz., Rev. J. Greene (*Proc. Ent. Soc. of London*, New Series, ii., p. xcviii.), Mr. Hewitson (*l.c.* iv., p. ii.), and Mr. A. H. Swinton (*Entomologists' Monthly Magazine*, xiii., p. 169, January, 1877), who describes the apparatus by which the noise is produced. On the under surface of the upper wing one of the nervures is roughened like a file, and upon this a raised nervure on the upper surface of the underwing plays; there is also a circular embossed patch of the wing-membrane destitute of scales, which Mr. Swinton thinks serves to "impress the musical tremours." The object of this stridulation, Mr. Swinton suggests, may be classed with those phenomena of rivalry and love so conspicuous in the *Orthoptera*, &c., but at the same time it is produced when the insects are disturbed, and possibly also when the sexes are coquetting in mid-air. Moreover, the development of the mechanism is greatest in the female, contrary to the usual rule. For my own part, I incline to think that the object of the sound is rather the intimidation of possible enemies than a sexual love-call. Both Mr. Greene's and Mr. Hewitson's cases occurred when insects that were hibernating were disturbed, and the sound was renewed whenever the disturbance was repeated. These butterflies hibernate in dark holes and corners, and the sound may be intended to suggest to the disturber the hiss of a snake or the note of an angry wasp or bee. As the perpetuation of the species depends for the most part on the female, she is provided with a stronger apparatus. If the sound is produced when the sexes are coquetting, it may be the butterfly expression of a playful "Get along with you."

2. The well-known case of *Acherontia* (the "Death's-head Moth").—The sound here also is probably for intimidation, and not a love-call. I cannot at present call to mind any observations on any disparity of the sound in the sexes.

3. *Setina*, several species, and

4. *Chelonia pudica*.

The sound emitted by these insects—which is compared to the ticking of a watch—is described by M. A. Guenée (*Ann. Soc. Ent. Fr.*, 4^e ser., vol. iv. 1864; translated in *Ent. Month. Mag.*, i. 223) who says that it is produced by two tympaniform vesicles situated in the pectoral region, and is much more developed in the male than in the female. This, M. Guenée remarks, is rather curious, for, as the females of *Setina* can scarcely fly, it would seem that, if the organ of sound is to produce a love call, it is the female, and not the male that should have it most strongly developed. M. Guenée consequently expresses himself unable to give any plausible reason to account for the object of the sound.

A reason has occurred to me and I here give it for what it may be worth. We know that the females of several Lepidoptera (especially wingless females) have the power of emitting a scent which attracts the males, often from considerable distances. When the male of *Setina* is hunting for the female and making probably his drums vibrate loudly, the sound reaching the concealed female may excite her to give out an increased odour, and thereby more surely attract the male. In short the drums are organs of excitation.

5. *Hylophila prasinana*.—This species Mr. Swinton (*Entom. Monthly Mag.*, vii. 231) has noticed to emit a twittering sound, which he thinks is produced by a structure between the thorax and abdomen.

I have been fortunate enough to have also had an opportunity of hearing the sound produced by this species (*Scottish Naturalist*, i. 213). The sound resembles a continuous squeaking and was heard on more than one occasion, and was audible at a distance of ten feet or upwards. All the specimens that I caught in the act of squeaking were males, so that I cannot say whether the other sex squeaks or not. The sound is emitted whilst the insect flies about the bushes, and the object of it is probably the same as I have suggested above in the case of *Setina*. The emission of the sound is quite voluntary on the part of the moth, as specimens taken in the act of squeaking and made to fly afterwards did not then give out any sound. Careful dissection revealed no structure that appeared capable of producing the noise except a tympaniform plate situated at the base of the hind body.

6. *H. quercana*.—According to Mr. Swinton (*l.c.*, viii. 70) this species can make a "membranous sound," which he thinks is produced by the wing catching a little horny lateral thoracic plate.

There may be other recorded instances of sound-producing *Lepidoptera*, but I cannot at present recall any to mind. It is probable moreover that more species than are generally supposed emit some kind of a sound. It is therefore much to be regretted that the many collectors of Lepidoptera—whose sole aim seems to be the amassing of large collections and whose lack of anything beyond the mere desire to accumulate specimens, has made entomology a bye-word amongst the sciences—would not spend some of their misplaced energy in really studying the objects of their attention.

Mr. Romanes' observation of the sensible appreciation moths have for high-pitched notes suggests a question. Does the shrill squeaking of bats convey an intimation to moths of the approach of one of their greatest enemies?

It is to be noted moreover that in the majority of cases the sounds emitted by moths, and indeed all insects, themselves, are high pitched.

F. BUCHANAN WHITE

Perth, January 12

P.S.—Since the above was written I see that my friend Mr. McLachlan has pointed out (NATURE, vol. xv. p. 254) another record of a sound-producing moth—*Euprepia matronula*.

THE perusal of Mr. McLachlan's letter on "Sense of Hearing &c., in Birds and Insects" has recalled to my memory another instance of a Lepidopterous insect which possesses the property of emitting a marked sound when on the wing. This is a common Brazilian butterfly (*Ageronia feronia*), and attention was long ago directed to its habits in this respect by Mr. Darwin in his delightful "Naturalists' Voyage" (p. 33). He there mentions that when watching a male and female of this species in flight, he "distinctly heard a clicking noise, similar to that produced by a toothed wheel passing under a spring catch."

This curious observation I had numerous opportunities of verifying in the course of three visits to Rio Janeiro in 1866, 1867, and 1869. ROBERT O. CUNNINGHAM

Queen's College, Belfast, January 19

I HAVE noticed that, when moles are burrowing, the worms near make their way to the surface. I have also observed that starlings gather round and under cows in pasture-fields. Their doing so I have been in the habit of ascribing to the tread and grazing-work of the cows producing tremors in the ground, which worms may mistake for mole-work, and therefore crowd to the surface; and I have offered the same explanation for the method of hunting pursued by blackbirds and thrushes. They have practically found out that (earth-tremors induced by) small hopping-runs make "the poor inhabitants below" seek safety above, and that thus the hunters most readily secure a breakfast. I am not acquainted with the habits of those hunters.

Cambuslang HENRY MUIRHEAD

Galton's Whistles

WITHIN the last few days I have had the opportunity of making observations with Galton's whistle upon a large number of people and upon some cats, and I have come to some conclusions which are curious and suggestive, even though they may not be absolutely exact. Thus, on the whistle a line is marked which is the usual limit of human hearing, and which represents, I should say, a number of vibrations somewhere between 41,000 and 42,000 per second. Out of many hundreds of persons examined I have only met with one instance, a young man, in which I was satisfied that a note higher than this was heard. As a rule the compass of the ear of women is markedly higher than it is in men, and age seems to lower it sooner in men than in women. Is this a result of the female animal always having the more intimate protection of the young as her work, the young having notes of higher pitch than the adult? The fact is at least suggestive.

Very few of the persons experimented upon seemed to have the compass of one ear exactly the same as that of the other, the right ear usually hearing a higher note than the left, and this is more marked in men than in women.

The sense of direction of the sound in the human ear seems to be lost at a very much lower point than appreciation of the note, but this is not the case with cats; for until the instrument ceases to produce a note altogether, or at least one within their compass, they turn their faces to the source of it the moment it is produced. These facts are also suggestive. The cat still depends to a large extent for its food supply on the appreciation of high notes, and quite as much on the appreciation of the direction from which they come. The power of hearing a note of a pitch beyond the limits of our sense of direction is suggestive that that sense has been blunted by disuse; and it would be extremely interesting to know if the compass of direction is higher in savage than in civilised peoples. From facts known concerning their other senses, I should say it is likely to be higher.

This difference in the two compasses is further indicative that the appreciation of direction is the work of a separate organ, and Dr. Crum Brown's experiments suggest the semicircular canals, or the utricle or succule in association with them, as the seat of this sense. If, as Dr. Brown seems to have shown, the semicircular canals are the organs of the general sense of position and direction, it would not be a far-fetched idea, that the utricle has to do with the sense of the direction of sound and that the canals are additions to it. An analogous relation of the cochlea to the saccule is suggested by the mere facts of anatomy. If it be, as Helmholtz believes, that the cochlea is the organ for the appreciation of *pitch*, the relations of the three divisions of the organ of hearing are to be easily understood, and these relations offer, at first sight, a singularly strong evolutionary argument. There is, first, the organ for the perception of sound vibrations, having a comparatively limited compass. To this is added an organ for the appreciation of the direction of the sounds, and another for the appreciation of highly-pitched notes; and a part of the first of these becomes so modified as to be capable of interpreting position and direction generally, independently of sound. The facts of the development of the ear support such a view, and we may conclude that the sense of direction is more important than the appreciation of high notes; for the semi-circular canals appear, or at least one exists, in the Myxine, whilst a very rudimentary cochlea does not appear till we get high up in the fishes.

Birmingham LAWSON TAIT

Atmospheric Currents

MR. CLEMENT LEY (in vol. xv. p. 157 of NATURE) asks me for the absolute proof which I suppose to exist (1) that the upper current return trades "flowing from the equator descend again to the surface of the ocean on the polar sides of the calms of Cancer and of Capricorn," and (2) that "these equatorial currents subsequent to their descent on the polar sides of Cancer and of Capricorn are known as the westerly winds of the temperate zones"; (3) he further asks "what proof exists that the upper currents from the polar depressions and those from the equatorial depressions cross one another in the calms of Cancer and of Capricorn so as subsequently to become the trades and anti-trades respectively," and suggests that it is more reasonable to suppose that their currents intermingle, and that their mixed volume is then drawn off north and south, as required, to restore the equilibrium of the atmosphere, as suggested by myself with reference to the equatorial calms. Mr. Clement Ley's three questions may, I think, be fairly answered as one, all depending upon the same proof.

The correctness of my assertions with reference to the atmospheric currents flowing from the equator can be referred to the one crucial test, viz., Are the atmospheric currents which descend to the surface of the ocean on the equatorial and on the polar sides of the two zones of high pressure, similar in their constituents (*i.e.*, when they first become established as winds on the surface of the ocean)? is their degree of electricity the same? is their degree of saturation the same? If these questions could be answered in the affirmative it would show that Mr. Ley's supposition with reference to the mixed volume of the upper currents was possible, but if, on the other hand, they are answered in the negative, Mr. Ley can hardly hold, I think, that I have put my statements forward too strongly.

Though I believe that the north-east and south-east trades meeting at the belt of equatorial calms are thrown upwards from the surface of the ocean, and in ascending do mix their volumes, the conditions of atmospheric currents meeting many thousand feet above the sea-level are entirely different, as they have not the ocean as a *point d'appui*, and there is no more difficulty in accounting for their currents passing one another and the heavier underrunning the lighter, than there is for the Labrador, augmented by the East Greenland current, meeting and underrunning the Gulf Stream.

At Teneriffe, and other mountainous regions, in the latitudes of the trades, observations have been made with reference to the height of the trade winds, and of the neutral strata intervening between them and the upper current, as also of the height of the lower portion of the equatorial return current, which flows at heights varying from 12,000 feet upwards above the sea-level.

Prof. C. P. Smyth, H.M. Astronomer for Scotland, in his very interesting work, "Teneriffe," gives us some very important data with reference to these currents, showing—

1. The extreme dryness of the north-east wind.
2. Its very moderate electricity.
3. The greater saturation of the south-west wind.
4. The descent of the south-west upper current.
5. The chemical difference between the two currents.

Though there is much that I might quote with advantage, I shall content myself with the following four paragraphs:—

Page 110. "If we must live in a wind by all means let it be the south-west, and not the north-east, that effete unwholesome and used-up polar stream. As to the chemical and sanitary qualities of the two winds there could be no comparison between them."

Page 170. "And so indeed we found before we had finished with our expedition, when the south-west wind descended to the very surface of the sea."

Page 184. "In short, whatever the north-east wind did, its electricity was always moderate."

Page 206. "The trade wind is undoubtedly a poor one for bringing water, but its position in Teneriffe during summer is favourable for making it deposit any which may be present."

I think from these extracts, which are supported by other passages in Prof. Smyth's work, I am quite justified in arguing that the trades and counter-trades are not similar in their constituents, that their degrees of electricity and of saturation are not the same, and that therefore it is not reasonable to suppose that their upper currents intermingle at the belts of tropical calms, and that their mixed volume descends and is then drawn off north and south as required, to restore the equilibrium of the atmosphere.

As these opposite currents flowing in the northern hemisphere from the north-east and the south-west (approximately) do not intermingle, and their mixed volume does not descend in the calms of Cancer it must necessarily follow that the south-west or return equatorial current, does descend to the surface of the ocean on the polar side of the calms of Cancer, and equally that the north-east upper current does descend on the equatorial side.

I have by no means exhausted what I have to say on this subject, but Mr. Ley will doubtless understand that I am unable to treat it at greater length in your columns. The same line of argument would have enabled me to answer Mr. Ley's questions separately had space permitted. DIGBY MURRAY

Mind and Matter

PERMIT me to correct a mistake on the part of Mr. Tupper (NATURE, vol. xv. p. 217), who, though starting with a correct notion that my letter (NATURE, vol. xv. p. 78) was intended to solve a problem, immediately fell into the error of regarding it as intended to prove an alleged fact.

The fact alleged, that consciousness depends on nervous organisation I assumed to be a fact, and undertook to indicate *how* the dependence might be conceived, or regarded, to exist.

First, I alleged that the hypothesis of matter being as susceptible of consciousness as spirit, was quite *conceivable, as a hypothesis*, whether or not it should be proved afterwards to be a wrong hypothesis.

Second, the connection of two so dissimilar entities as matter and subjectivity had not the objection of being anomalous or unique; for energy and matter were equally dissimilar and yet invariably united. The parity of mystery was not intended to establish "parity of probability as to the facts," but merely *parity of conceivability*. For it is surely some help to our entertaining a new conception if we can point to an existing similar conception.

Third, if such a mysterious entity as energy could be divided and combined (using the words in a loose sense) why should there be a difficulty in conceiving of the division and combination of subjectivity. By this I meant that as division of matter involved division of energy, as to *amount*, so division of matter might be conceived involving division of subjectivity, as to *amount*: so with combination.

Thus far, however, I had only cleared away difficulties "real or apparent" in the way of our *conceiving* the relation of consciousness to matter from the "materialistic" stand-point.

The essential part of my solution which indicated roughly the *modus* of the connection between matter and consciousness and which dealt with the great difficulty of the question—How to account for the *two* aspects of matter, the unconscious and conscious?—has not been touched by Mr. Tupper. This portion he excused himself from examining because he regarded it as based on the assumption that "the probability of subjectivity being a property of matter equals the fact of energy being related to matter," whereas it is based on the fact, or alleged fact, or assumption, that "the dependence of consciousness on nervous organisation seemed by the science of nerve-physiology to be fairly established." To mistake allegations of the conceivability of a notion for assumptions or intended proofs that the notion is true, as has been done by Mr. Tupper, is surely not equivalent to pointing out fallacies in the solution of a problem.

Will he admit that, if a "pointer" could "tell us" he scented a fox and immediately thereafter follow the scent of a hare, such would be an admirable analogy of how to practise "sound logic by the old *à priori* method?"

Stafford, January 17 W. S. DUNCAN

Pre-Glacial Man in America

DR. ABBOTT, in his interesting letter on the traces of preglacial man in America, supposes that it may be correct that the American aborigines migrated from the Old World. This may be the case with the Red Indians, but we know that they drove out an earlier people—the mound-builders. However, both mound-builders and Red Indians were certainly post-glacial in their occupation of the northern parts of America, and the oldest traces of their existence may not date back to an earlier time than a late stage of the Neolithic period in Europe.

Palæolithic man in America holds the same relative position to these later peoples as he does in the Old World, and we have so far obtained no evidence to show whether he occupied Europe or America first. The position of his remains in the auriferous drift of California is the same as in that of Siberia; in the löess of the Mississippi as in that of the Danube and the Rhine; in the caves of Brazil along with extinct mammalia as in those of Europe; and in the lowland gravels of Virginia as in those of France and England.

The question of the post or pre glacial age of palæolithic man depends in America as it does in Europe on that of the age of the deposits in which they are found, and this is at present a matter of inquiry and discussion which might be set at rest, as I have pointed out in the *Quarterly Journal of Science* for July of last year, by a thorough examination of the brick clays at Hoxn where palæolithic implements were first found in England.

Cornwall House, Ealing, January 27 THOMAS BELT

Holly Berries

REPORTS of the scarcity and abundance of holly berries have appeared in NATURE from the south-east of England and wes of Scotland respectively. It may be interesting to note the condition of the holly crop at a point somewhere about midwa between these two places. In North Staffordshire and Derbyshire the holly berries are by no means scarce They are not a plentiful as they were last year, but there is a fair average crop.

I have seldom seen such crops of them as I saw in severa places in South Wales about a month ago. It may be als worth adding that the most teeming bush I saw was at a place i Cardiganshire, which was as far as I could learn—and I mad diligent inquiries—between four and five miles from the neares hive of bees. I questioned closely several children on the spot who were intelligent enough to give me a minute description of most of the common birds and insects; not one of them had ever seen a bee. D. EDWARDES

Denstone College, Staffordshire

The Meteor of January 7

AMONG the "Notes" in NATURE, vol. xv., p. 244, there is a description of a large meteor, of which I was fortunate enough to secure a good observation; but on comparing the apparent path, as observed by myself, with that recorded in the paragraph, I find the latter somewhat imperfect; the apparent path, as seen from near London, seems to have been curtailed both at beginning and at end of flight; probably the observer in question could further amplify his remarks, or some other correspondent send an observation. The following is an abstract from my note-book:—

"Birmingham, January 7, 10·31 P.M. G.M.T.—Meteor pear-shape, deep yellow merging into ruby-red towards the tail; commenced as a luminous point near η Hydræ, gradually increased in size, motion very slow and unsteady, appeared to force its way with difficulty, and slight undulation. Near α Leonis it attained the apparent size of Venus, the forward hemisphere now showing signs of internal commotion by the projection of ebullition prominences, which were swept back towards the tail, then 8° long, and vaporous. The latter portion of its flight was intercepted by houses, but on emergence it burst with a flash below β Leonis at A.R. 182°, D.N. 16°. Length of path, 52°; time of flight, five to six seconds; radiant point (in Fluvius Eridanus), No. 96 Tupman, or No. 164 of the B. A. Catalogue. W. H. WOOD

Balsall Heath Road, Moseley Road, Birmingham

Spectrum of New Star

THE spectrum of the new star in Cygnus is changeable, and is now very unlike Cornu's representation of it in a recent number of NATURE (vol. xv., p. 158). Your readers may not be aware that it is easy to see several of the bright lines without a powerful instrument, though not to measure them accurately. As observed with a Browning's "miniature spectroscope" attached to a 4¼-inch refractor, the brightest line is now about at wave-length 503, and is probably that described by Cornu as sixth in order of brightness, at wave-length 500. At the end of last month the brightest line was about 484, probably the F hydrogen line. Since December 27 the new star has always appeared to me orange. Has not this star received any name yet?

Sunderland, January 26 T. W. BACKHOUSE

KÜHNE'S RESEARCHES ON PHOTO-CHEMICAL PROCESSES IN THE RETINA

ON January 5, Dr. W. Kühne, Professor of Physiology in the University of Heidelberg, read before the Naturhistorisch-Medicinisches Verein, of Heidelberg, a paper entitled "Zur Photo-chemie der Netzhaut," so full of interest to the physicist and physiologist, that I think an abstract of it will be acceptable to the readers of NATURE.

A short time since, Boll (a pupil of Max Schultz and Du Bois-Reymond, who now occupies the chair of Physiology in Rome) communicated to the Berlin Academy the remarkable fact that the external layer of the retina, *i.e.*, the layer of rods and cones, possesses in all living animals a purple colour. During life, according to Boll, the peculiar colour of the retina is perpetually being destroyed by the light which penetrates the eye; darkness, however, restores the colour, which vanishes for ever almost immediately after death.[1]

The wonderfully suggestive nature of Boll's discovery led Kühne to repeat his observations; in doing so, whilst he has confirmed the fundamental statement of Boll, he has ascertained a number of new facts of great interest.

Kühne's observations were made on the retinæ of frogs and rabbits. In the first place, implicitly relying upon the statements of Boll, he examined, as soon as possible after death, the retinæ of animals which had been kept for some time in darkness. He soon found that the beautiful purple colour persists after death if the retina be not exposed to light; that the bleaching takes place so slowly in gas-light, that by its aid the retina can be prepared and the changes in its tint deliberately watched; that when illuminated with monochromatic sodium light the purple colour does not disappear in from twenty-four to twenty-eight hours, even though decomposition have set in.

These first observations of Kühne on the vision-purple (*Sehpurpur*), as he terms it, whilst they showed that the disappearance of the colour is not, as Boll had asserted, a necessary concomitant of death, removed many of the difficulties which stood in the way of a careful investigation. Carrying out his preparations in a dark chamber illuminated by a sodium flame, Kühne was able to discover the conditions necessary to the destruction of the vision-purple as well as some facts relating to its restoration or renewal.

As long as the purple retina is kept in the dark or is illuminated only by yellow rays, it may be dried upon a glass plate without the tint changing; the colour is not destroyed by strong solution of ammonia, by saturated solution of common salt, or by maceration in glycerine for twenty-four hours. On the other hand, a temperature of 100° C. destroys the colour, and alcohol, glacial acetic acid, and strong solution of sodium hydrate produce the same effect.

Kühne's next observations were directed to the discovery of the influence of light of different colour upon the vision-purple. It would appear that the more refrangible rays of the spectrum have the greatest action, and that the red rays are as inactive as the yellow.

Kühne now found the incorrectness of Boll's assertion that the retina of the living eye exposed to ordinary daylight does not exhibit the vision-purple, for on preparing the eyes of animals which had just been exposed to light, as rapidly as possible in the chamber illuminated by sodium light, he discovered that the retina was of a beautiful purple. It was only when eyes were exposed for a considerable time to the direct action of the sun's rays that a fading of the purple colour was perceived.

A most suggestive experiment now threw some light upon the circumstances which retard the decolorisation, and which restore the vision-purple. The two recently extirpated eyes of a frog were taken; from one the retina was removed, whilst an equatorial section was made through the other eye, so as to expose the retina and still leave it *in situ*. Both preparations were exposed to diffuse daylight, until the isolated retina had lost its purple colour. On now taking the other preperation into the yellow chamber and removing the retina, it was found that its colour yet remained: it was *dark red*, but was bleached when exposed in its naked condition to daylight.

This experiment was confirmed by others, in which the effect of strong sunlight was substituted for that of diffuse daylight.

But the most curious results of Prof. Kühne's experiments have reference to the restoration of the vision-purple. If an equatorial section be made through a recently extirpated eye, and a flap of retina be lifted up from the underlying choroid and exposed to light, the purple colour of the flap will be destroyed, whilst the colour of the rest of the retina persists. If, however, the bleached portion of the flap be carefully replaced, so that it is again in contact with the inner surface of the choroid, comple restoration of the vision-purple occurs. This restoration is a function of the *living* choroid, probably of the living retinal epithelium (*i.e.* of the hexagonal pigment cells, which used formerly to be described as a *part* of the choroid), and it appears to be independent of the black pigment which the retinal epithelium normally contains. As it is absolutely dependent upon the life of the structures which overlie the layer of rods and cones, it is natural that it should be observed to occur for a longer time after somatic death in the frog than in the rabbit.

Kühne's researches, though suggested by the interesting observation of Boll, have not only corrected many errors which that observer had committed, but have led to the discovery of facts which add immensely to the importance of the newly-observed vision-purple.

They have shown that the living retina contains a substance which under the influence of light undergoes chemical changes, which vary in intensity according to the intensity and character of the luminous rays, and they point to the existence of structures in connection with the retina which as long as they are alive are able to provide fresh stores of substance sensitive to light.[1]

Since the above account of Kühne's researches was written, he has published in the *Centralblatt der medicinischen Wissenschaften* (January, 1877, No. 3) a short paper, dated January 15, in which he announces the startling confirmation to his previous researches afforded by his *having been able to obtain actual images on the retina which corresponded with objects which had been looked at during life* (!).

The discoveries of Boll and Kühne must, as the latter remarks, have led to the thought that after all there might be some truth in the stories which we all have heard of images of things seen in death being left imprinted upon the eye. After his first researches Kühne endeavoured over and over again to observe on the retina of rabbits bleached spots corresponding to the images of external objects, but his endeavours failed. As Kühne remarks, and as all readers who have understood his experiments will allow, in order to obtain a permanent photograph, or, as he terms it, *optogramme*, the effect of the light would have to be so prolonged or so intense as to destroy the balance between the destruction of the vision-purple and the power of the retinal epithelium to restore it.

Kühne took a coloured rabbit and fixed its head and one of its eye-balls at a distance of a metre-and-a-half from an opening thirty centimetres square, in a window-shutter. The head was covered for five minutes by a black cloth and then exposed for three minutes to a somewhat clouded midday-sky. The head was then instantly decapitated, the eye-ball which had been exposed was rapidly extirpated by the aid of yellow light, then opened, and instantly plunged in 5 per cent. solution of alum. Two minutes after death the second eye-ball, without removal from the head, was subjected to exactly the same processes as the first, viz., to a similar exposure to the same object, then extirpation, &c.

On the following morning the milk-white and now toughened retinæ of both eyes were carefully isolated, separated from the optic nerve, and turned; *they then exhibited on a beautiful rose-red ground a nearly square sharp image with sharply-defined edges; the image in the first eye was somewhat roseate in hue and less sharply defined than that in the second, which was perfectly white. The size of the images was somewhat greater than one square millimetre.*

Prof. Bunsen was amongst the witnesses of this beautiful experiment.

ARTHUR GAMGEE

---

[1] This account of Boll's researches is taken from Kühne's paper. The latest number of the *Monatsberichte* of the Berlin Academy which has yet reached Manchester, which includes the Proceedings for September and November, does not contain Boll's communication, which is of later date (November [illegible]).

[1] I have repeated all the more important observations of Kühne with the eyes of several *Rana temporaria*, and with those of two rabbits, of which one was an albino, and can entirely confirm all his interesting facts. In ordinary daylight, the purple-red colour of the frog's retina, and its subsequent decolorisation, may be most satisfactorily demonstrated. The use of the dark chamber illuminated by sodium is, however, useful in cases where [illegible]

ON THE PRECESSIONAL MOTION OF A LIQUID[1]

THE formulas expressing this motion were laid before the meeting and briefly explained, but the analytical treatment of them was reserved for a more mathematical paper to be communicated to the Section on Saturday. The chief object of the present communication was to illustrate experimentally a conclusion from this theory which had been announced by the author in his opening address to the Section, to the effect, that, if the period of the precession of an oblate spheroidal rigid shell full of liquid is a much greater multiple of the rotational period of the liquid than any diameter of the spheroid is of the difference between the greatest and least diameters, the precessional effect of a given couple acting on the shell is approximately the same as if the whole were a solid rotating with the same rotational velocity. The experiment consisted in showing a liquid gyrostat, in which an oblate spheroid of thin sheet copper filled with water was substituted for the solid fly-wheel of the ordinary gyrostat. In the instrument actually exhibited, the equatorial diameter of the liquid shell exceeded the polar axis by about one-tenth of either.

Supposing the rotational speed to be thirty turns per second, the effect of any motive which, if acting on a rotating solid of the same mass and dimensions, would produce a precession having its period a considerable multiple of $\frac{1}{4}$ of a second, must, according to the theory, produce very approximately the same precession in the thin shell filled with liquid as in the rotating solid. Accordingly the main precessional phenomena of the liquid gyrostat were not noticeably different from those of ordinary solid gyrostats which were shown in action for the sake of comparison. It is probable that careful observation without measurement might show very sensible differences between the performances of the liquid and the solid gyrostat in the way of nutational tremors produced by striking the case of the instrument with the fist.

No attempt at measurement either of speeds or forces was included in the communication, and the author merely showed the liquid gyrostat as a rough general illustration, which he hoped might be regarded as an interesting illustration of that very interesting result of mathematical hydro-kinetics the quasi-rigidity produced in a frictionless liquid by rotation.

P.S.—Since the communication of this paper to the Association, and the delivery of my opening address which preceded it on the same day, I have received from Prof. Henry No. 240 of the Smithsonian Contributions to Knowledge, of date October, 1871, entitled "Problems of Rotatory Motion presented by the Gyroscope, the Precession of the Equinoxes and the Pendulum," by Brevet Major-Gen. J. G. Barnard, Col. of Engineers, U.S.A., in which I find a dissent, from the portion of my previously-published statements which I had taken the occasion of my address to correct, expressed in the following terms:—

"I do not concur with Sir William Thomson in the opinions quoted in note p. 38, from Thomson and Tait, and expressed in his letter to Mr. G. Poulett Scrope (NATURE, Feb. 1, 1872). So far as regards fluidity, or imperfect rigidity, within an infinitely rigid envelope, I do not think the rate of precession would be affected."

Elsewhere in the same paper Gen. Barnard speaks of "the practical rigidity conferred by rotation." Thus he has anticipated my correction of the statements contained in my paper on the Rigidity of the Earth, so far as regards the effect of interior fluidity on the precessional motion of a perfectly rigid ellipsoidal shell filled with fluid.

I regret to see that the other error of that paper, which I corrected in my opening address, had not been corrected by Gen. Barnard, and that the plausible reasoning which had led me to it had also seemed to him convincing. For myself, I can only say that I took the very earliest opportunity to correct the errors after I found them to be errors, and that I deeply regret any mischief they may have done in the meantime.

Addendum.—Solid and Liquid Gyrostats.—The solid gyrostat has been regularly shown for many years in the Natural Philosophy Class of the University of Glasgow as a mechanical illustration of the dynamics of rotating solids, and it has also been exhibited in London and Edinburgh at conversaziones of the Royal Societies and of the Society of Telegraph Engineers, but no account of it has yet been published. The following brief description and drawing may therefore even now be acceptable to readers of NATURE:—

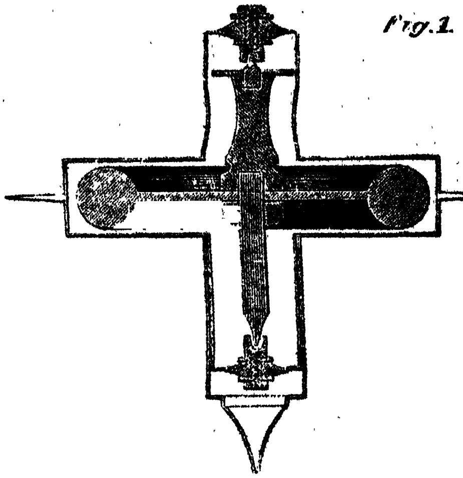

Fig. 1.

The solid gyrostat consists essentially of a massive fly-wheel possessing great moment of inertia, pivoted on the two ends of its axis in bearings attached to an outer case which completely incloses it. Fig. 1 represents a section by a plane through the axis of the fly-wheel, and Fig. 2 a section by a plane at right-angles to the axis and cutting through the case just above the fly-wheel. The containing case is fitted with a thin projecting edge in the plane of the fly-wheel, which is called the bearing edge. Its boundary forms a regular curvilinear polygon of sixteen sides with its centre at the centre of the fly-wheel. Each side of the polygon is a small arc of a circle of radius

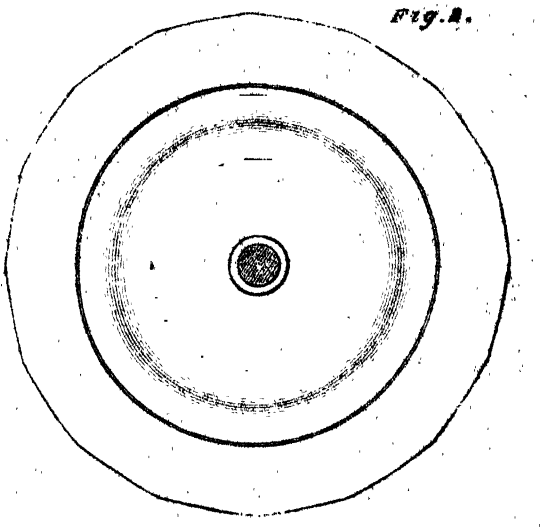

Fig. 2.

---

[1] Communicated to Section A of the British Association, Thursday, September 7, 1876.

greater than the distance of the corners from the centre. The friction of the fly-wheel would, if the bearing-edge were circular, cause the case to roll along on it like a hoop, and it is to prevent this effect that the curved polygonal form described above and represented in the drawing is given to the bearing-edge.

To spin the solid gyrostat a piece of stout cord about forty feet long and a place where a clear run of about sixty feet can be obtained are convenient. The gyrostat having been placed with the axis of its fly-wheel vertical, the cord is passed in through an aperture in the case, two-and-a-half times round the bobbin-shaped part of the shaft, and out again at an aperture on the opposite side. Having taken care that the slack cord is placed clear of all obstacles and that it is free from kinks, the operator holds the gyrostat steady so that its case is prevented from turning, while an assistant pulls the cord through by running, at a gradually increasing pace, away from the instrument, while holding the end of the cord in his hand. Sufficient tension is applied to the entering cord to prevent it from slipping round on the shaft. In this way a very great angular velocity is communicated to the fly-wheel, sufficient, indeed, to keep it spinning for upwards of twenty minutes.

Fig. 3

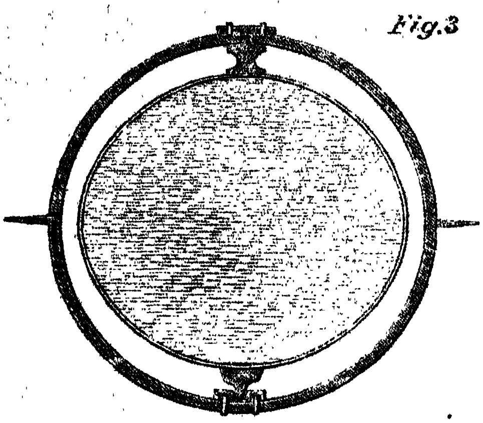

Fig. 4

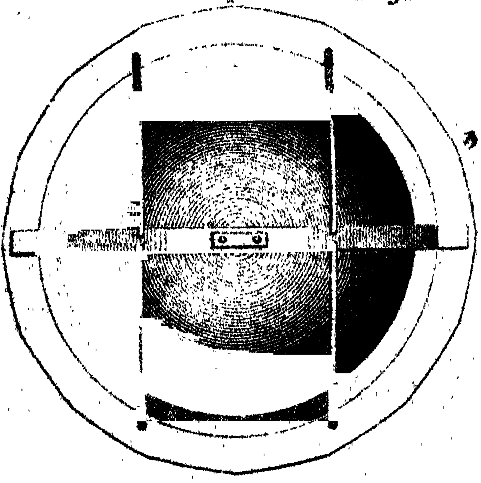


If when the gyrostat has been spun it be set on its bearing edge with the centre of gravity exactly over the bearing point, on a smooth horizontal plane such as a piece of plate-glass lying on a table, it will continue apparently stationary and in stable equilibrium. If while it is in this position a couple round a horizontal axis in the plane of the fly-wheel be applied to the case, no deflection of this plane from the vertical is produced, but i rotates slowly round a vertical axis. If a heavy blow with the fist be given to the side of the case, it is met by wha seems to the senses the resistance of a very stiff elasti body, and, for a few seconds after the blow, the gyrosta is in a state of violent tremor, which, however, subside rapidly. As the rotational velocity gradually diminishes the rapidity of the tremors produced by a blow als diminishes. It is very curious to notice the tottering condition, and slow, seemingly palsied, tremulousness of th gyrostat, when the fly-wheel has nearly ceased to spin.

In the liquid gyrostat the fly-wheel is replaced by a oblate spheroid, made of thin sheet copper, and filled wit water. The ellipticity of this shell in the instrument exhibited is $\frac{1}{10}$, that is to say, the equatorial diamete exceeds the polar by that fraction of either. It is pivote on the two ends of its polar axis in bearings fixed in circular ring of brass surrounding the spheroid. Thi circle of brass is rigidly connected with the curved polygonal-bearing edge which lies in the equatorial plane o the instrument, thus forming a frame-work for the suppor of the axis of the spheroidal shell. In Fig. 3 a section i represented through the axis to show the ellipticity, an Fig. 4 gives a view of the gyrostat as seen from a point i the prolongation of the axis. To prevent accident to th shell when the gyrostat falls down at the end of its spin cage bars are fitted round it in such a way that no plan can touch the shell.

The method of spinning the liquid gyrostat is simila to that described for the solid gyrostat, differing only i the use of a very much longer cord and of a larg wheel for the purpose of pulling it. The cord is firs wound on a bobbin, free to rotate round a fixed pin. Th end of it is then passed two-and-a-half times round th little pulley shown in the annexed sectional drawing, an thence to a point in the circumference of the large whee to which it is fixed. An assistant then turns the whee with gradually increasing velocity, while the frame of th gyrostat is firmly held, and the requisite tension applie to the entering cord to prevent it from slipping round th pulley.

WILLIAM THOMSON

REMARKABLE PLANTS

I.—THE COMPASS-PLANT.

> "Look at this delicate plant that lifts its head from the meadow,
> See how its leaves all point to the north, as true as the magnet;
> It is the compass-plant that the finger of God has suspended
> Here on its fragile stalk, to direct the traveller's journey
> Over the sea-like, pathless, limitless waste of the desert"
>
> LONGFELLOW's *Evangeline*

IT has long been known that there grows on th prairie-lands of the south-western part of the Unite States of America, especially Texas and Oregon, plant which has the peculiar property of turning it leaves towards the north, and which hence serves as magnet to the traveller when no other means is availab of ascertaining the points of the compass. It is probabl however, from Longfellow's description of it as a "delicate plant" on a "fragile stalk," that he never saw i growing. The Compass-plant is a member of the enormous natural order Compositæ, known to botanists a *Silphium laciniatum*. It is described as a stout perennia plant from three to six feet in height, with ovate, deeply pinnatifid leaves and large yellow heads of unisexua flowers, the ray-florets strap-shaped and female, the disc florets tubular and male. It is also known as the pilo weed, polar-plant, rosin-weed, and turpentine-weed, th two last names being derived from the abundant resi exuded by the stem; and is occasionally to be seen i English gardens.

The "polarity" of the leaves of this singular plant ha long been familiar to hunters and other denizens of th prairie, who, "when lost on the prairies in dark night easily get their bearings by feeling the direction of the leaves." But the first occasion on which it was brought under the notice of scientific men appears to have been in communications addressed to the National Institute at Washington in August, 1842, and January, 1843, by General Alvord. The accuracy of his statement having been questioned, the General presented another communication at the second meeting of the American Association for the Advancement of Science, held at Cambridge, Mass., in August, 1849, in which he confirms his own observations by those of other officers, all agreeing in the conclusion that the radical leaves of the plant really present their edges north and south, while their faces are turned east and west, the leaves on the developed stems of the flowering plant, however, taking rather an intermediate position between their normal or symmetrical arrangement and their peculiar meridional position. For the following particulars respecting the phenomena exhibited by the compass-plant we are indebted mainly to a paper by Mr. W. F. Whitney, read before the Harvard Natural History Society and printed in the *American Naturalist* for March, 1871, and to some subsequent notes by Prof. Asa Gray and Mr. Thos. Meehan.

The Compass-plant (*Silphium laciniatum*).

The cause of the ordinary position of the leaves of most plants, one surface being directed towards the sky and the other towards the earth, is generally believed to be a difference in the sensitiveness to light of the two surfaces, the epidermal tissue of the upper being generally denser and less pervious to light than that of the under surface. It is possible also that something may be due to the fact that the under surface of the leaf is almost always more copiously furnished with stomates or "breathing-pores," as they are often inaccurately termed, minute orifices, which serve to promote a diffusion of gases between the external air and the intercellular cavities within the tissue, and especially an abundant exhalation of aqueous vapour. A microscopical examination of the leaves of the compass-plant shows that the structure of the epidermal tissue of the two surfaces is similar, and also that the number of stomates in each corresponds, affording in this respect a contrast to other allied species of the genus *Silphium*, which do not exhibit the phenomenon of polarity, and in whose leaves the stomates were found to be from two to three times as numerous on the under as on the upper surface. If, therefore, the object to be gained is an equal sensitiveness to light, it is obvious that the two surfaces will receive an equal mean amount of light during the twenty-four hours, if they face the east and the west, rather than if they face the north and the south, or the earth and the sky. An attempt has also been made to explain the phenomenon of polarity by currents of electricity induced by the peculiar chemical composition of the substances secreted by the stem and the leaves, but not with much success.

In a recent communication to the Academy of Natural Sciences at Philadelphia, Mr. Meehan says that those who affirm that the leaves are directed to the north, and those who say that there is no such tendency, are both right. He watched a plant in his own garden, and observed the unmistakable northern tendency in the leaves when they first came up, and until they were large and heavy, when winds and rain bore them in different directions, and they evidently had not the power of regaining the points lost. It would appear, therefore, to depend on the season when the observation is made whether the leaves are seen to bear northwards or not.

The same observer records also the following facts with regard to the flowers of the compass-plant. The expansion of the ray-florets in August was observed to begin at daybreak, 4 A.M.; forty minutes afterwards the florets of the disc began to open, and the whole of the corollas were expanded in about three-quarters of an hour, after which there was no further growth in the corollas. The stamens and pistils were gradually protruded beyond the corolla, and the lengthening of the stamens ceased at 6 A.M. After 6.20 no further growth was noticed in the flowers. Later on they were visited by insects, causing the detachment of the florets of the disc, and the scattering of the pollen on to the ray-florets which were thus fertilised. There appear, in fact, to be three phases of growth, with a slight rest between each, the pistil taking the most time, then the stamens, and the corolla the least; but the whole growth of the day is included within two hours.

The geographical range of the plant is stated to be from Texas on the south to Iowa on the north, and from Southern Michigan on the east to 300 or 400 miles west of Missouri and Arkansas. Its chief habitat is rich prairie land. Our illustration is taken partly from the plate in Jacquin's "Eclogæ," the only good drawing of the plant published, assisted by comparison with dried specimens in the Kew Herbarium.

A. W. B.

EXPERIMENTS WITH THE RADIOMETER[1]

II.

HAVING ascertained that the action of the radiometer was due to the internal movement of the molecules of the residual gas, it became important to obtain as much information as possible respecting the physical properties of this residue.

In the apparatus constructed for this purpose a vertical plate is suspended by a glass fibre, which it twists in opposite directions alternately, instead of continuously rotating in one direction, as in the ordinary radiometer. Attached to this apparatus there is:—*a*, a sprengel pump; *b*, an arrangement for producing a chemical vacuum; *c*, a lamp with scale, on which to observe the luminous index reflected from a mirror; *d*, a standard candle at a fixed distance; and *e*, a small vacuum tube, with the internal ends of the platinum wires close together. I can therefore take observations of—

1. The logarithmic decrement of the arc of oscillation when under no influence of radiation.

---

[1] Continued from p. 227.

2. The successive swings and final deflection when a candle shines on one end of the blackened bar.

3. The appearance of the induction spark between the platinum wires.

1 measures the viscosity of the gas; 2 enables me to calculate the force of radiation of the candle; and 3 enables me to form an idea of the progress of the vacuum according as the interior of the tube becomes uniformly luminous, striated, luminous at the poles only, or black and non-conducting. The movement is started by rotating the whole apparatus through a small angle, and the observation consists in noting the successive amplitudes of vibration when the instrument is left to itself, a mirror and spot of light being employed for this purpose. The amplitudes form a decreasing series, with a regular logarithmic decrement. Up to the point at which the vacuum is apparently equal to a Torricellian vacuum, the logarithmic decrement is nearly constant; but as the exhaustion proceeds beyond this point, it becomes smaller, and the force of repulsion approaches a maximum; when the logarithmic decrement is about one fourth of what it was at the commencement, the force of repulsion begins to diminish, and at much higher exhaustions it nearly ceases.

I have experimented with different gases in the apparatus, and by means of a McLeod gauge attached to a mercury-pump, I have been able to measure the atmospheric pressure at any desired state of exhaustion. From the results of the measurements of the force of repulsion and of the viscosity of the residual gas, I have plotted the observations in curves, which show how the viscosity of the residual gas is related to the force of repulsion exerted by radiation.

I have supposed my scale to be 1,000 metres long, and to represent one atmosphere. Each millimetre, therefore, stands for the millionth of an atmosphere.

When the residual gas is air, the viscosity, measured by the logarithmic decrement of the arc of oscillation, is practically constant up to an exhaustion of 250 millionths of an atmosphere, or 0·19 millim. of mercury, having only diminished from 0·126 at the normal pressure of the atmosphere, to 0·112. It now begins to fall off and at 0·1 of a millionth of an atmosphere the logarithmic decrement has fallen to about 0·01. Simultaneously with this decrease in the viscosity, the force of repulsion exerted on a black surface by a standard light varies. It increases very slowly till the exhaustion has risen to about 70 millionths of an atmosphere; at about 40 millionths the force is at its maximum; and it then sinks very rapidly till at 0·1 millionth of an atmosphere it is less than one-tenth of its maximum.

When the residual gas is oxygen the logarithmic decrement is 0·126 at the atmospheric pressure, and at 2 millionths of an atmosphere it is 0·02. The force of repulsion in oxygen increases very steadily up to an exhaustion of about 40 millionths of an atmosphere; it is at its maximum at about 30 millionths, and thence declines very rapidly.

It is not necessary to get so high an exhaustion with hydrogen as with other gases to obtain considerable repulsion. The viscosity at the normal pressure is measured by a logarithmic decrement of 0·063; at 50 millionths it is 0·046, when it rapidly sinks. The force of repulsion is very great in a hydrogen vacuum being, in comparison with the maximum in an air vacuum as 70 to 41.

Carbonic acid has a viscosity of about 0·01 at the normal pressure, being between air and hydrogen, but nearer the former. The force of repulsion does not rise very high and soon falls off.

A long series of observations have been taken, at different degrees of exhaustion, on the conductivity of the residual gas to the spark from an induction coil. Working with air I find that at a pressure of about 40 millionths of an atmosphere, when the repulsive force is near its maximum, a spark, whose striking distance at the normal pressure is half an inch, will illuminate a tube having terminals 3 millimetres apart. When I push the exhaustion further the ½-inch spark ceases to pass, but a 1-inch spark will still illuminate the tube. As I get nearer to a vacuum more power is required to drive the spark through the tube, but, at the highest exhaustions, I can still get traces of conductivity when an induction coil, actuated with five Grove's cells, and capable of giving a 6-inch spark, is used.

When so powerful a spark is employed it sometimes happens that the glass is perforated, thus causing a very slight leakage of air into the apparatus. The logarithmic decrement now slowly rises, the repulsive force of the candle increases to its maximum and then slowly diminishes to zero, the logarithmic decrement continuing to rise till it shows that the internal and external pressure are identical.

In preparing experimental radiometers I prefer to exhaust direct to one or two millionths of an atmosphere. By keeping the apparatus during the exhaustion in a hot air-bath heated to about 300° C. for some hours, the occluded gases are driven off from the interior surface of the glass and the fly of the radiometer. The whole is then allowed to cool, and attenuated air from the air-trap is put in in small quantities at a time, until the McLeod gauge shows that the best exhaustion for sensitiveness is reached; if necessary, this point is also ascertained by testing with a candle. In this manner, employing hydrogen instead of air for the gaseous residue, and using roasted mica vanes at an angle with the axis, I can get very considerably increased sensitiveness in radiometers. I am still unable, however, to get them to move in moonlight, while my sensitive torsion balance does easily.

I have tried many experiments with the view of putting the theory I have referred to in my former paper (NATURE, vol. xv. p. 224) to a decisive test. The repulsive force being due to a molecular disturbance causing a reaction between the fly and the glass case of a radiometer, it follows that, other things being equal, the fly should revolve faster in a small bulb than in a large one. I therefore constructed a double radiometer which shows this fact in a very satisfactory manner. It consists of two bulbs, one large and the other small, blown together so as to have a wide passage between them. In the centre of each bulb is a cup, held in its place by a glass rod, and in the bulbs is a small four-armed fly with roasted mica discs blacked on one side. The fly can be balanced on either cup. In the smaller bulb there is about a quarter of an inch between the vanes and the glass, whilst in the larger cup there is a space of half an inch. The mean of several experiments shows that in the small bulb the fly rotates about 50 per cent. faster than in the large bulb when exposed to the same source of light.

One of the arms of another radiometer was furnished with roasted mica discs blacked on alternate sides. The other arm was furnished with clear mica discs. The two arms were pivoted independently of each other, and one of them was furnished with a minute fragment of iron, so that by means of a magnet I could bring the arms in contact, the black surface of the mica then having a clear plate of mica in front of it. On bringing a lighted candle near the instrument and allowing it to shine through the clear plate, on the blackened mica, the clear plate is at once driven away, till the arm sets at right angles to the other.

Two currents of force, acting in opposite directions, can exist in the same bulb. I have prepared a double radiometer in which two flys are pivoted one over the other, and having their blackened sides turned in opposite directions. On bringing a lighted candle near the flys rotate in opposite directions.

Experiment shows that the molecular disturbance which constitutes the force can be reflected from a plane surface in such a manner as to change its direction. A two-disc radiometer was made having flat opaque mica discs blacked on one side. In front of the black surface of the mica and about a millimetre off, is fixed a larger disc of thin clear mica. On bringing a candle near, the molecular pressure streaming from the black surface is caught by the clear plate and thrown back again, causing pressure behind instead of in front, and the result is rapid rotation in the negative direction, the black side now moving towards the light.

The above actions can be explained on the "evaporation and condensation" theory, as well as by that of molecular movement. I therefore devised the following test to decide between these two theories. A radiometer has its four discs cut of very clear and thin plates of mica and these are mounted in a somewhat large bulb. At the side of the bulb in a vertical plane, a plate of mica, blacked on one side, is fastened in such a position that each clear vane in rotating shall pass it, leaving a space between of about a millimetre. If a candle is brought near, and by means of a shade the light is allowed to fall only on the clear vanes, no motion is produced; but if the light shines on the black plate the fly instantly rotates as if a wind were issuing from this surface, and keeps on moving as long as the light is near. This could not happen on the evaporation and condensation theory, as this requires that the light should shine intermittently on the black surface in order to keep up continuous movement.

The experiments with the double radiometer of different sizes showed that the nearer the absorbing surface was to the glass the greater was the pressure produced. To test this point in a more accurate manner a torsion balance was fitted up with a glass suspending fibre and a reflecting mirror. At one end of the beam is a disc of roasted mica blacked on one side. In front of this black surface, and parallel to it, is a plate of clear mica so arranged that its distance from the black surface can be altered as desired at any degree of exhaustion without interfering with the vacuum. This apparatus has proved that when light falls on the black surface molecular pressure is set up, whatever be the degree of exhaustion. A large series of observations have been taken with it with the result of not only supplying important data for future consideration, but of clearing up many anomalies which were noticed, and of correcting many errors into which I was led at earlier stages of the research. Among the latter may be mentioned the speculations in which I indulged as to the pressure of sunlight on the earth.

I now tried similar experiments to the above, using the best conductors of heat instead of the worst. A radiometer, the fly of which is made of metallic plates perfectly flat and lampblacked on one side, is much less sensitive to light than one of mica or pith; but, as I proved in a paper sent to the Royal Society in January last year, it is more sensitive to dark heat, which indeed causes the black face of a metal radiometer rapidly to rotate in a negative direction, the black continuing to advance until the temperature has become uniform throughout; but as soon as the source of heat is removed the fly commences to revolve with rapidity the positive way, the black retreating as it would if light shone on it.

Experiments with discs of aluminium, mounted diamond-wise and turned up and folded at different angles, show that shape has even a stronger influence than colour. A convex bright surface is strongly repelled, whilst a concave black surface is not only not repelled by radiation, but is actually attracted.

Carefully-shaped cups of gold, aluminium, and other metals, have been tried, as well as cones of the same materials. If a two-disc, cup-shaped radiometer, facing opposite ways and both sides bright, is exposed to a standard candle 3·5 inches off, the fly rotates continuously at the rate of one revolution in 3·37 seconds. A screen placed in front of the concave side so as to let the light shine only on the convex surface, the latter is repelled, causing continuous rotation at the rate of one revolution in 7·5 seconds. When the convex side is screened off so as to let the light strike only on the concave side, continuous rotation is produced at the rate of one revolution in 6·95 seconds, the concave side being attracted.

These experiments show that the repulsive action of radiation on the convex side is about equal to the attractive action gradation on the concave side, and that the double speed with which the fly moves when no screen is interposed is the sum of the attractive and repulsive actions.

With a two-disc, cup-shaped aluminium radiometer as above, lampblacked on the concave surfaces, the action of light is reversed, rotation taking place, the bright convex side being repelled and the black concave attracted. When the light shines only on the bright convex side no movement is produced, but when it shines only on the black concave side this is attracted, producing rotation.

Light shining on a cup-shaped radiometer similar to the above, but having the convex side black and the concave bright, causes it to rotate rapidly, the convex black being repelled. No movement is produced on letting the light shine on the bright concave surface, but good rotation is produced when only the black convex surface is illuminated.

With a cup-shaped radiometer like the above, but blacked on both sides, a candle causes rapid rotation, the convex side being repelled. On shading off the light from the concave side the rotation continues, but much more slowly; on shading off the convex side the concave is strongly attracted, causing rotation.

Radiometers have also been made with cups and cones of plain mica, roasted mica, pith, paper, &c., and they have been made either plain or blacked on one or both surfaces. These have also been balanced against each other, and against metal plates, cups, and cones. The results are of considerable interest but too complicated to explain without numerous diagrams. The broad facts are contained in the above selections from my experiments.

Some of the phenomena produced by the action of light on the cup-shaped vanes of a radiometer may be explained on the assumption that the molecular pressure acts chiefly in a direction normal to the surface of the vanes. A convex surface would therefore cause greater pressure to be exerted between itself and the inner surface of glass than could a concave surface. But it is not easy to see how such an hypothesis can explain the behaviour of those instruments where the action of the bright convex surface more than overcomes the superior absorptive and radiating power of the concave black surface; and the explanation appears to fail to account for the powerful attraction which a lighted candle is seen to exert on the concave surfaces in other instruments.

These experiments, interpreted by the light of the dynamical theory given in my last communication, explain very clearly how it was that I obtained such strong actions in my earlier experiments when using white pith, and employing the finger as a source of heat; and how it happened that I did not discover for some time that dark heat and the luminous rays were essentially different in their actions on black and white surfaces. Rays of high intensity pass through the glass bulb without warming it; they then, falling on the white surface, are simply reflected off again; but, falling on the black surface, they are absorbed, and raising its temperature, produce the molecular disturbance which causes motion. Rays of low intensity, however, do not pass through the glass to any great extent, but being absorbed, raise its temperature. This warmed spot of glass now becomes the repelling body through the intervention of the molecules rebounding from it with a greater velocity than that at which they struck it. The molecular pressure, therefore, in this case streams from the inner surface of the warm spot of glass on which the heat rays have fallen, and repels whatever happens to be in front of it, quite irrespective of the colour of its surface.

WILLIAM CROOKES

THE SPONTANEOUS GENERATION QUESTION

TWO contributions have recently been made to this subject through the Royal Society by Dr. W. Roberts and Prof. Tyndall. Dr. Roberts's communication is as follows[1] :—

In a recent communication to the Royal Society, Dr. Bastian[2] brought forward some experiments to show that while an acid urine usually remains barren after being boiled a few minutes, the same urine becomes fertile when similarly treated, if previously neutralised or rendered alkaline by liquor potassæ, especially if it be afterwards maintained at a temperature of 115° F. or 122° F. In this respect urine only conforms to the general rule observed by myself and formulated in my previous communication to the Society[3]—that "slightly alkaline liquids were always more difficult to sterilise (by heat) than slightly acid liquids."

This difference came out strongest in my own experiments in the case of hay-infusion—the acid infusion invariably remaining barren after a few minutes' boiling, and the neutralised infusion invariably becoming fertile after a similar boiling. Accordingly I utilised hay-infusion to determine the cause of the difference in question. It could evidently only be due to one of two things—either (1) the change of reaction enabled germs pre-existing in the infusion to survive the ebullition; or (2) the addition of the alkali exercised a positive influence in exciting a *de novo* generation of organisms. To decide which of these two interpretations was the true one, an experiment was contrived in which the liquor potassæ could be added to the infusion, not before, but after it had been boiled, and thereby rendered permanently sterile. When added in this way, I found that liquor potassæ had not any power to excite germination. The infusions invariably remained barren when the alkali was added to them after they had been sterilised. I therefore concluded that the effect of the change of reaction consisted simply in enabling pre-existing germs to survive a brief ebullition. Dr. Bastian, in repeating his experiment in the case of urine, arrived at an opposite conclusion: he found that whether the alkali was added before or after ebullition he obtained the same result—the urine in both cases became fertile; and he concluded that the alkali had a positive power of promoting the origin of organisms in the urine.

This experiment, if properly performed, is obviously a crucial one, and it is recognised as such by Dr. Bastian. But two conditions are essential to the validity of the experiment. In the first place it must be ascertained beyond doubt that the boiled acid fluid has been really deprived of its germs—in other words, that the ebullition has been sufficiently prolonged to render it permanently barren; and secondly, that in adding the liquor potassæ due care is taken that no new germs are introduced at the same time. In repeating my experiment, Dr. Bastian appears to have departed from my procedure in two points, and he has thus possibly laid himself open to the two sources of fallacy just mentioned. In my own experiments, the acid infusion, after it had been boiled, was set aside in a warm place for a fortnight in order to test its sterility; and the liquor potassæ was not added to it until the lapse of time had satisfied me that it had been rendered permanently barren. In Dr. Bastian's experiments the liquor potassæ was added as soon as the vessels had cooled, so that he had no certainty that their contents would not have germinated without the addition of the alkali.[4] In the second place, instead of heating the tubes containing the liquor potassæ (as I had done) to 150° F., and thus ensuring the destruction of all germs contained in the air imprisoned therein with the alkali, he contented himself with subjecting them for an inconsiderable period to the heat of boiling water.

Seeing these two possible sources of fallacy, I determined to repeat Dr. Bastian's experiments with urine, but taking care to avoid these defects. I proceeded as follows :—

A flask with a longish neck was charged with an ounce of normal acid urine. The due quantity of liquor potassæ requisite to exactly neutralise this (as ascertained by previous trials) was inclosed in a sealed glass tube drawn to a capillary portion at one end. The tube was then heated in oil up to 280° F., and maintained at that temperature for fifteen minutes. The tube was then introduced into the body of the flask. The neck of the flask was next drawn to a narrow orifice; then the urine was boiled for five minutes, and the orifice sealed in ebullition. Ten such flasks were charged and treated in the same manner. They were then set aside in a warm place (from 70° F. to 80° F.) for a fortnight. At the end of this time the contents of the flasks were found perfectly transparent; the urine was therefore assumed to be permanently sterilised. The liquor potassæ was then liberated by shaking the tubes against the sides of the flasks and thus breaking their capillary points. The previously acid and barren urine was thus neutralised. The flasks were then placed in an incubator and maintained at a constant temperature of 115° F. At the end of two days it was found that the urine in each flask had deposited a sediment of earthy phosphates, but the supernatant liquor was perfectly transparent. The flasks were again placed in the incubator and maintained at a constant temperature of 122° F. for three days. At the end of this period they were withdrawn and opened for examination. Not one of them showed the slightest evidence of living organisms; the supernatant liquor was perfectly transparent, and no Microphytes could be detected under the microscope. The precipitated phosphate in some of the flasks presented a granular appearance, which might, by the unwary, be mistaken for Micrococci, but any such illusion was at once dissipated by adding a drop of hydrochloric acid, which instantly dissolved the phosphate and restored the perfect transparency of the urine. This acid has no effect on the turbidity caused by Microphytes.

These experiments therefore negative the conclusion that liquor potassæ, or a temperature of 115° F. to 122° F., or both conditions combined, have the power of exciting the generation of organisms in sterilised urine.

The effect of elevated temperature was also tested in another way. I had by me twenty-nine preparations of fermentible liquids which had remained over from my previous experiments in 1873–74. These consisted of

15 alkalised hay-infusons,
5 pieces of boiled egg-albumen in water,
1 piece of turnip in water,
2 diluted ascitic fluid,
1 blood with water,
1 albuminous urine,
4 pieces of meat or fish in water.

These had all been sterilised by the heat of boiling water two or three years ago, and were contained in large bulbs with long necks. Ten of the hay-infusions were hermetically sealed; the rest were all open to the air, under the protection of a plug of cotton-wool. All possessed perfectly transparent supernatant liquors, and showed no signs of containing organisms, nor of having undergone any fermentive or putrefactive changes.

These twenty-nine preparations were introduced into the incubator, and maintained at a constant temperature of 115° F. for two days, and then at a temperature of 122° F. for three days. At the end of this period not one of them showed any signs of fertility. The supernatant liquid in each bulb was quite transparent, and some of them, which were opened for microscopic examination, showed no traces of living organisms.

I can, however, fully confirm the statement of Dr. Bastian, that Bacteria, or certain kinds of them, grow and multiply freely in (unsterilised) urine, both acid and neutralised, when exposed to a temperature of 115° F. to 122° F.

The following is Prof. Tyndall's paper[1] :—

The communication "On the Influence of Liquor Potassæ and an Elevated Temperature on the Origin and Growth of Microphytes," which, at Dr. Roberts's request, I have had the pleasure of presenting to the Royal Society, causes me to say earlier than I should otherwise have done, that the subject which has occupied Dr. Roberts's attention has also occupied mine, and that my results are identical with his.

---

[1] "Note on the Influence of Liquor Potassæ and an Elevated Temperature on the Origin and Growth of Microphytes," by W. Roberts, M.D. Communicated by Prof. Tyndall, F.R.S., December 21, 1876.

[2] "Researches Illustrative of the Physico-Chemical Theory of Fermentation," &c., read before the Royal Society, June 15, 1876.

[3] "Studies on Biogenesis." Phil. Trans. vol. lxiv. p. 457.

[4] It is not sufficient to rely in such a case on a central flask or retort. Each flask or retort should have its own individual sterility tested, because it is practically impossible to apply the heat exactly in the same degree in any two cases.

[1] "Note on the Deportment of Alkalized Urine," by Prof. Tyndall, F.R.S. Communicated December 21, 1876.

In some of the experiments the procedure described by Dr. Roberts was accurately pursued save in one particular, which has reference to temperature. Small tubes with their ends finely drawn out were charged with a definite amount of caustic potash, and subjected for a quarter of an hour to a temperature of 220° Fahr. They were then introduced into flasks containing measured quantities of urine. The urine being boiled for five minutes, the flasks were hermetically sealed during ebullition. They were subsequently permitted to remain in a warm place sufficiently long to prove that the urine had been perfectly sterilised by the boiling. The flasks were then rudely shaken so as to break the capillary ends of the potash tubes and permit the liquor potassæ to mingle with the acid liquid. The urine thus neutralised was subsequently exposed to a constant temperature of 122° Fahr., which is pronounced by Dr. Bastian to be specially potent as regards the generation of organisms.

I have not found this to be the case, for ten flasks prepared as above described towards the end of last September, remained perfectly sterile for more than two months. I have no doubt that they would have remained so indefinitely.

Three retorts, moreover, similar to those employed by Dr. Bastian, and provided with potash tubes, had fresh urine boiled in them on September 29, the retorts being sealed during ebullition. Several days subsequently the potash tubes were broken and the urine neutralised. Subjected for more than two months to a temperature of 122° Fahr. they failed to show any signs of life.

These results are quite in accordance with those obtained by Dr. Roberts. His potash tubes, however, were exposed to a temperature of 280° Fahr., while mine were subjected to a temperature of 220° only.

With regard to the raising of the potash to a temperature higher than that of boiling water, M. Pasteur is in advance both of Dr. Roberts and myself. In a communication to the French Academy, on July 16 last, M. Pasteur showed that when due care is taken to add nothing but potash (heated to redness if solid, or to 110° C. if liquid) to sterilized urine, no life is ever developed as a consequence of the alkalisation.[1]

M. Pasteur has quite recently favoured me with sketches of the simple, but effectual apparatus, by means of which he has tested the conclusions of Dr. Bastian. Since his return from his vacation at Arbois, he has carefully gone over this ground with results, he reports to me, not favourable to Dr. Bastian's views.

I may add that I have by no means confined myself to the thirteen samples of urine here referred to. The experiments have already extended to 105 instances, not one of which shows the least countenance to the doctrine of spontaneous generation.

It gives me pleasure to refer to the skill and fidelity with which here, as in other cases, Mr. Cottrell has carried out my directions.

OUR ASTRONOMICAL COLUMN

THE NEW STAR IN CYGNUS.—In No. 2,115 of the *Astronomische Nachrichten*, Prof. Schmidt publishes the results of his observations on the intensity of light exhibited by this star between November 24, the date of its discovery, and December 15, when it was last perceptible to the naked eye. Having laid down his estimates of magnitude graphically on a large scale, he reads off therefrom the magnitude for every sixth hour, the differences showing a marked uniformity except about November 28, when the diminution of brightness was much more rapid. The magnitudes at midnight are as follow :—

	m.		m.		m.
Nov. 24 ...	2·97	Dec. 1 ...	5·27	Dec. 8 ...	6·44
„ 25 ...	3·03	„ 2 ...	5·47	„ 9 ...	6·55
„ 26 ...	3·14	„ 3 ...	5·65	„ 10 ...	6·64
„ 27 ...	3·38	„ 4 ...	5·81	„ 11 ...	6·71
„ 28 ...	4·06	„ 5 ...	6·00	„ 12 ...	6·79
„ 29 ...	4·74	„ 6 ...	6·16	„ 13 ...	6·86
„ 30 ...	5·06	„ 7 ...	6·32	„ 14 ...	6·92

In the forty-eight hours following November 27^{d} 18^{h}, there was a diminution to the extent of nearly 1¼m. It is remarked that on the night of discovery its brightness was such as to render its near neighbour, 75 Cygni, invisible, while on December 14 and 15, 75 Cygni (6·4m.) in its turn nearly obliterated the new one; at 10 P.M. on the latter date it was only by great exertion of the eye that a trace of the star could be discerned. Prof. Schmidt did not remark any decided change of colour : it was at no time decidedly of an orange tint, but less ruddy than γ, ε, and ζ Cygni, yet of a full yellow, 5·6 to 5·8 on his scale.

The curve resulting from the Athens observations accompanies Prof. Schmidt's description, and for comparison with it similar curves are added to show the law of diminution to the limit of unassisted vision, in the cases of the so-called new stars of 1848 (Hind, April 27) and 1866 (Birmingham, May 12). The descent was slowest in the former case and quickest in the latter, but the curve for the star of 1848 appears to be drawn from a small number of observations. Prof. Schmidt assigns for the interval between discovery and disappearance to the unaided vision, twenty-five days in 1848, nine days in 1866, and twenty-one days in 1876; the writer is able to state that the star of 1848 was just perceptible without the telescope as late as May 27, four days after the termination of Prof. Schmidt's observations and thirty days after its discovery, and there was a decided check in the star's descent between May 1 and 6; on May 1 it was a little less than 20 Ophiuchi, and on May 6, certainly a little brighter than that star. On April 29 it was so nearly equal to ν Serpentis that close attention was necessary to decide which was the brighter; ν was found to be in a very trifling degree superior.

VARIABLE COMPONENTS OF DOUBLE STARS.—A suspicion of variability in the small companion of δ Cygni has been entertained by several observers, Prof. Secchi, among others, having remarked that the star has appeared single at times when the atmospheric circumstances would not afford an explanation. But the case of 72 Ophiuchi, No. 342 of the "Pulkova Catalogue" of 1850, is a much more suspicious one. The discoverer, M. Otto Struve, says, "I have very often looked at this star, and have many times noted it single. Yet on three occasions I have seen it double, always in about the same direction, and at a distance of 1″·5. I do not know how to explain these discordances, except on the supposition that the satellite is very variable." Secchi found the star single at the epochs 1856·53 and 1857·71; at 1857·57 a doubtful companion was noted in the direction 345°·9, but at the epoch 1859·61 he records it "certainly double, and well separated," the measures giving the position 3°·75, and distance 0″·608. This star does not occur in the more recent revision of the Pulkova list, by the Baron Dembowski.

To such cases may be added those of α Herculis and β Cygni, where the companions do not vary to such an extent as to cause the objects at times to appear single.

THE BINARY STAR γ CENTAURI.—While awaiting further measures of this fine double star, it may be remarked that admitting the measures of Sir John Herschel in 1835-36, to require an alteration of 180°, in order to render them comparable with those of Capt. Jacob and Mr. Powell, the latest published angle measured by the latter observer in 1860, indicates a motion in a retrograde direction of upwards of 160° between 1835·85 and 1860·68, the distance having increased about 0″·4. The star will be in all probability one of comparatively short period, and, as such, deserves attention at the hands of southern observers. The alteration of 180° in Sir John Herschel's measures is quite justified by the near equality of the stars.

THE MINOR PLANETS.—M. Perrotin, of the Observatory at Toulouse, met with a small planet on January 10, in a region of the sky where it is probable that Nos. 77 and 149, Frigga and Medusa, are at present situated, and the same planet was detected some ten days later by Prof. Peters at

---

[1] That alkaline liquids are more difficult to sterilise than acid ones was announced by Pasteur more than fourteen years ago. See *Annales de Chimie*, 1862, vol. lxiv. p. 62.

Clinton, U.S. On January 13, M. Borrelly, at Marseilles, also found a small planet distinct from that of Perrotin and Peters. It is remarked in M. Leverrier's *Bulletin*, that the first of these planets is unlikely to be Frigga, since the rough ephemeris in the *Berliner Jahrbuch* gives a contrary motion in declination. The object found by M. Borrelly, however, presents indications of identity, though a considerable correction of the elements of Frigga, brought up to 1874, December, by Dr. Powalky, would be required. If we employ these elements it will be found that with $\delta M = -3° 17'·67$, the computed and observed longitudes of Borrelly's planet on January 13 will agree, but there is an outstanding difference of + 1° 39′ between the latitudes. The comparisons with the observation on this date and one on January 15, are as follow:—

	Long. c – o	Lat. c – o
January 13 ...	0′·0 ...	+ 1° 39′·1
„ 15 ...	– 4′·4 ...	+ 1° 36′·9

NOTES

The eminent physicist, Prof. J. C. Poggendorff, for many years professor in the Berlin University and editor of *Poggendorff's Annalen*, has died in Berlin, in his 81st year. We hope to be able to give a memoir of Prof. Poggendorff next week.

The eminent Belgian botanist, Prof. Bellynck, died at Namur in December.

The first four names in the Cambridge Mathematical Tripos list, are Messrs. Donald McAlister, St. John's, Frederick M. de M. Gibbons, of Gonville and Caius College, R. C. Rowe and Mr. James Parker Smith, both of Trinity College. The Senior Wrangler, who was born at Perth in May, 1854, has had a most distinguished career as a student.

The Society of German Naturalists and Physicians holds ts annual session at Munich, February 18, and celebrates at the ame time its fiftieth anniversary.

The Council of the Royal Dublin Society have elected Villiam Archer, F.R.S., Secretary for Foreign Correspondence o the Royal Irish Academy, as head of their Library Department, and the members of the Society, as well as the literary nd scientific public in Dublin are to be congratulated on the ccasion.

The Russian Archæological Society holds its Annual Congress at Kasan, July 31.

According to a Report of the French Minister of Public nstruction, the salaries of the Inspectors-General of Public nstruction, the Professors of the Collége de France, and the rofessors of the Museum of Natural History, have been raised o 10,000 frances, and of the Professors of the School of Living riental Languages, to 7,500 francs.

In 1855 Napoleon III. proposed a prize of 50,000 francs for e most important improvement made in the use of voltaic electricity during the previous ten years. The prize was last awarded o M. Ruhmkorff, who, it is known, is a German physician established in Paris. M. Waddington has recently appointed a ry to award the prize for the third time. Any improveent in any industry using voltaic electricity comes within the ompetition, consequently the sphere is a very wide one. Regutions will shortly be issued.

Prof. Nordenskiöld proposes to take command of an exedition next year which will examine the Siberian coast from e mouth of the Jenissei to Behring Straits. The return journey ill be by way of China, India, and the Suez Canal.

The remarkable entomological collections of the late Dr. Breyer are to be purchased for the Royal Museum for Natural History of Brussels, for the very low price of 240*l*. They contain above 21,000 specimens of insects, classified by the late eminent entomologist.

We observe that the following honorary members have been elected by the New York Academy of Sciences:—In this country, Mr. G. Bentham and Prof. Boyd Dawkins; on the Continent, Profs. Brandt, De Candolle, Milne-Edwards, Hoffmann, M. de Verneuil, and Herr von Siebold.

We have lately alluded to the very large ethnographical additions made to the Berlin Museum by Dr. Lenz, Dr. Bastian, and Dr. Jagor. A still more valuable collection has lately been presented by Dr. Nachtigal, and is now in process of arrangement. It embraces a vast variety of objects gathered amidst widely-diversified tribes by this well-known traveller during his last extensive tour through Africa, and affords a rare opportunity for comparative ethnographical study.

A credit of 13,668*l*. has been requested from the Belgian Chamber of Representatives by the Minister of the Interior, for the astronomical and meteorological observatory of Brussels. Besides the construction of new astronomical and magnetical instruments, this sum will be used for the enlargement of observations upon the periodical phenomena of vegetation. Special arrangements will be made for carrying on the observations in the garden of the observatory, on plants especially selected for the purpose from the double point of view of the botanical geography of the present time, and of the study of former climates of the earth.

The Belgian Chamber of Representatives passed, on January 26, a resolution of great importance to geologists, allowing the necessary sums for the publication, first, of the beautiful coloured maps of the soils and sub-soils of Belgium, prepared about thirty years ago by André Dumont, on the scale of 1 : 160,000, and which are long ago out of print; and second, of the MSS. of Dumont, with his numerous geological sketches and drawings, and of the numerous notes he took during his travels in Belgium. The MSS., which were purchased by Government, are already arranged for publication, and their appearance, as well as that of the maps, is expected about the end of this year.

The Belgian Geological Society is engaged in the elaboration of a scheme for the preparation and publication of a detailed geological map of Belgium, on a large scale. The idea of such a publication being already approved by the government, the point under discussion now is the best means of engraving the work, and the Society proposes to entrust the task to two special committees, geological and cartographical; both committees will be placed under a common directorship.

At the session of the Berlin Anthropological Society on January 20 Prof. Virchow gave an extended account of a large collection of diluvial remains found in the neighbourhood of Weimar. They consisted of the bones of such animals as the elephant, rhinoceros, arctic bear, deer, wild swine, &c. Apart from their palæontological value, they are extremely important from an anthropological point of view, as among the bones are several flints, remains of fires, and peculiarly divided fragments of bone, all indicating the presence of man in company with the animals mentioned. Dr. C. Jung described the superstitious observances and use of charms and amulets among the aborigines of Australia. The bones of animals which have been eaten, or the bones of dead relatives are regarded with peculiar reverence by almost all of the tribes. There was also a discussion on the supposed Phœnician inscription lately found on a block of stone in North Russia, Dr. Wettstein declaring it impossible to connect it with known Phœnician characters.

In the January session of the Swedish Anthropological Society H. Torell gave the results of an interesting comparative study of the Esquimaux and Japanese. The anatomical and ethnographical resemblances are so striking that they give additional strength to the theory of the settlement of America from Asia by the way of Behring's Straits.

H. v. Schlagintweit-Sakünlünsky publishes, in connection with his report on the botany of the Himalayas, presented before the Berlin Academy of Sciences, an interesting comparison between the snow limits of the great Asiatic mountain chain and those of the Swiss Alps. The Himalaya range shows a snow limit at the height of 16,600 feet on the northern side, and 16,200 feet on the southern side. That of the Kuenlun range varies from 15,100 feet on the northern side, to 15,800 on the southern. The snow limit of the Alps shows an average height of 9,000 feet, 8,900 feet on the northern side, and 9,200 feet on the southern.

In the last session of the Austrian Meteorological Society, Prof. A. von Obermayer read a paper on the nature of fogs, strongly advocating the theory regarding them as minute drops of water, the specific gravity of which is overcome by the friction between the particles of air, according to Stokes's hypothesis.

In a communication in the *Daily News* of January 25, in reference to the Cairo Geographical Society, by the Alexandria Correspondent of that paper, some interesting details are given of papers read on the Eastern Sudan and on Darfur.

The use of rock crystal for normal scientific apparatus has recently been advocated by S. Stein, of Bonn, in a communication to the German Chemical Society. For scale-beams and scale-pans it is especially adapted, as it is entirely unaffected at ordinary temperatures by acids, bases, or the gases and moisture present in the atmosphere, while possessing nearly the same specific gravity as aluminium—2·65—and being comparatively unelastic. It is equally practicable for standards of measure, longitudinal as well as circular. Discs to be used for telescopes, theodolites, quadrants, &c., if cut at right angles to the chief axis, show an almost absolute unchangeability of form. The smallness of the coefficient of expansion renders it also eminently well fitted for normal thermometers, where accuracy and not cost is the chief requisite.

Commander Cameron having been invited by the Geographical Society of Paris to deliver a lecture on his journey across Africa did so at an extraordinary meeting held by the Society in the large hall of the Sorbonne, on January 26. The place, although fitted to accommodate 2,000 people, was crowded to inconvenience. On Saturday a banquet was given to Commander Cameron by the Fellows of the Geographical Society, about 200 being present. The President of the Republic was represented by his first aide-de-camp, the Marquis D'Abzac, and the Minister of Public Instruction by his general secretary, M. Watteville, who delivered to Commander Cameron the University gold palms and diploma. The knife and fork used by Livingstone in his African travels, and which had been purchased by MM. Rambaud, the large French traders established in Zanzibar, and presented to the Geographical Society of Paris, were used by Cameron. A magnificent album of the portraits of all the persons present at the banquet will be sent to Commander Cameron. MM. Hachette and Co. are preparing a magnificent French edition of Cameron's work.

At the session of the Berlin Academy of Sciences on January 25, Prof. Du Bois-Reymond gave a report of the investigations carried on in connection with the Humboldt foundation intrusted to the Academy. At present two travellers are supported by the funds—Dr. Hildebrandt, who is studying the snowy regions of the Kilimanjaro Mountains in Eastern Africa, and Dr. C. Sachs, engaged in researches in Brazil on the nature of the electricity of the electric eel.

A piece of burnt stone resembling a piece of partially burnt slate coal, with white sparkling specks on it, fell at Ecclefechan on the evening of the 2nd January. Two men, walking on the Glasgow road, heard a noise behind them, and on turning round they found the stone referred to embedded in the ground to the extent of half-an-inch or more. One of them attempted to lift it but got his hand burnt. The stone, which measures about four inches by two, and weighs nine ounces, took twenty minutes to cool. A volume of smoke proceeded from it.

A few years since, M. Delacour, sub-director of the Danish Meteorological Institute, invented the so-called phono-telegraphic system. Since then he has carried on an extensive series of experiments, the cost of which has been defrayed by the Danish Government, with the view of perfecting the new system. The results of his investigations were displayed a few days since to a company of electricians and members of the Danish Parliament. As is already known this system is based upon the application of vibrating currents, tuning-forks of the same number of vibrations per second being brought within the influence of current at both ends of the wire. M. Delacour made use on the above occasion of twelve different pairs of tuning-forks, all of which were connected at the same time with a single telegraphic wire. He was then able to send simultaneously twelve messages by means of the tuning-forks as well as one by the ordinary method, and most satisfactorily solved the problem with regard to the use of a single wire for the forwarding of numerous messages at the same time.

Prof. Anton Kerner, author of the "Means of Protection in Flowers against Unwelcome Visitors" (Nature, vol. xv. p. 237), has lately received from Charles Darwin the following characteristic epistle:—"Allow me to express to you my heartiest thanks for the pleasure experienced in reading your work. You have opened up an entirely new field of research, and explained many things which were previously enigmas to me. I find that I have fallen into many mistakes, in the preparation of my last book, when touching upon the subject which you have considered so fully."

The last number of the *Jahrbuch der k. k. geologischen Reichsanstalt* (vol. xxvi. No. 3) contains a very valuable elaborate paper by K. M. Paul—"Grundzüge der Geologie der Bukowina" —with a map on a scale of 1 : 280,000, reduced from that of the Geological Survey, and embodying the results of the survey, made during the last four years, together with the data furnished by former explorations. The southern, hilly corner of the Duchy is occupied by an island of crystalline rocks, bordered on one side by a zone of mesozoic limestone (Dyas and Trias). A broad zone of the so-called Carpathian sandstones (Neocomian, Gault, and Upper Chalk, and probably Eocene) follows, as is generally the case at the northern slope of the Carpathian, and crosses the land in a north-western direction. Further to the north-east we see a broad district covered with Neogene formations (Lower and Upper Mediterranean, and Garmathian stages), diluvial deposits, and loess, which district meets with the Galician plains to the west, and the Podolian to the north.

The geological structure, and especially the volcanoes of the southern parts of Luzon (Philippines) are the subject of an interesting note by Dr. Drasche, being a preliminary report upon his recent travels in the interior of the island, which appeared in Tchermak's *Mineral. Mitth.*, 1876, Heft 3. The note is accompanied by a map on the scale of 1 : 1,000,000, constructed after that of M. Jagor ("Reise in den Philippinen") and by some views and geological sections. The volcanoes of the Taal district, the Majajai, the Monte Labo," and Sierra Corasi, the Ysarog, Buhi, and Mayon, or Albay, were visited by the author, and are shortly described. Among other interesting observations we notice the very steep slopes (32°) on which lava-floods may flow sometimes without being interrupted for distances of more than 300 feet, observed on the Mayon. The height of this last being 2,374 metres (7,787 feet), Dr. Drasche points out the error in the index of volcanoes, given in the late Mr. Poulett Scrope's work, where the height of the Mayon is given as 3,200 English feet. Another error of the Index is that an active volcano is reported to exist on "the little island Mindoro," whilst on this rather large island (250 square geographical miles) there are no volcanoes at all, neither active nor extinct.

In a communication to the Vienna Academy on the nature of gas molecules, M. Boltzmann abandons the notion that they behave like aggregates of material points (the atoms). He considers that in estimating the impact action of the molecules, we may almost regard the whole aggregate, which we denote as an individual gas molecule, and which may consist of different substances, perhaps even ether atoms, as rigid. It is found that then the ratio of the heat-capacities of the gas must be 1⅔, when the gas molecules have ball-form. The ratio of the heat-capacities will be 1·4 if the molecules have the form of rigid bodies of rotation, but which are not balls; and 1⅓ if they are of any other form of rigid bodies. These numbers at least seem to agree so far with those found experimentally, that one cannot say that experiment furnishes a contradiction of the theory thus modified. It is further shown that the values experimentally got for the heat-capacity, under this view, are in satisfactory agreement with the heat-capacities of solid bodies. Of course the gas molecules cannot be absolutely rigid bodies; this is already disproved by spectral analysis, but it may be that the vibrations producing gas spectra are merely brief shiverings during the shock of two molecules, comparable to the sound perceived on the shock of two ivory balls.

The current opinion as to the Ural range not bearing any traces of former glaciers, is now contradicted by M. Poliakoff. This explorer, who has had during the last ten years many opportunities of making a close acquaintance with glacial formations in Southern Finland, in the basin of Lake Onego, and on the Valdai plateau, reports that, while the lower parts of the Ural ridge are connected under large alluvial deposits, its upper parts, especially east of the water-parting, exhibit unmistakable morainic deposits with scratched boulders. The rocks bear also, sometimes, true glacial striae running from north-west to south-east, and certainly such striae would be found more numerous, were the localities more thoroughly explored than M. Poliakoff could do as he crossed the ridge on his way to the Obi. A lower secondary ridge, the last crossed by the highway before Ekaterinburg, exhibits also many *traînées* of immense boulders running in parallel directions, such as are found in Finland, Erthonia, and northern Russia. Further east, on the shores of the Obi (near to the mouth of the Irtysh), the lowest parts of the loose deposits, which are roughly stratified sands, contain a good deal of well-polished and striated boulders of glacial origin. These observations make it very desirable that the Ural were thoroughly explored by a geologist well acquainted with glacial formations.

The Göttingen Academy announces the following subject for prize competition in the physical class till November, 1878:—The question what special actions (if such there be) breathing in pure oxygen gas of the ordinary density of atmospheric air has on the animal organism, has not hitherto been answered by researches with sufficient agreement. Further researches, ther fore, are desired, both on homoiothermal and, as far as pract cable, on poikilothermal animals; in these should be shown, quit specially, along with the phenomena externally observable in t animals, the nature of the change of blood and material (excre tion of carbonic acid, nature of urine). In the view of certa data, the purity of the oxygen from all foreign matters occurri in its preparation must be carefully looked to, while a mixture atmospheric nitrogen within narrow limits, hardly to be avoide would not essentially vitiate the results. In the mathematic class of the same Academy, new researches are desired on t nature of the unpolarised light-ray, calculated to bring the ide regarding natural light from any source, near to those whic theory connects with the different kinds of polarised light.

We have received the Fourth Report of the New Cro Microscopical and Natural History Society, which, we are gla to see, continues to prosper. It contains an address by the pr sident, Dr. F. T. Taylor, on "Spontaneous Generation."

From the Seventh Annual Report of the Wolverhampton Fre Library Committee, we are glad to learn that a Naturalists' an Archæological Department has been established in connectio with that institution.

In 1875 a Bedfordshire Natural History Society was forme and it has just issued its first Abstract of Proceedings. It ha made a very fair beginning both as to numbers and as to th quality of the papers read. We hope it will receive more en couragement from residents in the county than it appears to hav done, and that it will work diligently at local natural histor One of the papers, accompanied by a map, is "On the Botan cal Division of Bedfordshire," by Mr. W. Hillhouse, F.L.S.

Among the papers in the *Proceedings* of the Belfast Natura History and Philosophical Society for 1875-6, is one by Mr. J J. Murphy on the Glacial Climate and the Polar Ice-cap. M R. Lloyd Patterson has a concluding note on some of the swim ming birds of Belfast Lough.

The additions to the Zoological Society's Gardens during th past week include two Vervet Monkeys (*Cercopithecus lalandi* from South Africa, presented by Mr. T. G. Butler; two Arcti Foxes (*Canis lagopus*) from the Arctic Regions, presented b Sir Thomas Erskine, Bart, F.Z.S.; a Ring-Necked Parrakee (*Palæornis torquata*) from India, presented by Miss Smith three Silky Marmosets (*Midas rosalia*) from Brazil, purchased.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, December 21, 1876.—"On the Rotation the Plane of Polarisation of Light, by Reflection from the Pol of a Magnet," by George Francis Fitzgerald, M.A. Communi cated by G. Johnstone Stoney, F.R.S.

At the last meeting of the British Association, the Rev. J Ker described a delicate and very remarkable experiment, from which it appeared that when plane polarised light is reflecte from the polished surface of the end of a powerful magnet, th plane of polarisation is rotated. Mr. Geo. F. Fitzgerald ha recently communicated to the Royal Society an explanation of thi curious phenomenon, of which the following is an abstract:—

It is known from Faraday's and Verdet's experiments tha when plane polarised light is transmitted through transparen diamagnetic or ferro-magnetic media, while under the influence o a powerful magnet, the plane of polarisation will be rotated, s that the plane of polarisation of the emergent beam will diffe from that of the incident light. This action is most powerfu when the direction of transmission coincides with the direction o the streams of magnetic influence, and in general the rotation i in opposite directions in diamagnetic and in ferro-magnetic media. Now, if we regard the incident light as formed of the two circularly polarised beams which are equivalent to it, we learn from Faraday's and Verdet's experiments that one of these beams i retarded more than the other in passing through the medium, or, in other words, that they have different refractive indices. And of course if a powerful iron magnet were transparent, we might expect to find a much more powerful action of this kind upon transmitted light. Iron, however, is not transparent, so that the effect on transmitted light cannot be observed. But any effect which this difference between the refractive indices can produce upon *reflected* light may be made the subject of experiment, and Mr. Fitzgerald has shown that the observation made by Mr. Ker is an effect of this kind.

To show this, Mr. Fitzgerald splits the incident plane polarised light into its two *equivalent* beams of circularly polarised light. These circularly polarised beams are one right-handed and the other left-handed, and, before incidence, are equal in intensity to one another. If, however, their indices of refraction in the magnet are very different, as Faraday's and Verdet's experiments lead us to suppose, their intensities after reflection will be sensibly unequal, and their phases also will in general be unequally affected. Hence their united effect after reflection is to produce in general an elliptically-polarised beam, the major axis of which is inclined to the plane of original polarisation, thus producing that appearance of a slight change of the plane of polarisation which was observed by Mr. Ker.

Mr. Fitzgerald has repeated Mr. Ker's experiment, and ascertained that the reflected light is, in fact, elliptically polarised, as indicated by the theory. He has also found that when the polished pole of the magnet is gilt the observed effect disappears. This is a further confirmation of the theory, since gold is diamagnetic, and therefore too feeble to produce an appreciable effect, if the effect is due to the cause which Mr. Fitzgerald has pointed out.

January 11.—"On some Phenomena connected with Vision," by B. Thompson Lowne, F.R.C.S., Arris and Gale Lecturer at the Royal College of Surgeons, &c., communicated by Prof. Stokes.

The author arrives at the conclusion that the intensities of the sensations produced by various illuminations of a white surface vary as the square roots of the intensities of illumination, by comparing the shadows, cast in Lambert's well-known experiment, with ruled shades, as those of engravings and wood-cuts, taking the amount of reserved white in the latter to indicate directly the intensities of the sensations produced by them. He considers the number of rods and cones stimulated on a given area of the retina as the measure of sensation, and proportional to the reserved white.

He further finds, by a repetition of the experiment of MM. Delbœuf and Plateau, that the grey ring seen on a rotating disc with a black or white sector, disappears when the sector is sufficiently narrow and the rotation sufficiently rapid, and that the rate of rotation necessary to produce this result with the same disc and sector varies as the square root of the intensity of the illumination of the disc.

Lastly, he proposes a modification of Fechner's formula, which only requires a change of Fechner's convention that the liminal increment of sensation is constant. The author proposes to consider that $\frac{\Delta x}{\sqrt{x}} \propto \Delta S$. The formula then becomes, in accordance with his experiments, $2K\int\frac{dx}{\sqrt{x}} = K\sqrt{x} = S$, which he regards as a physiological instead of a psychical one.

Anthropological Institute, January 23.—Col. Lane Fox, F.R.S., president, in the chair.—A new member was announced.—Col. Fox then read his report to the Anthropometric Committee of the British Association on the Second Royal Surrey Militia. The measurements, which comprised the profession, race, origin, age, height, weight, chest measurement, colour of hair and eyes, and strength of arm, &c., of 459 individuals afforded some interesting facts concerning what might be called a fairly representative number of men from within a radius of twenty miles round Guildford. It appeared that the colour of the hair was in 391 cases brown or dark brown, and in only two cases black, and in two cases red, one of the latter being Irish. As to eyes, 311 were grey, light blue, or blue, 133 brown or dark brown. Col. Fox proposed some modifications of the existing tests of strength of arm and sight; suggesting that in the first the test should be the same as in drawing a bow, neither hand being in any way supported, and the pull being from an object not fixed. From a table of twenty comparative cases the average of strength showed in the case of pulling from a fixed point, 165·55 lbs., while the same men pulling with the one hand against the other only 81·95 lbs. From the general results Col. Fox considered that the muscular strength, vital capacity, &c., of our reserve and regular forces would show very favourably in comparison with those of the ordinary population, and so dispose of some of the frequent alarms given by the "man in the street" as to the deterioration of our forces in physique.—Mr. Street, President of the Philological Society, read a very interesting paper on the development of language, and Mr. E. B. Tylor and the President and others took part in the discussion.—Papers by Mr. Knowles, of Ballycully, Ireland, on the classification of arrow-heads, and on the "Portstewart find," were also read, and numerous objects illustrating the papers were exhibited.

Physical Society, January 20.—Prof. G. C. Foster, president, in the chair.—The following candidate was elected a member of the Society: Mr. A. G. Greenhill, M.A.—Dr. Huggins exhibited an enlarged view of a photograph, half an inch in length, of the spectrum of the star α Lyræ, which he has recently taken in a manner similar to that in which the spectrum of Sirius has already been obtained. The first results were very unsatisfactory, in consequence of the clockwork being insufficient for maintaining the image of the star on the slit for a length of time. Mr. Grubb has, however, devised a secondary control apparatus, the employment of which renders it impossible for the error to exceed one-tenth of a second. In the spectroscope employed the prism was of Iceland spar, and the lenses of quartz. Dry plates were employed, and the necessary breadth was secured by slightly changing the position of the image instead of by the use of a cylindrical lens. Dr. Huggins has also been engaged in taking a series of photographs of the moon, and hopes to obtain some information in regard to the question of a lunar atmosphere of small extent. In the spectrum of α Lyræ a line occurs corresponding with H_1 in the solar spectrum, and several more refrangible ones which he is at present unable to explain.—Mr. Lockyer considered the results which Mr. Huggins is obtaining to be of extreme importance, and he pointed out how he hopes a large series of photographs of stellar spectra will afford valuable information in regard to the constitution of certain substances now supposed to be elementary, such as calcium. Some time ago he communicated a paper to the Royal Society on the spectrum of this metal, and he considers that it is not a simple substance, but that the H lines are due to two elementary substances of which it is composed, and this supposition is confirmed by the fact that in the photographs exhibited by Dr. Huggins only one of the H lines is present, that is, only one of the constituents of the metal calcium is present in the star α Lyræ.—Mr. W. C. Roberts read a paper on the artificial production of columnar structure. He gave an account of the several theories which have hitherto been given as accounting for this phenomenon and that of cross-jointing, as observed in the Giant's Causeway, and he dwelt specially on the views of Mr. R. Mallet and Prof. James Thomson. He found as the result of experiment, that when certain masses of clay and sand are heated to about 1300° C. they contract to about the same amount as a basalt does in passing from the molten to the solid state, and that beautiful columnar forms are produced. He had hoped, by accumulating a number of specimens, to have been able to establish a relation between the strains at the point of rupture and the dimensions of the hexagons, but in the small masses employed the strains were so numerous that it was impossible to apportion their influences. He had, however, obtained a number of specimens which possessed much interest.—Mr. Lecky referred to a very fine columnar cliff in the island of Bedness, in Valencia Harbour, which he has examined in the hope of finding cross-joints, but, although some breaks exist, there are none at all comparable to those in the north of Ireland.—Prof. Guthrie showed an arrangement he has recently devised, in the hope of making the mercurial as sensitive as the water barometer. It consists of an ordinary siphon barometer in which the two vertical tubes are united by means of a long uniform horizontal tube having a diameter considerably less than that of the main tubes. The instrument is filled in the same manner as the ordinary siphon barometer, except that a bubble of air or dilute acid is left in the narrow tube. For a given rise of pressure the absolute amount of mercury which passes from the shorter to the longer tube depends upon their diameters, and as these are great in comparison with the tube uniting them, the motion of the bubble will be considerable in comparison with that of the summit of languages, very probably, as Mr. Douse suggests, through the medium of *ky*. But in spite of his arguments to the contrary, *kw* still seems to me a harder sound than simple *k*, so that even if we accept his own test of the principle of least effort, the latter sound should be derived from the former, and not the converse.[1] He confesses himself, moreover, that his theory fails to explain the equivalence of the Sanskrit *jív* and the European reduplicated root *gwi-gwi* "to live" (as in the Latin *vivere* and our *quick*), an equivalence which can only be accounted for by supposing that in this particular instance the Indian dialect has preserved the labial semi-vowel of the original root. Equally instructive is the equivalence of the Greek γαστὴρ, and the Latin *venter* (for *gwenter*), which Mr. Douse does not notice, as it shows that Greek could sporadically deal with the guttural in the same way that Indian and Lithu-Slavic habitually did. I can see no reason why these dialects should not have sibilated *k* pure, very possibly through an intermediate *ky*, at the same time that *kw* was being reduced to simple *k*. I have heard *kyind* and *conker* from the same lips. To the instance of words with primitive *ghw* given by Mr. Douse, may be added ἐλαχύς, Lat. *levis* (for *legvis*), and βραχὺς, Lat. *brevis* (for *bregvis*).

The excellence of Mr. Douse's book has led me to dwell upon the points which seem to me open to objection, and I have left myself no space to draw attention to the many striking suggestions and new points of view scattered through the volume. I cannot, however, quite pass over the note in which he maintains the existence of bivocalised roots (*aka*, *ata*, &c.), and acutely suggests that the Greek ἐμέ and ἐκεῖνος imply dissyllabic roots as much as the archaic Latin *enos* or the Sanskrit *ana*, Lat. *ille* (for *onulus*). Mr. Douse has materially helped forward the solution of the problem of Grimm's Law, and if his theory is not secure from attack in every particular, in its main outlines it will doubtless prove correct. At all events the chronological hypothesis which derives the phonetic systems of the Indo-European languages from one another can never again be upheld.

A. H. SAYCE

STEELE'S "EQUINE ANATOMY"

Outlines of Equine Anatomy. By J. H. Steele, M.R.C.V.S. (London: Longmans and Co., 1876.)

ALTHOUGH this manual is intended, as we are informed on the title-page, for the use of veterinary students in the dissecting-room, we think it quite possible that it may have a larger sphere of usefulness.

As long as the study of zoology and comparative anatomy was confined to those who had entered on the medical profession, the human frame formed an excellent standard with which every mammalian animal might be compared in all its parts. Of late, however, since biology has been introduced into general education, those who have taken to it in earnest have not been long in finding that without a pretty thorough knowledge of the details of what may be termed the typical vertebrate structure they are on all sides beset with difficulties; they make errors in nomenclature, they cannot appreciate the significance of bony processes, and are unable to generalise with safety.

Whether it is possible that the requisite amount of detail will be mastered by those who are not stimulated by the severity of rigid examinations on the way to a professional career is a question which we will not discuss upon the present occasion; nevertheless, those teachers who are anxious that their pupils should have a reliable work on the anatomy of some one of the lower animals cannot do better than recommend the one at present under notice. The ass is an animal the expense of whose carcase is not excessive. Its size is sufficient for the easy investigation of all its important parts, and its structure is normal enough to form the basis for a competent knowledge of all the essential parts of the mammalian organisation. It is superior to the dog or the cat, because both are as a rule too small for the satisfactory demonstration of many of the more delicate systems, such as the vascular and nervous, except by those who have already had considerable experience in dissecting. Another advantage is that the requirements of the veterinary colleges *have* led to the production of such works, and there are more elaborate ones, such as that of Chauveau, the translation of which by Mr. George Fleming we reviewed some time ago (NATURE, vol. viii. p. 158), to fall back upon where greater detail is called for. On the other hand, a treatise on the anatomy of the dog would with great difficulty repay any author for the time and labour required in its production.

Mr. Steele's work commences with a chapter on the methods and terms employed. The osteology of the horse is then considered in detail, each bone being fully described. This is followed by a section on arthrology, in which the nature and action of each joint is explained. The fourth part of the volume is devoted to special anatomy, which is treated in the same way as is human anatomy in dissecting manuals generally. Appended are tables of nerves and vessels. The style in which the whole subject is treated is not inferior to that adopted in the best works on anthropotomy, at the same time that the language is clear and concise. We do not quite know why fascia should be spelt "faschia" throughout.

In his account of the liver, Mr. Steele reproduces an error found in most works on the subject. This we cannot correct better than by quoting the accurate description given by Prof. Flower in his Hunterian Lectures before the College of Surgeons in 1872.[1] There we learn that "The liver is tolerably symmetrical in its general arrangement, being divided nearly equally into segments by a well-marked umbilical fissure. Each segment is again divided by lateral fissures, which do not extend quite to the posterior border of the organ. Of the central lobes thus cut off, the right is rather [decidedly] the larger, and has two fissures in its free border dividing it into lobules. . . . The two lateral lobes are subtriangular in form. The spigelian is represented by a flat surface between the portal fissure and the posterior [the vertebral] border, not distinctly marked off from the left lateral by a fissure of the ductus venosus, as this vessel is buried deep in the hepatic substance; but the caudate is distinct and tongue-shaped, its free apex reaching nearly to the border of the right lateral lobe. In most works on the anatomy of the horse (as those of Gurlt and Leisering) [to which we may add Chauveau and Steele] this has been confounded with the spigelian lobe of man."

---

[1] Mr. Rhys reminds me that in the Keltic languages at any rate *kw* (*qu*) is proved to have passed into simple *k* (*c*).

[1] *Medical Times and Gazette*, August 31, 1872, p. 219.

In conclusion, we are sure that all teachers of anatomy will agree that, in an educational point of view, Mr. Steele's volume is a most valuable addition to the literature of the subject on which he treats.

OUR BOOK SHELF

Dutch Guiana. By W. G. Palgrave. (London: Macmillan and Co., 1876.)

Canoe and Camp Life in British Guiana. By C. Barrington Brown, Assoc.R.S.M. (London: Stanford, 1876.)

THESE two works deal with a small portion of a region of considerable interest from various scientific points of view, but of which we as yet know comparatively little; indeed much of the region included under the name Guiana is a *terra incognita*, and presents a fine field for an enterprising explorer. Mr. Palgrave, whose long silence since the publication of his classical work on Arabia many have wondered at and regretted, spent only a fortnight in Dutch Guiana, and this volume testifies made a diligent use of his time. The work is more connected with the historical, social, and commercial aspects of the Dutch colony than with the strictly scientific, but contains much valuable information about a country of which even the Dutch themselves, we suspect, know little. Mr. Palgrave has gathered many facts about the colony from various quarters, and ingeniously weaves these into his pleasant narrative, so that a reader who gets to the end of the little volume will have a very fair idea of its history, present condition, and future prospects. In a graphic and popular way he describes the journeys he made up the rivers near the coast, and conveys a fair idea of the productions, the people, and the aspect of the district visited. To the ethnological reader, one of the most interesting chapters is that on the Bush Negroes. Scattered all over the colony to the number, Mr. Palgrave thinks, of about 30,000, are various tribes of independent negroes, descendants of former slaves, who rose against their Dutch masters, fought for and obtained their freedom and liberty to settle pretty much where they chose, and have lived peaceably beside their former masters ever since. These Bush Negroes are descended mostly from Africans of the same type, but are now divided into three main tribes, and several subordinate branches, with chiefs and sub-chiefs, each tribe named from the place at which its treaty of peace and freedom was signed, as Aucan, Saramaccan, and Moesinga. The interesting point is that "the grouping, once made, perpetuated, and in the course of years it has produced in each instance a distinct type, till what was at first merely nominal and accidental has become permanent and real." Mr. Palgrave's work is one of great interest from beginning to end. It contains a clear map and a plan of Parimaribo.

Mr. Brown is a much better surveyor and explorer than he is a book-maker. As Government Surveyor of British Guiana, he has visited nearly every corner of it—the tracings of his routes on the map forming a regular network of blue lines—and during his journeys has collected a vast amount of valuable information about its physical aspect, geology, fauna, flora, and people. The reports on the physical features and descriptive geology of the colony have, he says, been already published by the Treasury Commissioners, and in the present volume he professes to give only a popular narrative of his travels. But the volume is something more than this, as almost every page contains notes on the fauna and flora and geological features, as well as natives that came under his observation. All these notes are put down miscellaneously in the order of time, amid the notes of the incidents that occurred during the journeys, so that i is difficult for one interested in the natural history o the country to ferret out and classify the observations Mr. Brown would have done great service both to th general and the scientific reader, had he gathered thes notes together and arranged them in an appendix, o even if he had taken care to see that his work was pro vided with a carefully compiled index. In another edi tion we hope the latter want will be supplied, as i will certainly add much to the value of the work, which notwithstanding the defects in plan we have mentioned is an important contribution to the information w already possess about British Guiana. Mr. Brown, i may be remembered, was the discoverer of the magnifi cent Kaieteur Fall, on the river Potaro, a tributary of th Essequibo, an account of which we gave in NATUR shortly after its discovery in 1870 (vol. iii. p. 108). Th excellent map and well-executed illustrations add muc to the interest and value of Mr. Brown's work.

The Royal School of Mines' Magazine. (London Wyman and Sons, 81, Great Queen Street, Lincoln's Inn Fields, W.C.)

THIS magazine, the first number of which we have jus received, is to be issued three times a year, under th auspices of the students of the Royal School of Mine and is to be devoted to articles on travel, athletics, foo ball, and to other matters connected with the school. Th present number contains several articles, by former stu dents, on travel, an article on football, together wit a record of matches played by the Royal School Mines' Football Club, during the session 1875-76. It als contains a list of papers on mining and metallurgy; re sults of Royal School of Mines for 1875-76; a report the annual dinner of the club; besides two original poem both of which are good.

We confess we are a little disappointed that greate attention has not been paid to scientific subjects; w have no doubt, however, that this will be rectified i future, and we heartily recommend the magazine to al interested in the Royal School of Mines. J. McD. C.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expresse by his correspondents. Neither can he undertake to return or to correspond with the writers of, rejected manuscripts No notice is taken of anonymous communications.*]

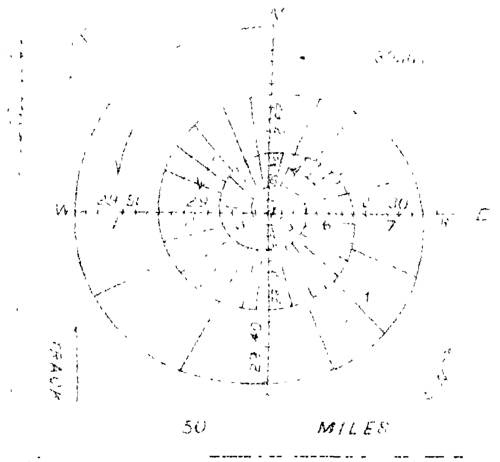
Storm Waves of Cyclones

I BEG to submit the following suggestion, to explain in general way by the accompanying diagram the view that migh be taken of the rise and great height of storm waves of cyclone at sea, such as occurred in the Bay of Bengal, and inundated an devastated extensive tracts of the coasts and islands on Octobe 31 and November 1, 1876.

It is generally observed that when the winds blow into a re-entering angle of any sea-walls or quays, that the surge of the wave rises higher in it than against the plane sea wall, and frequently it shoots up the corner in a kind of spouting form. Again, the tides in estuaries and friths, having bell-shaped mouths facing the ocean, and contracted inner ends receiving a river, rise to very extraordinary heights, as in those of the Severn and Thames, where disastrous floods have just occurred.

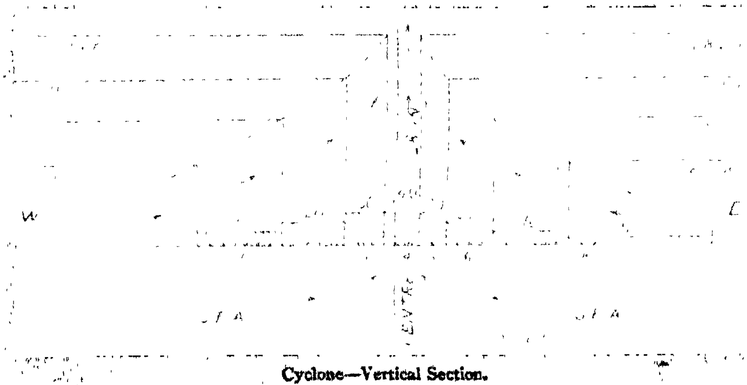
These heights are much increased when the winds blow into them, as westerly into the Severn estuary, and easterly into the Thames mouth, as during the recent gales. The ordinary rise on the south coast of England of the tides is generally only about ten feet, but at Bristol they may rise to thirty or forty feet, which, in fact, would be greater than the height of any storm-wave in a cyclone in India. Now if the course of the revolving winds in a storm mass be considered as a spiral from the outside to the inside, like a coiled watch-spring, then the section of each spiral turn may be considered as decreasing from the outside to the centre inside. This will therefore resemble a long re-entering angle or estuary tube twisted upon itself as a helix, and therefore if the water be driven in at the large end and up to the small end of the spiral, it should considerably increase in height as it went along and move with greater rapidity.

When arrived at the extremity of the spiral, it may be considered to remain there for some time and spread itself out laterally in bulk at the high level as long as the violence of the storm lasted. But when the force of the wind began to diminish, this heaped aqueous mass would more or less suddenly subside, and rush down on all sides to seek its natural level. This might occur at sea, and be evidenced by the long swell or rollers frequently seen, or might be translated by progressive motion to launch its tremendous weight on the land, and inundate it. This, it may be conjectured, could only be effected over lands about the level of the sea, over which the base of the funnel of the cyclone would advance, carrying the inclosed mass of water with it for part of the area of the revolving circle, which would so far be still able to draw its supplies from the sea on the coast yet included in its motion. As soon, however, as the southern or equatorial limb of the circle had so far progressed as to leave the sea behind it, then the friction of the earth would prevent the inclosed mass of water following the cyclone, which had been already cut off from its aqueous communication, and it would be left behind to expand over and deluge the country lying under its level.



Cyclone—Horizontal Plan.

In speculating on the dimensions of the Bengal storm-wave we may assume, from the statements in the newspapers, that it was a disc of fifty miles in diameter and twenty feet deep, when viewed as a frustrum of a cylinder, which might also represent, when in a state of gyration, a cone of the same diameter and forty feet high in the centre. The contents of this space would amount to about, in bulk, 1,094,785,668,000 cubic feet, representing a weight of 70,339,979,169,000 lbs of sea-water, which would have flooded over a perfectly level district of a disc of about 700 miles in diameter, or 39,270 square feet in area to the depth of one foot horizontally.



Cyclone—Vertical Section.

The means for counteracting the disastrous effects of the storm or cyclone-wave in the Delta of the Ganges on life and property would probably be found in the erection of *mounds*, as proposec by a writer in the *Times*. As this tract of country would b destitute of stone or rock, and be composed chiefly of mud anc sand, it would be requisite to convert this into *bricks* first, as th mud-mounds would not stand the impact of the storm-waves even in this country.

The design for the construction of these mounds would probably be most suitable after the model of the celebrated *Towe of Babel*, projected by the post-Diluvial inhabitants of Mesopotamia for a like purpose of self-preservation from inundation.

VORTEX

"Polar Cyclones"—Etna Observatory

IN reply to Mr. Clement Ley's letter in NATURE, vol. xv p. 253, I fear I cannot at all agree with him as to the cause o the polar depressions of the barometer. He says: "The 'pola cyclones' appear to be themselves aggregates of those local depressions, or cyclones, which have penetrated into the Arctic o Antarctic regions, and have there partially or wholly coalesced.' Now, let us test the question in this way:—Suppose the surfac of our planet were all land, so that there was no watery vapou in the atmosphere; there would be no cyclonic storms, for the are due to what Espy truly calls steam power;—would the pola depressions of the barometer be observed as they are in ou actual atmosphere? Mr. Clement Ley's reasoning seems t require him to say that they would not; I have no doubt tha they would. The causes which produce the west winds of th middle latitudes (Maury's "counter-trades") would act as in ou actual atmosphere, and their centrifugal force, in rotating roun the poles, would produce a space of shallow atmosphere at an around each pole, exactly like the depression at the centre of a vortex of water, which would show itself, as at present, by a depression of the barometer.

I see in NATURE of the same date that it is proposed to for a meteorological observatory on Etna. I hope the opportunit may be taken of obtaining what is one of the greatest desiderat in the present state of meteorology—I mean a set of comparativ observations of the barometer taken at two neighbouring stations, one at the sea-level, and the other at a great height. One such set, continuous or taken at short intervals, extending over a few years, and accompanied by observations of temperature an wind (the latter by self-registering anemometers), would probably give more information on the physics of barometric waves tha could be obtained by any amount of observations, all taken a the sea-level. I have urged this in NATURE before, but it is s important I hope I may do so again.

JOSEPH JOHN MURPHY

Old Forge, Dunmurry, Co. Antrim, January 20

The Boomerang

REFERRING to my letter on the "Boomerang" which you were so good as to publish in NATURE vol. xiv. p. 248, I may, perhaps, be permitted t add a few more statements on the same subject Concerning the use of the boomerang by th North Gippsland aboriginal natives, I have n more to add, but I have acquired some information in respect to its use among the blackfellow of South Australia, which may be of interest.

My informant is Mr. James, now a senior constable in the Victorian police, but formerly, an when I first became acquainted with him, managing a large cattle station at Blanchewater, on th borders of the so-called Lake Torrens Basin Mr. James has had great experience among th blacks of that district during many years bot before and after the time I first met with him during my second expedition into Central Australia.

I quote Mr. James's statements to me just as I noted them:—

"Among the blacks about Blanchewater the boomerang i made for killing game. It is principally thrown among flock of ducks, pigeons, and water-hens. It is not used often fo fighting nor for killing kangaroo. They might use it in a ro when short of weapons, and if their adversaries were not mor than twenty or thirty yards distant. The blacks did no generally like to use them except for killing small game, as they often broke, and they have told me that their boomerangs were not 'strong enough' to kill a man. For fighting they have no throwing weapons—no throwing-sticks for their spears, but throw them by the hand, and only do so in extremity, for the spear is too valuable a weapon. It is only used as a pike; and they obtain their spears by barter from some tribe to the north. In ordinary fighting they use a weapon like a boomerang from 4 to 5 feet in length. It is held in both hands and blows are struck with the convex edge. They were not warded off when I saw it used, but the blows were struck indiscriminately—a sort of free fight. These weapons are made by themselves of boxwood.

"In throwing the boomerang I have seen it usually held nearly parallel with the horizon. When thus thrown it would rise and return towards the thrower, but the blackfellows always told me that although they could ensure its returning near them they could not tell exactly where it would come to. They could tell the direction but not the distance. If the boomerang strikes anything its course ceases.

"Some years ago the blackfellows living in the mountains just south of Blanchewater had no boomerangs and no spears. Their weapons were yamsticks and stones. They had no shields. Boomerangs, spears, and shields were acquired by them from the Blanchewater blacks, in return for which they bartered Wallaby rugs; at that time the Blanchewater and Deerie blacks had absolutely no clothing.

"This system of barter is said to have been instituted by a Hill blackfellow named Pompey, who, in 1856, was concerned in the spearing of two men at Angepina. He escaped and went north to the Deerie blacks, having first stayed some time with the Blanchewater blacks, who understood both languages, being a border tribe. He took up to the Deerie blacks some flour, sugar, tobacco, and for some time settled at Kopparamanna. He endeavoured to raise a confederacy to drive the white settlers out of the Flinders Range, and is said at that time to have instituted the system of barter.

"I knew this Pompey in 1857, when he sent another blackfellow, named Blanchewater Charley, to offer his services as 'nauto shepherd.' When Pompey then came in he told me much of the above concerning himself, which was also current among the tribes. He was a very shrewd fellow, and thus became a leader among them. He was afterwards shot for killing station-blacks. The national weapons of the Blanchewater blacks are stones. These are thrown of the size of the fist, and are perhaps thrown as far as a hundred yards, and with precision for forty yards; and in throwing, a rotatory motion is imparted to the stone. At about forty to fifty yards they can hit a small mark, such as a bottle, almost without fail. In fighting at close quarters they ward off spear blows by means of a short stick held in the hand, and if possible, in cases where the spear has been thrown, clutching it in passing with the other. They do not use a shield for stopping spears, but against stones, which, as I have said, are the national weapons."

Although much of the above cannot be said to be strictly belonging to the "boomerang," I have preferred to give Mr James's statements in full as given to me.

Much that he says corroborates the statements I have made in the letter referred to.

It is much to be regretted that no one else than myself among your readers in Australia has recorded their observations on the "boomerang," in reply to your correspondent's request.

Bairnsdale, Gippsland, Victoria A. W. HOWITT

Longmynd Rocks

MR. H. B. WOODWARD, in his "Geology of England and Wales," p. 28, states that, near Shrewsbury, the Longmynd Rocks are overlaid conformably by the Lingula Flags. I should be glad to see the evidence upon which this conclusion is based. So far as I have examined the district, the facts do not sustain Mr. Woodward's view. Arenig fossils are found at the very head of the ravines which cut back nearly to the quartzite of the Stiper Stones. The beds under the quartzite are similar in lithological character to the Arenig shales above, and I have not heard of the lower shales yielding Lingula flag fossils. At the base of the escarpment is the fault which separates the Stiper Stones rocks from the Longmynd beds. I believe the Stiper Stones beds are Arenig, in the absence of proof to the contrary. The quartzose band of the Stiper Stones may represent the arenaceous bed adopted by the Geological Survey as the base of the Arenig. CHARLES CALLAWAY

Wellington, Salop, January 15

The Measurement of the Height of Clouds

IT has always been a matter of some interest to obtain measures of the height of clouds, independently of observations made from balloons or on mountains.

During last July and August I made a series of measures of cloud-altitudes—the first, I believe, of their kind—by photographing the clouds simultaneously from different stations.

The details of the process would occupy too much space to be inserted here, but I have reason to believe that the results obtained are not as much as three per cent. in error. The cirrus clouds which I measured varied in height from 22,000 to 25,000 feet; massive cumuli from 6,000 to 7,000 feet. I did not get any good examples of cirro-cumulus or stratus. Rain-clouds appeared at all altitudes up to 4,000 feet. I hope to resume the measures at some future time. ARNULPH MALLOCH

Terling Place, Witham

Mimetic Habit of Bats

IN September, 1875, whilst paddling in a dorey (dug out boat) through a narrow and dark creek leading from Belize River, Honduras, to Reid's lagoon, we disturbed a number of small bats which were clinging to the trunks and branches of the mangroves overhanging the water. These bats were about six inches in expanse and of a grey colour so exactly corresponding with that of the trees on which they settled as to be with difficulty distinguishable even at a distance of only a few feet. They invariably *clung* to the trunk or bough *with wings expanded*, and were never, so far as I noticed, suspended from the branches.

I saw the same species in Black Creek of the same river in February last year clinging to the trees in a similar manner, and conclude it is the natural position of the animal when at rest. I send this note as I do not recollect having anywhere seen this curious mimetic resemblance and peculiar habit remarked upon.

101, Grove Street, Liverpool, January 22 S. ARCHER

THE SPONTANEOUS GENERATION QUESTION[1]

THE following paper on this subject was read at the Paris Academy of Sciences on January 8[2]:—

The Academy has perhaps not forgotten that at the *séance* of July 10 last, Dr. Bastian announced the discovery by him of the physico-chemical conditions necessary and sufficient for the spontaneous generation of certain varieties of microscopic objects of the genus *Bacteria*. The experiment which, according to Dr. Bastian, realises these conditions is very simple; it consists in exactly neutralising by liquor potassæ urine deprived of every organic germ and exposing the mixture to a temperature of fifty degrees. In those conditions certain varieties of bacteria promptly appeared.

Dr. Bastian has no doubt as to the bearing of his conclusions. To all who are attentive to medical movements it is evident that the debate relative to spontaneous generation has been removed into the domain of the etiology of contagious diseases.

I immediately repeated the experiment, and I proved, among other things, that it is sufficient to determine the saturation of the urine by solid potash instead of potash in aqueous solution (which does not modify whatever be the physico-chemical conditions to which it is subjected) for the mixture to remain perfectly sterile. I hence concluded that the interpretation given by Dr. Bastian to his experiment was totally inadmissible.

Dr. Bastian replied (*Comptes Rendus*, July 31 and August 21); he did not at all dispute the legitimacy of my reasoning, but he affirmed that I reproduced his experiment badly and exceeded the exact point of neutralisation of the urine. Such is, according to him, the cause of the sterility of the liquid in my hands.

The question is then limited to the point: Have I done anything else but replace the liquor potassæ by melted potash, and specially, have I exceeded the point of saturation of the urine, and is there anything amiss in so doing?

I have examined the debate reduced to these terms, along with M. Joubert, with all the attention of which we are both of us capable, and we are able to declare to the Academy, on the basis of new experiments, that the exact neutralisation of the urine by solid potash, which we had melted, left the urine sterile. We add, although that may not be indispensable, that there is no obstacle to the fertilisation of urine, in the experiment of Dr. Bastian, in exceeding the point of saturation, even sensibly.[1]

---

[1] Continued from p. 303.

[2] Note on the Alteration of Urine in reference to Recent Communications of Dr. Bastian, by MM. Pasteur and Joubert.

The conclusion of my reply of July 17 last is then unassailable, consequently it is not accurate that Dr. Bastian has found the physico-chemical conditions for the spontaneous generation of bacteria.

We have examined experimentally, with not less attention, all the other points treated by Dr. Bastian in his papers of July 31 and August 21, subsequent to his original note of July 10. We are prepared to discuss them, but as they might distract attention from the main point of the debate we shall return to them later if convenient. One thing is of importance at the present moment, to know if Dr. Bastian is still convinced that urine, exactly neutralised by potash, yields microscopic organisms.

What we have said on the influence of solid potash may be repeated for liquor potassæ after it has been raised to 110°. But we wish to reply to-day to Dr. Bastian solely by the facts relative to solid potash, which suffice by themselves alone to condemn the conclusions which he has deduced from his experiments.

The reader will doubtless remark that in the preceding abstract we have scrupulously avoided introducing the word *germ* and opposing a doctrine to a doctrine. We have to do with a fact: Yes or no, does urine which has been boiled so as to be sterile, and better still, fresh, natural urine, just from the bladder, not having been submitted to any preliminary boiling—does this at 50° yield organisms after having been neutralised by potash? Dr. Bastian says yes, and this is his pretended great discovery. We say no, and we demonstrate by proving that Dr. Bastian would have obtained a result absolutely contrary to that which he published if he had made use of the substance KO,HO, which alone, in cases when it is pure or only associated with mineral matters in small quantity, has the exclusive right of being called potash.

The following reply to the above by Dr. Bastian was read at the Paris Academy, January 22[2]:—

At the *séance* of the Academy of January 8 M. Pasteur, in conjunction with M. Joubert, contributed another "Note sur l'Altération de l'Urine," in reply to the last communication which I had the honour of submitting to the Academy at its *séance* of August 21 of last year.

It may, perhaps, be permitted to me to state that an account of my researches on the fermentation of urine, much fuller than what has appeared in the *Comptes Rendus*, is now to be found in the *Proceedings* of the Royal Society No. 172, 1876; and to this paper I would particularly call the attention of all those who are interested in the question of the mode of origin of Bacteria and other related problems.

I have found, as stated in an earlier communication to the Academy, that previously sterile urine, when exactly neutralised by boiled liquor potassæ (of the British Pharmacopœia) will rapidly ferment and swarm with Bacteria, if the mixed fluids are maintained at a temperature of 50° C. M. Pasteur, after repeating my experiments with certain variations, said (*Compt. Rend.*, July 17, p. 178): "Je m'empresse de déclarer que les expériences de M. le Dr. Bastian sont, en effet, très-exactes; elles donnent *le plus souvent* les résultats qu'il indique." He then explains why he differs from me as regards the interpretation of these experimental results. It is somewhat confusing, therefore, to find M. Pasteur now saying in his most recent communication: "une seule chose importe en ce moment, c'est de savoir si le Dr. Bastian est toujours convaincu que l'urine neutralisée exactement *par la potasse* donne des organismes microscopiques?" My reply is simple. M. Pasteur has implied (*loc. cit.* p. 179) that solid potash heated only to 100° C. does lead to such an effect; I, however, have made no experiments with solid potash, though, in operating with the boiled liquor potassæ already named, I have many times obtained the result indicated, and am quite prepared to demonstrate to others the fact of the occurrence of fermentation in urine under these conditions.

In using solid potash M. Pasteur departed from the conditions of my experiments in a way which was wholly needless. It will be found much more convenient for others to repeat them exactly. Seeing that a strong solution of potash in suitable quantity can be easily heated in a closed glass tube to the temperature which M. Pasteur desires (110° C.), there is absolutely no reason for substituting solid potash as he has done. The *liquor potassæ* used by me has always been procured from Mr. Wm. Martindale, of 10, New Cavendish Street, London.

In his "Note" of July 17, the interpretation given by M. Pasteur of my results was that the liquor potassæ used by me immediately after it had been heated to 100° C. induced fermentation in the urine because it contained living germs not killed at this temperature of 100° C., but which would have been killed had the potash solution been heated to 110° C. M. Pasteur has strangely understood my meaning if he thinks, as he now intimates, that I have not contested the legitimacy of his reasoning. I am very far from regarding it as "irreproachable," and that for reasons which I have previously given. If, however, I have not been able to make myself understood it will be well for me to repeat the reasons on account of which I still absolutely reject M. Pasteur's interpretation. They are these:—(1) It is to me incredible that a fluid so caustic as the strong liquor potassæ which I have employed could contain living germs after it has been raised to 100° C., and it is not too much to ask that he who makes such an assertion should prove it; (2) that liquor potassæ (*when added in proper quantity to the urine*) is just as efficacious after it has been heated to 110° C. as when it has only been heated to 100°; (3) the decisive proof that liquor potassæ previously heated to 100° does not induce fermentation in sterile urine by reason of its containing living germs, is to be found in the fact that the addition of one or two drops of it only (when much more would be required for neutralisation), subsequently leaves the urine as barren as if no solution of potash had been added; whilst if the liquor potassæ really induced fermentation in the cases mentioned above (2) because of its containing living germs, then one or two drops of it would always suffice to infect any quantity of sterile urine to which they may have been added.

In his last communication to the Academy, M. Pasteur says:—"La question se trouve donc limitée à la connaissance de ce point:—Ai-je fait autre chose que de remplacer la potasse en solution par de la potasse fondue, et notablement, ai-je depassé le point de saturation de l'urine, et y a-t-il quelque inconvénient à le faire?" To these three questions I reply as follows:—(1) Yes, too much potash was also added; (2) Yes, in those experiments in which you obtained negative results, you expressly state that potash was added in quantity sufficient to render the fluid "alcaline" *Compt. Rend.* t. lxxxiii. pp. 179 and 377; (3) Yes, according to my experience, any amount of potash beyond what is sufficient to neutralise the urine in its unboiled state is decidedly prejudicial to the inducement of fermentation, and I have especially cautioned experimentalists on this subject (see *Proceedings* of Royal Society, No. 172, pp. 152 *note* †, and 155.

I would also call M. Pasteur's attention to the fact that in his last communication to the Academy, as printed in the *Compt. Rend.* for January 8, on the two occasions on which he professes to describe my experiment, he does it inaccurately. Thus, on p. 65, lines 2 and 3, and also on p. 66, in the sixth line from the termination of his note, he omits to mention the important fact that the added liquor potassæ was previously boiled.

Further discussion between M. Pasteur and myself seems to me in the present phase of the question to be almost useless. Certainly, no good can come from our alternate enunciation of opposite experimental results, when precisely the same methods have not been had recourse to. For my own part I am perfectly ready to reproduce before competent witnesses the results of which I have above spoken; or, failing this opportunity, I shall also be content patiently to await the ultimate decision of other properly informed fellow investigators, both here and on the Continent, as to the correctness of the facts which I have had the honour of announcing to the Academy.

JOHANN CHRISTIAN POGGENDORFF

SCIENCE has lost one of her most diligent and devoted servants by the death of Prof. Dr. J. C. Poggendorff, in Berlin, on January 24. He was born in Hamburg on December 29, 1796. The early deaths of both parents forced him at a comparatively tender age to engage in the rougher conflicts of life; a circumstance which, however, contributed in a great measure to the rapid development and maturity of his mental powers. At the age of sixteen he entered the establishment of a pharmaceutical chemist, and was actively engaged for eight years in this occupation. His hours of leisure were devoted to scientific study, and his aspirations gradually rose above the narrow limits in which he was confined. These longings were gratified in 1820, when he was enabled to enter the University of Berlin as a student of physics. With restless energy Poggendorff entered upon his chosen field and quickly gave evidences of more than ordinary talent. In 1821 Oken's *Isis* contained his first paper, "Physico-chemical Investigations upon the Magnetism of the Voltaic Pile." In this article he describes his discovery of the electro-magnetic multiplier or galvanometer, formed by carrying a wire several times round a magnetic needle in a vertical plane; an apparatus which with Schweigger's later improvements, is in universal use. Other articles on closely-allied subjects appeared at this period in Gilbert's *Annalen*. The abilities of the young physicist were soon recognised, and he received from the Royal Academy of Sciences at Berlin the post of "observator," which enabled him to continue his scientific investigations. The leading *savants* of the day—G. Rose, H. Rose, v. Buch, Alexander v. Humboldt, Mitscherlich, and others—gave him also a warm welcome into the circle of their friendship.

---

[1] It is not useless to say here that, contrary to what is generally admitted, urea in aqueous solution or in urine is decomposed at 100° C. and even at temperatures much lower. The product of decomposition is carbonate of ammonia.

[2] On the Fermentation of Urine; Reply to M. Pasteur. By Prof. H. C. Bastian.

In 1824 Poggendorff conceived the plan of issuing a new physico-chemical journal on a more extensive basis than any other hitherto existing in Germany. The above-mentioned investigators, as well as Berzelius, Arfredson, Bonsdorff, and other prominent foreign chemists and physicists promised a hearty co-operation in the new enterprise. Before the completion of the preparations, the death of Prof. L. W. Gilbert, of Leipzig, who for twenty-five years had issued Gilbert's *Annalen der Physik*, left that periodical without an editor. Poggendorff entered at once into negotiations with the publisher. The result was that he edited the seventy-sixth and closing volume of Gilbert's series, and then issued the first number of the *Annalen der Physik und Chemie*. This was the decisive step of Poggendorff's life. Although but four years had elapsed since the commencement of his university studies, he brought to the new undertaking a breadth of knowledge, a keenness of discrimination, and a true love and enthusiasm for his work which, united with the warm co-operation of leading investigators, gave the *Annalen* at once a prominent position among scientific periodicals. The somewhat exacting duties of the new position did not prevent the continuance of his researches. In 1827 he invented the magnetometer for the measurement of minute magnetic variations. At this time, also, papers appeared from him on the vibrations of light, on the aurora borealis, on the law of diffusion of gases, on the decomposition of chemical compounds, on the relations between the elements of ternary compounds, &c., all of which evidenced a comprehensive grasp of the varied departments of chemistry and physics In 1834 he received the degree of Ph.D. from the University of Berlin, and in 1844 the degree of M.D. from the University of Königsberg. In 1834 he was elected to the position of extraordinary professor of physics at Berlin, in which relation he continued to the time of his death. The Royal Academy of Sciences at Berlin elected him to membership in 1839, and the most important of his subsequent researches were published in the *Transactions* of the Academy. These were confined almost exclusively to galvanism and electricity, and form altogether one of the most valuable and extensive contributions which has been made to our knowledge in this department. His labours were chiefly directed to the study of electro-chemical and thermo-electric phenomena, methods of measuring the intensity of the galvanic current, the laws of galvanic polarisation, the resistance of various conducting mediums, &c., as well as the invention of numerous pieces of apparatus applicable in this branch of physics. In 1837 Prof. Poggendorff was actively engaged with Liebig in the preparation of the first volume of the well-known "Handwörterbuch der Chemie," but was unable to continue his co-operation in the succeeding volumes. A series of biographical sketches, "Lebenslinien zur Geschichte der exacten Wissenschaften," appeared from his pen in 1853, and were followed in 1863 by a compendious "Biographisch-literarisches Handwörterbuch zur Geschichte der exacten Wissenschaften." This book of about 3,000 pages includes the biographies and fragments of works and papers of the scientific men of all nations and all times, and involved an immense amount of time in the preparation.

Valuable as were the experimental results and encyclopædic labours of Prof. Poggendorff, they assume a subordinate position by the side of the great life-work on which his energies were chiefly expended. In the long series of over 160 volumes of the *Annalen der Physik und Chemie*, he has left behind him the most enduring monument to his zeal and devotion in the cause of science. His rare combination of talents, his fine critical powers, his unflagging industry, and his long period of service render his scientific editorial career strikingly similar to that of the recently-deceased founder and editor of the *Revue des deux Mondes* in the world of politics and letters. The translation of the articles of foreign investigators formed no small part of his editorial labours. The seventy-six contributions of Faraday alone occupy between two and three volumes, those of Brewster and Regnault require each over a volume. It has been calculated that about one-fifth of the total number of volumes of the *Annalen* would be occupied alone with the editor's translations. The original plan of making the *Annalen* a complete record of all advances made in both chemistry and physics gradually became impossible, as the opportunities and incitements for original research increased. With the appearance of the various chemical serials in Germany, the department of chemistry became less and less prominent, until the *Annalen* has assumed an almost purely physical character.

Ever watchful to detect and recognise merit in fellow-labourers, he stood upon peculiarly intimate and friendly relations with a large proportion of his extensive staff of contributors. Their feelings of love and respect found opportunity for expression three years ago, when many of them gathered to celebrate the fiftieth anniversary of the foundation of the journal. The occasion was very fitly observed by the presentation to the aged editor of a jubilee volume of the *Annalen*, compiled under the direction of the contributors, and containing special articles from a number of leading physicists. The hope then expressed that it might be followed by many more volumes under his editorship was not destined to be fulfilled. He had reached his eighty-first year with unimpaired possession of mental and physical powers, when death suddenly removed him from his sphere of earnest, useful activity, after a brief and painless illness. A large assembly of men famous in literature and science, gathered at the burial ceremonies, to pay the last tribute to the memory of their departed friend. It is not alone in science that Poggendorff will be missed. His kindly, genial, appreciative disposition endeared him in the hearts of men from all classes of society; and the generous hospitality of his home will not easily be forgotten by those who have learned to know him in the midst of the family circle.

T. H. N.

THE NEW STAR IN CYGNUS

THE following three letters are published in *the Astronomische Nachichten*, Nos. 2115, 2116:—

On December 3 I received the news of the discovery of the new star in Cygnus, but the unfavourable weather did not allow me to search for it till the 5th, The star on that day, when the sky cleared up for a few hours, was of magnitude, 4-5; it appears then to have decreased considerably in brightness, for Schmidt estimated the star on November 24, at magnitude 3. The colour of the star is not remarkable—yellowish-red; the spectrum is one of the most interesting that I know. It is the coloured band crossed by numerous (from eight to ten) dark bands, and besides there are several bright lines visible.

I have prepared an accurate drawing of the spectrum, which exactly agrees with a drawing made shortly before by Dr. Lohse. At the very first sight the spectrum of the new star appeared to me entirely different from those of the reddest stars, and a later accurate comparison with the drawing has enabled me to discover no satisfactory connection either with the so frequently met with band spectrum III.*a*, or with the rare class III.*b* (Secchi's type, III. and IV. respectively). Of the bright lines there was one specially conspicuous in the farthest red, as also one on the boundary of the green and blue, and two lines in the blue. In the yellow and green appeared some very bright stripes (? bands), which I, however, cannot consider proper bright lines (of which the specimen of glowing gas consists), but of which I believe there are places in the spectrum, which, by contrast with the neighbouring dark absorption bands, stand out conspicuously. In the case of the very marked band spectra of Class III.*a*, one has very often, and especially with a disturbed sky, the impression that there are bright lines in the spectrum, while with favourable atmospheric conditions, it is clearly perceived that regions of the spectrum deficient in lines in the neighbourhood of dark bands produce that impression.

The observations were made by means of a small spectroscope formerly described by me. With a larger Browning instrument some measurements were later attempted, and one of the bright lines undoubtedly recognised as the second hydrogen line F. The lines in the blue gave the wave-lengths 474 and 470 mill. m.m. Bright places in the spectrum (very possibly bright lines) were further observed with 512 and 498 mill. m.m. wave-lengths. We did not manage to measure the red lines.

In further characterising the spectrum, I might state that the blue and violet, in comparison with other stars which showed a band spectrum, was very well seen, and that, at all events, in consequence of the proportionally small general absorption which this part of the spectrum undergoes, the colour of the star differs little from the mean star colour.

On December 8 I succeeded in confirming and completing the observations herewith sent. I estimated the star at magnitude 5—perhaps it was even less. By means of the small spectroscope several measurements were obtained of bright lines and stripes (? bands) of the spectrum; especially was it possible to observe very accurately the position of the red lines, and to identify them with the red hydrogen line C. The following further measurements were made :—

Wave-lengths.	
587-589	Bright lines.
469-470	Bright stripes, very possibly bright lines.
526-528 (E)	
513-514	
507-509	
497-499	
485-486 (F)	Bright line.

The state of the atmosphere was bad, and very often the observations were interrupted by clouds for a long time. The double numbers for the wave-length should indicate the limits within which the particular line lies according to the measurements. It is hereby evident that besides the hydrogen lines C and F the line D_3 (wave-length 487-5) appears bright in the spectrum of the star. The magnesium line (6) I have not been able to see bright, but I have repeatedly measured a bright stripe, somewhat more broken than 6, which very possibly is identical with a bright line which, under special circumstances, stands out as the brightest line in the spectrum of the hydrocarbons. A line appeared to me to shine out temporarily in the violet, apparently the third hydrogen line in the neighbourhood of G.

I hope to be able, ere the star becomes too weak for spectroscopic research, to obtain some more accurate measurements in the positions of the bright lines.

I may in conclusion add the remark that in the constellation Cygnus there are three stars,[1] whose spectra are without parallel; we have therefore, in a tolerably circumscribed space of the sky, including Schmidt's new star, four objects which give a spectrum entirely differing from the many hundred stars examined hitherto.

H. VOGEL

Since the receipt of the first account of Dr. Schmidt's Nova the weather here has generally been of the most unfavourable character, and it was not until January 2 that the new star could be examined with the 15-inch refractor of this observatory. On the evening of that day the Nova was of about the seventh magnitude and of a decided red colour. The spectrum, as shown in a spectroscope of Dr. Vogel's construction, was of surprising brilliancy, and consisted of a faint continuous spectrum interrupted by five bright lines. The positions of these lines determined in parts of the scale of the instrument, and afterwards reduced to wave-lengths by comparing the spectra of moonlight and various elements are as follows :—

No.		Mill. m.m.	
1	W. L.	655	Intense bright red.
2		581	Middle of a rather bright band in the yellow, fading off rapidly on both sides.
3		504	Bright, well-defined line.
4		486	,, ,, ,,
5		456	Faint line in the violet.

It is remarkable that four of these wave-lengths agree closely with those of bright lines previously observed. Nos. 1 and 4 are obviously the C and F lines of the hydrogen spectrum. No. 3 coincides almost exactly with the brightest line of gaseous nebulæ, and lastly, No. 2 corresponds very nearly with one of the bright lines in the spectra of the three remarkable stars in the Swan, pointed out by Messrs. Wolf and Rayet, and subsequently observed by Dr. Vogel (see *Berichte d. Königl. Sächs. Ges. der Wiss. Math. Phys. Cl.*, 1873, p. 556 ff.). As yet it has been impossible to confirm the above results, but considering the great interest of the subject I venture to lay this imperfect account before the readers of the *Astronomische Nachrichten*.

RALPH COPELAND

Lord Lindsay's Observatory, Dunecht, January 8

Yesterday night I observed the star of M. Schmidt; it was about the seventh or eighth magnitude, of a colour tending to greenish, but yellower than on the preceding day. The spectrum is formed of two strong lines, of which one corresponds to hydrogen and the other to magnesium. The sodium was still more marked and bright. There was besides another line in the violet, probably also hydrogen. The red of this gas is very weak and does not bear measurement. Besides these four very beautiful lines there were a number of small lines between D and the magnesium, but the space where are the two bright lines of magnesium and the F and the H is almost devoid of light. After these two bright lines towards the violet there is a dark gap, and then follows a group of very fine lines. So that the description given by M. Cornu is correct; only the bright lines are not bordered by nebulosity, but are as perfectly defined as the bright lines of nebulæ.

Rome, January 9 P. A. SECCHI

---

[1] B.D. No. 4001, 40013 + 35°; 3956 + 36°; by Wolf and Rayet discovered, by me accurately examined. Communicated to the *K. Sächs. Gesellsch. der Wiss.*, December 12, 1873.

From flowers so simple as those of *G. lutea*, which openly offer their honey to all flying insects, but, in spite of their extraordinary conspicuousness, are incapable of securing cross-fertilisation by the various visitors, the genus Gentiana advances to such species as exclude from the honey the majority of the less industrious visitors, and at the same time compel the most industrious of the larger Apidæ, chiefly the humble-bees, to effect cross-fertilisation, whenever they fly from flower to flower. By what modifications of structure this improvement has been effected, may at once be seen in Fig. 96, which represents a flower of *Gentiana punctata*, longitudinally bisected from above to near the base. The petals, in *G. lutea*, nearly completely separated, are here united, and form an obliquely upright bell, wide enough to inclose the whole body of any humble-bee. The pistil, just as in *G. lutea*, stands exactly in the centre of the flower, and is terminated by two reflexed branches of the stigma, but the filaments, diverging in *G. lutea*, here incline together, so that the anthers, developing some time after the stigma, and dehiscing extrorsely, closely surround the pistil somewhat beneath the stigma. The honey being secreted, as in *G. lutea*, by an annular swelling at the base of the pistil (*n*, Fig. 97), every humble-bee is induced to creep towards the base of the bell-shaped corolla, and, when doing so, first touches the stigma and dusts it with pollen of previously-visited flowers, thus effecting cross-fertilisation; then with the same portion of its hairy body it touches the anthers and charges itself with fresh pollen. The exclusion of the majority of useless visitors from the honey is effected by the base of the corolla being constricted, and the base of the filaments united with it (as far as *ch*, Fig. 96); the narrow interstice between the ovary and the corolla being thus divided by the filaments into as many narrow channels as there are petals and filaments (in *G. punctata* commonly seven, in *G. acaulis*, *excisa*, and others five). By these narrow channels humble-bees may easily pass their proboscides as far as the honey, whereas saw-flies, flies, and most beetles are unable to reach the honey.

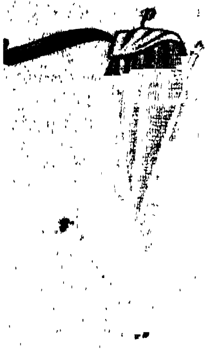


FIG. 100.

FIG. 101.

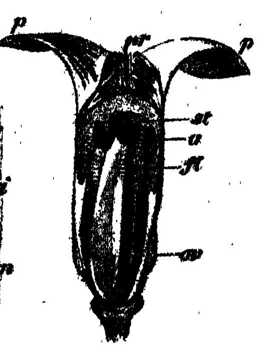

FIG. 102.

Thus the variety of visitors has been greatly diminished; but the humble-bees, for which alone the honey is reserved, are hence induced to make more eager and frequent visits; and, as by these visits not fortuitously, as in *G. lutea*, but regularly pollen is brought from one flower to the stigma of another, cross-fertilisation in the species of this group is far more certain than in *G. lutea*; and the possibility of self-fertilisation, indeed, seems to have been lost.

Of twenty-six species of Gentiana inhabiting Germany and Switzerland, eleven belong to the present group, which must almost necessarily be cross-fertilised by humble-bees; namely, besides the three above-mentioned species inhabiting the plain and lower mountain region, the following eight Alpine ones: *G. punctata*, *purpurea*, *pannonica*, *asclepiadea*, *Frœlichii*, *frigida*, *acaulis*, and *excisa*. But hitherto only three of these eleven species have been actually observed to be visited and cross-fertilised by humble-bees, namely, *G. acaulis*, by Ricca ("Atti della Soc. Ital. di Sc. Nat.," xiv. 3, 1871), *G. pneumonanthe* (H. Müller, "Befruchtung," p. 333), and *G. excisa*,[1] by myself.

3. *Alpine Species of Gentiana, adapted at the same time to Apidæ and to Lepidoptera.*—Whilst in the foregoing group Diptera and other useless visitors are prevented from gaining the honey by the base of the corolla being constricted and by the filaments dividing the interstice between the corolla and the ovary into narrow channels, in the present group (*G. tenella*, Fig. 98-102; *G. nana*, Fig. 103-105) the same effect has been attained by the entrance to the tubular corolla being barred by hairs (*pr* Fig. 98, 99, 102-105), between which only four or five small openings (*o*, Figs. 99, 103) are to be seen. The corolla, in the previous group wide enough to inclose the whole body of a humble-bee, is here so narrow that any proboscis attempting to reach the honey will graze the stigma and the anthers, and, when passing from flower to flower, will effect cross-fertilisation. But only Apidæ will be enabled to thrust their proboscides between the protecting hairs, and only Lepidoptera have proboscides slender enough to penetrate the small openings. Thus, in these flowers the visits of Lepidoptera are useful for the cross-fertilisation of the plant, while in the foregoing group they are useless.

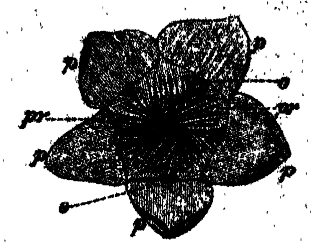

FIG. 103.

FIGS. 103-105.—*Gentiana nana*, Wulf.—FIG. 103.—Flower seen from above (7 : 1). FIG. 104.—The same flower bisected longitudinally. FIG. 105.—A piece of the corolla, with petals, protecting hairs, stamens, and nectaries (7 : 1).

Most probably the present group is not descended from the foregoing; besides the narrowness of the corolla and the protecting hairs, the position of the nectaries is so peculiar to this group, that it is rather to be considered

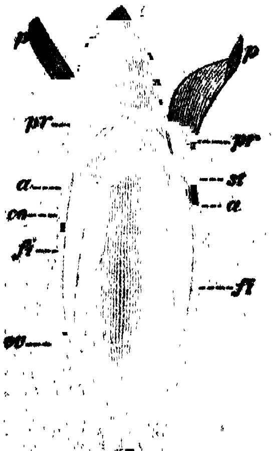

FIG. 104.

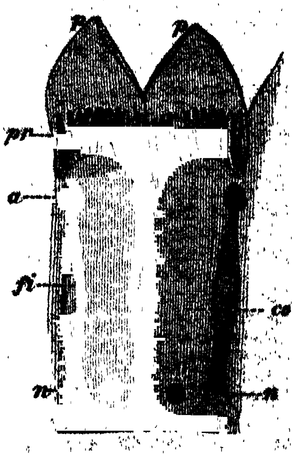

FIG. 105.

---

[1] I found, in the Alps, *G. excisa* visited and cross-fertilised by *Bombus lapponicus*, F., and *B. mendax*, Gerst. Once, in the Albula Pass, July 28, 1876, I saw a moth, *Plusia hochenwarthi*, creeping into a flower and sucking its honey, but without touching stigma or anthers. Also some small Diptera and three specimens of a small beetle, *[illegible]*, Redt., can only be registered as useless guests.

as a separate branch, diverging from the common stem of the genus Gentiana, even before *G. lutea*. For whilst in all other species of Gentiana the honey is secreted by an annular swelling of the base of the pistil, in this group the nectaries are situated at the base of the corolla itself, between the filaments (*n*, Figs. 101, 105). As hitherto *G. tenella* and *G. nana* have been distinguished only by somewhat fluctuating characteristics, it may be of especial interest that in *G. tenella* I have found each interstice between two filaments to contain two nectaries (*n*, Fig. 101), in *G. nana* only a single one (*n*, Fig. 105).

To the same group belong *G. campestris*, *germanica*, *amarella*, and *obtusifolia*, two of which have been directly observed by myself to be visited both by Lepidoptera and butterflies. For instance, near Pontresina and in the Val del Fain, August 6-8, 1876, I saw *G. campestris* repeatedly visited by *Bombus mendax*, Gerst. ☿, but also by butterflies (*Argynnis pales*, *Hesperia serratulæ*, *Colias phicomone*, *Lycæna argus*).

The fourth group of Alpine species of Gentiana exclusively adapted to cross-fertilisation by Lepidoptera, will be treated of in my next article.

(*To be continued.*)

DEEP SEA MUDS[1]

DURING the present session I propose to lay before the Society several papers on subjects connected with the deposits which were found at the bottom of the oceans and seas visited by H.M.S. *Challenger* in the years 1872, 1873, 1874, 1875, and 1876.

Instruments in use for obtaining information of the deposits.

It will be convenient to introduce this first communication with a brief description of the instruments and methods employed on board H.M.S. *Challenger* with the view of obtaining information and specimens of these ocean deposits. The instrument in most frequent use was the tube or cylinder forming part of the sounding apparatus.

During the first six months of the cruise this cylinder was one having less than an inch bore, and was so arranged with respect to the weights or sinkers that it projected about six inches beneath them. The lower end of the cylinder was fitted with a common butterfly valve. This arrangement gave us a very small sample of the bottom.

In July, 1873, this small cylinder was replaced by one having a two-inch bore, and it was also made to project fully eighteen inches below the weights. This was a great improvement, as it gave a much greater quantity of the bottom in most soundings.

The tube was, in the clays, frequently forced nearly two feet into the bottom. On its return to the ship, the butterfly valves were removed, and a roll of the clay or mud, sometimes eighteen inches in length, could be forced from it. In this way we learned that the deeper layers were very frequently different from those occupying the surface.

In the organic oozes—as the Globigerina, Pteropod, Radiolarian, and Diatom oozes—the tube did not usually penetrate the bottom over six or seven inches, these deposits offering more resistance than the clays and muds. Occasionally the tube came up without anything in it, but the outside was marked with streaks of the black oxide of manganese. In about thirteen out of nearly four hundred soundings we did not get any information of a reliable nature about the deposit.

The dredge in use was a heavy modification of Ball's naturalist's dredge, and the trawl was the ordinary beam trawl of the fishermen.

Both of these instruments had generally a bag of canvas or other coarse cloth sewed into the bottom of the netting, to prevent the soft clay or ooze from being entirely washed out. In this way we, at many stations, got, along with animals, a large quantity of ooze, clay, stones, or manganese nodules.

While trawling or dredging the ship often shifted her position a mile or two, but we could not tell whether the dredge or trawl had been working over all that distance, or had merely taken a dip into the deposits. This should be remembered when comparing the captures in one locality with those of another.

Altogether there is much uncertainty about the behaviour of the trawl and dredge in deep water. It occasionally happened that when the greatest care was taken, and when it was believed that the trawl had been dragging for some hours, it came up without anything in it, or any evidence upon it or in the attached tow-nets to show that it had been on the bottom.

During the last year of the cruise a tow-net was attached to the dredging line just below the weights, which last were placed a few hundred fathoms in front of the trawl or dredge. Tow-nets were also attached to the trawl and dredge. These nets frequently came up nearly full of mud, and almost always contained minute things and fragments from the surface layers of the bottom.

At times the water-bottle attached to the sounding line came up with clay or ooze in it, or had some of the deposit adhering to its under-surface.

These then were the means and methods employed for getting information concerning ocean deposits, and collectively they have furnished us with a large amount of material. A careful examination of the specimens procured has already much increased our knowledge of the nature and distribution of ocean deposits, of the sources of the materials of which they are built up, and of the chemical processes taking place in the deep waters and on the floor of the ocean.

The Volcanic débris in Ocean Deposits and some of the Products of its Disintegration and Decomposition.

In a preliminary report to Prof. Wyville Thomson, which has been published in the *Proceedings* of the Royal Society of London, I pointed out the wide-spread distribution of volcanic *débris* in ocean deposits, and its probable influence in the formation of deep sea clays, and manganese nodules or depositions. In this paper I propose to treat of these subjects in more detail, and to give some of the results of observations which have been made since the above report was written.

Pumice-Stones.

The form of volcanic *débris* most frequently met with in ocean deposits is pumice stone.

Specimens of these stones, varying from the size of a pea to that of a foot-ball, have been taken in dredging at eighty of our stations. I have placed the position of these stations on a map, from which it will be seen that they occur all along our route.

Near volcanic centres the dredge has frequently brought them up in great numbers, as off the Azores in the Atlantic, off New Zealand and the Kermadec Islands, at several places among the Philippine Islands, off the coast of Japan, and elsewhere. As a rule, they are not numerous in shore deposits when these are distant from volcanic regions. In deposits far from land they are most abundant in deep sea clays, from which the shells and skeletons of surface organisms have been all or nearly all removed.

In the North Pacific the trawl brought up bushels of them from depths of 2,300 and 2,900 fathoms. Perhaps in no single instance have we trawled successfully on any of our deep sea clays without getting numbers of these stones. If there be an exception it is in the North Atlantic. But here it is to be remembered that while we were investigating the conditions of the North Atlantic, our attention had not yet been directed to the importance of detecting the presence of pumice, and we have not preserved such large samples of the North Atlantic deposits as those of other regions.

On the whole, pumice-stones are more numerous in the Pacific than in the Atlantic deposits.

In the Globigerina and other organic oozes, they are abundant or otherwise, according as the deposit is near or far removed from volcanoes. In these oozes they never occur so abundantly as in the clays. They are more or less masked and covered up by the accumulated remains of foraminifera, diatoms, or other surface organisms. In like manner they are obscured in shore deposits by river and coast detritus. Besides those specimens, which are sufficiently large to be examined by the hand, we detected with the microscope minute particles of feldspar in all our ocean deposits.

An inspection of the specimens which I have placed on the table will show that the majority of these pumice stones have a rolled appearance. Some of them have undergone much decomposition, while others are little altered. Some are coated with the peroxide of manganese, or have streaks of this substance running through them. They are the most frequent nucleus of the manganese nodules, to which I shall presently refer. Some specimens which were dredged from a depth of over three miles, will, when dried, float for weeks in a basin of water; others, which have undergone partial decomposition, sink at once.

---

[1] "On the Distribution of Volcanic Débris over the Floor of the Ocean: its Character, Source, and some of the Products of its Disintegration and Decomposition," by Mr. John Murray. Read at the Royal Society, Edinburgh.

They present a great variety of texture and composition. They are white, grey, green, or black in colour. They are highly vesicular, or rather compact and fibrous. There would appear to be every gradation from common feldspathic to dark green pyroxenic kinds.

We find in them crystals of sanidin, augite, hornblende, olivine, quartz, lucite, magnetite, and titaniferous iron. Magnetic iron ore was found in all the specimens examined, either in crystals or in the form of dust. The other minerals vary in kind and abundance in the different specimens. The same crystals which we find in the pumice occur in all the kinds of ocean deposits.

Sources of the Pumice-Stones.

The pumice-stones which we find at the bottom of the sea have most likely all been formed in the air. Some of them may have fallen upon the sea; but the great majority seem to have fallen on land, and been subsequently washed and floated out to sea by rains and rivers. After floating about for a longer or shorter time they have become water-logged and have sunk to the bottom. Both in the North Atlantic and Pacific small pieces of pumice were several times taken on the surface of the ocean by means of the tow-net. Over the surface of some of these serpulæ and algæ were growing, and crystals of sanidin projected, or were imbedded in the feldspar. During our visit to Ascension there was a very heavy fall of rain, such as had not been experienced by the inhabitants for many years. For several days after many pieces of scoriæ, cinders, and the like were noticed floating about on the surface of the sea near the island. Such fragments may be transported to great distances by currents.

On the shores of Bermuda, where the rock is composed of blown calcareous sand, we picked up fragments of travelled volcanic rocks. The same observation was made by General Nelson at the Bahamas. Mr. Darwin noticed pieces of pumice on the shore of Patagonia, and Prof. L. Agassiz and his companions noticed them on the reefs of Brazil. During a recent eruption in Iceland, the ferry of a river is said to have been blocked for several days by the large quantity of pumice floating down the river and out to sea. All the pumice which we find need not be of quite recent origin. Mr. Bates informs me that great quantities of pumice are continually being floated down the Amazon. These come from near the foot of the Andes, where the head-waters cut their way through fields of pumice-stones. In the province of Wellington, New Zealand, two of the rivers run through areas covered with pumice, and during floods bear great quantities out to sea.

Prof. Alex. Agassiz has kindly furnished me with the following note:—

"The river Chile, which flows through Arequipa, Peru, has cut its way for some thirty miles through the extensive deposits of volcanic ashes which form the base of the extinct volcano, Misti. Some of the gorges are even 500 feet in depth, forming regular cañons. The whole length of the river bottom is covered by well-rolled pieces of pumice from the size of a walnut to that of a man's head. In the dry season (winter) there is but little water flowing, but in the summer, or rainy season, the river, which has a very considerable fall (7,000 feet in a distance of about ninety miles), drives down annually a large mass of these rolled pumice-stones to the Pacific. The volcanic ashes are not recent. There is no tradition among the Indians of any eruption within historic times."

Capt. Evans, the present hydrographer to the navy, informs me that he frequently picked up pumice on the Great Barrier Reef of Australia.

Volcanic Ashes.

Near volcanic centres, and sometimes at great distances from land, we find much volcanic matter in a very fine state of division at the bottom of the sea. This consists of minute particles of feldspar, hornblende, augite, olivine, magnetite, and other volcanic minerals. In the South Pacific, many hundred miles from land, and from a depth of 2,300 fathoms, the trawl brought up a number of pieces of tufa entirely composed of these comminuted fragments. These particles appear to me to have been carried to the areas, where we find them, by winds, in the form of what is known as volcanic dust or ashes. Sir Rawson Rawson sent to Sir Wyville Thomson a packet of the volcanic ashes which fell on the island of Barbadoes, after an eruption in 1812 on the island of St. Vincent, W.I., one hundred and sixty miles distant. I have examined this, and find it made up of fragments of the same character as those in the tufa to which I have just referred, some of the particles being perhaps a little larger. We have sometimes found this ash in considerable abundance mixed up with the shells in a globigerina ooze. In the deposits for hundreds of miles about the Sandwich Islands there are many fragments of pyroxenic lava, which I believe have been borne by the winds, either as ashes, or in the form of Pele's hair.

At Honolulu we were informed that threads of Pele's hair were picked up in the gardens there after an eruption of Kilauea, one hundred and eighty miles from the volcano. This Pele's hair bears along with it small crystals of olivine.

Obsidian and Lava Fragments.

Small pieces of obsidian and of feldspathic and basaltic lavas were frequently found in deposits near volcanic islands.

At two stations in the South Pacific, many hundred miles from land, we dredged pieces of this nature of considerable size larger than ordinary marbles. It is difficult to account for the transference of these fragments to the places where they were found. It is, however, in this region, and this alone, that it may be necessary to bring in a submarine eruption to account for the condition of things at the bottom.

A consideration of these observations, and the specimens which are laid on the table, will, I think, justify the conclusion that volcanic materials, either in the form of pumice-stones, ashes, or other fragments, are universally distributed in ocean deposits.

They have been found abundantly or otherwise in our dredgings, according as these have been near or far from volcanoes, or as there has been much or little river and coast detritus, or few or many remains of surface organisms in the deposits.

Some of the Products of the Decomposition of Volcanic Débris.

Clay.—Pure clay, as is well known, is a product of the decomposition of feldspar, and the clay which we find in ocean deposits appears to have had a similar origin.

In the deposits far from land the greater part of the clay originates, I believe, from the decomposition of the feldspar of fragmental volcanic material, which we have seen to be so universally distributed.

Pumice-stone is largely made up of feldspar, and from its areolar structure is peculiarly liable to decomposition. Being permeated by sea-water holding carbonic acid in solution, a part of the silica and the alkalies are carried away, water is taken up, and a hydrated silicate of alumina or clay results.

Like most clays our ocean clays contain many impurities, these last being as varied as the sources whence the materials of the deposits are derived.

Let us briefly enumerate the sources of these materials.

We have (1) the matters derived from the wear of coasts, and those brought to the sea by rivers, either in a state of suspension or solution. The material in suspension appears to be almost entirely deposited within two hundred miles of the land.

Where great rivers enter the sea, and where we have strong currents, as in the North Atlantic, some of the fine detritus may be carried to a greater distance, but its amount can never be very large. In oceans affected with floating ice we have land *débris* carried to a greater distance than above stated; for instance, we can detect such materials in the deposits of the North Atlantic as far south as the 40th paral'el N., and in the South Pacific as far north as the 40th parallel S.

Some of the substances in solution, as carbonate of lime and silica, are extracted by animals and plants to form their shells and skeletons; these last, falling to the bottom, form a globigerina, a pteropod, a radiolarian, or a diatom ooze. We have also the bones of mammals and fish mixed up in different kinds of deposits. These, as well as animal and vegetable tissues, generally are a source of phosphates, fluorides, some oxides of iron, and possibly of other inorganic material.

Sir Wyville Thomson, early in the cruise, suggested that much of the inorganic material in deposits is derived from the source to which I have just alluded. Our subsequent observations have, I think, shown that originally Sir Wyville gave too much importance to this as a source of the materials in our deep deposits.

2. We have the dust of deserts, which is carried great distances by the winds, and which, falling upon the ocean, sinks to the bottom and adds to the depositions taking place. In the trade-wind regions of the North Atlantic we have a very red-coloured clay, in deep water, which is largely made up of dust from the Sahara. Such dust frequently falls in this region as what is called blood-rain.

3. We have the loose volcanic materials, which have been shown to be universally distributed as floating pumice, or as ashes carried by the wind.

This short review shows that the clay in shore deposits is chiefly derived from river and coast detritus. As we pass beyond about one hundred and fifty miles from the shores of a continent the character of the clayey matter changes. It loses its usual blue colour, and becomes reddish or brown, and particles of mica and rounded pieces of quartz give place to pumice, crystals of sanidin, augite, olivine, &c. All this goes, I think, to show that in deposits far from land the clay is chiefly derived from volcanic *débris*, though in the region of the North Atlantic trade-winds much of it may be derived from the feldspar in the dust of the Sahara.

The pumice which floats about on the surface of the sea must be continually weathering, and the clay which results and the crystals which it contains will fall to the bottom, mingling with the deposit which is in course of formation. In our purest globigerina ooze this clay and these crystals are present. If a few of the shells, say thirty foraminifera, are taken from such a deposit, and carefully washed, and then dissolved away with weak acid, a residue remains, which is red-brown or grey in colour, according to the region from which the ooze came. If the same number of shells be collected from the surface and dissolved away in the same manner, no perceptible residue is observed. The clayey matter would therefore seem to have infiltrated into the shells soon after they fell to the bottom.

I have already mentioned several instances of pumice-stones having been found on coral-reefs. Many more instances could be given. These stones, undergoing disintegration in these positions, add clay, crystals of augite, hornblende, magnetic iron ore, &c., to the limestones which the coral animals are building up.

I have found these crystals in the limestones and red earth of Bermuda, and in a specimen of the limestone from Jamaica.

This observation, it appears to me, points out that the red earth of Bermuda, Bahamas, Jamaica, and some other limestones, may originally have been largely derived from fragmental volcanic materials, which were carried to the limestone while yet in the course of formation. There are also small particles of the peroxide of manganese in the red earth of Bermuda.

(*To be continued.*)

CHEMISTRY AND TELEGRAPHY[1]

DISCLAIMING at the outset any pretensions which could be advanced in his behalf for the honour conferred upon him, Prof. Abel assumed that his advancement to the position of president was intended more as a recognition of the special importance of chemical science in its application to telegraphy. Proceeding upon this assumption he made chemical science the basis of his address, and went on to show the principal directions in which it bears importantly upon the work of the telegraph engineer.

No stronger evidence of the value attaching to a combination of chemical with electrical research need be sought for than that which is to be found in the labours of the late Dr. Matthiessen. His investigations into the causes of the differences in the resistance of various kinds of commercial copper were followed by most important results.

The series of experiments so carefully conducted by him showed the influence which the principal metalloids and metals known to be naturally associated with copper exerted upon the conducting power of the pure metal, and he afterwards determined the conducting power of important varieties of commercial copper, and thus rendered it possible to assign to their real causes the enormous differences in the value of various kinds of commercial copper as conductors of electricity. For instance, amongst the many facts established by Matthiessen's experiments was the important one that by no combination of any other metal or alloy was it possible to increase the conducting power of pure copper, but that, on the contrary, a most prejudicial effect was exerted upon it by the presence of some of the non-metallic elements—notably oxygen and arsenic—which are almost invariably to be found as impurities in the copper of commerce. It was these non-metallic impurities he found rather than the presence of any of the other metals which chiefly impaired the conductivity of copper, although both iron and tin exercised a deleterious influence. Thus, fixing the conductivity of pure galvano-plastic copper at 100, the addition of merely traces of arsenic reduced it to 60; while an addition of 5 per cent. brought it as low as 6·5; the existence, again, of 1·3 per cent. of tin in pure copper reduced its conductivity to 50·4, and with only 0·48 per cent. of iron present the conductivity fell to 36.

Specially interesting were the experiments made by Matthiessen to ascertain the cause of the good effects which had long before his day been observed to be produced upon the working qualities of refined copper by the addition of minute quantities of lead. The existence of 0·25 per cent. of lead in copper renders it so rotten that it cannot be drawn into wire; the presence of even so minute a trace as 0·1 per cent. unfits it for wire-drawing. Some special action must therefore take place during the melting of copper which would serve to account for the toughening and softening effects obtained by the addition of a small quantity of lead. The fact that the copper when subjected afterwards to a most careful analysis shows nothing but the merest traces of lead, would indicate that during the process of melting, the lead combines with and removes from the copper some impurity which would otherwise materially affect its toughness and ductility. The well-known affinity of lead for oxygen, combined with the fact that the presence of oxygen in copper beyond some narrow limit was known to affect its quality prejudicially, afforded good reasons for supposing that this impurity could be nothing else than oxygen, and this view, which was further supported by the beneficial influence of lead when employed in casting operations with copper and gun metal, received the strongest confirmation of its correctness from Matthiessen's experiments. Thus, the addition of 0·1 per cent. of lead to a sample of copper (the two being fused together in a current of carbonic acid), raised its conductivity from 87·25 to 93, and the amount of lead remaining in the metal after that was too minute to be detected. So with tin, the alloying of 1·3 per cent. of which with copper reduced, as has been already stated, its conductivity to 50·4; yet on melting the sample fused in contact with air with 0·1 per cent. of tin raised its conductivity to 94·55.

It was these investigations of Matthiessen which indicated to the wire manufacturer whence he could obtain or how best fulfil the conditions for the purity of a quality of copper, which would meet the requirements of a conductor whose size might be laid down by the telegraph engineer, whilst his researches into the preparation of alloys brought the most valuable aid to the B.A. Committee of 1861, in their determination of the standards of electrical resistance.

But it is not only in facilitating the selection of suitable materials for *conductors*, as well as in raising their quality as such that chemical science has brought important aid to the telegraph engineer; it has been most usefully applied in the investigation and determination of the materials most suitable as the *dielectrics* of telegraph cables, and it is in this direction that telegraphy may look in the future for the most valuable results from the labours of the chemist. Dr. Miller's investigations (instituted at the desire of the Submarine Telegraph Committee) into the causes of the decay of gutta-percha and india-rubber, confirmed the results which Hoffman had already communicated in 1860 to the Chemical Society and which Mr. Spiller had obtained some years afterwards. But Miller examines more in detail than either of his predecessors has done, into the changes which these gums undergo, and firmly established the fact that the alterations in their structure, resulting in the gradual destruction of their insulating powers, was due entirely to atmospheric influence, accelerated by the exposure of the material to light. He further pointed out that intermittent exposure to moisture, especially if solar light has access, rapidly destroys gutta-percha, whilst if kept continually immersed in water it remains unchanged for an indefinite period. He also showed that commercial gutta-percha contained, previous to any special exposure to oxidising influences, as much as 15 per cent. of resinous matter and a considerable amount of water (2·5 per cent.) mechanically diffused through it. Considerable improvements had doubtless been made since that date in the mechanical processes for preparing gutta-percha, but these do not appear to have been attended with similar improvements in the quality of the material as indicated by its chemical composition, for the highest quality of sheet gutta-percha which Prof. Abel himself had been able to find contained 12·7 per cent. of resinous matter and 5 per cent. of water. Much greater pains are no doubt taken to consolidate the material and express the water from the gutta-percha coatings of wire than in the manufacture of sheet gutta-percha. Nevertheless, that a considerable amount of inclosed water still remains is evidenced by the fact that in two samples of covered wire, submitted by the same manufacturers as lately as September and November last, the one contained 1·86 per cent., and the latter 3·97 per cent. of water. Little doubt now remains that the processes of "mastication" (to which gutta-percha is subjected for the removal of certain impurities and the production of a mechanically homogeneous material) favours oxidation, so that the destruction of some of the most valuable qualities of gutta-percha as an insulator depend upon the degree of completeness to which the mechanical impurities have been removed. An examination of *old* gutta-percha seems to show that, provided the material has been reduced to a compact condition, oxidation due to exposure to the air and light proceeds but slowly.

---

[1] Abstract of Address at the opening meeting of the Society of Telegraph Engineers, January 24, by the President, Prof. Abel, F.R.S.

Dr. Miller also points out that mastication promoted the oxidation of *india-rubber*, and further experience has established the similarity of the two gums in this respect. The application of vulcanising to india-rubber was hailed as a most important step in submarine telegraphy; but although many chemists have made this same process of vulcanising a subject for study and investigation, it remains imperfectly understood even to the present day. The wire manufacturer had no difficulty in meeting the most important objection urged against the application of the vulcanising process (viz., the injury done to the conductor by the chemical action of the sulphur in the dielectric upon it) by availing himself of the fact that tin would not be equally affected, and so protecting the copper by the simple process of tinning. Still the tendency to an alteration, either in the chemical or mechanical structure of vulcanised india-rubber, exhibited by it when kept submerged in water, has developed serious elements of uncertainty in cables prepared by the vulcanising processes. Prof. Abel then proceeded to give some interesting illustrations drawn from his own personal experience of the uncertainty of our existing knowledge regarding the chemical and other conditions to be fulfilled in the application of vulcanising processes to the preparation of telegraph cables.

A number of half-mile lengths, for instance, of vulcanised telegraph cable—some for field service, others for firing broadsides on board ship—were found, after a period varying from eighteen months to three years, to have undergone considerable deterioration; the dielectric in some instances had become so porous that even the variations in the hygroscopic condition of the atmosphere on board ship, where the wires were placed between decks, caused decided differences in the results obtained with a particular battery power; and this alteration was not distributed uniformly over a length, the porosity in some instances extending along a few feet only, the adjacent portions being in very good condition; an inspection of a large quantity of the same sort of cable which had remained untouched in store showed precisely similar results.

The uncertainty attaching to this is still further illustrated by the fact that in armoured cables with multiple cores of this description some of the cores remain comparatively good, whilst the insulation of others had fallen off to a very great extent.

Scarcely less conflicting is the experience gained with cables prepared according to Hooper's system. This system consists in maintaining the inner portion of the india-rubber surrounding the conductor in an unvulcanised condition by means of a "separator," which contains a preparation of a metal possessing the power of arresting the passage of the sulphur beyond it during and subsequent to the application of the vulcanising process.

The deterioration due to the alteration of the india-rubber being caused by oxidation, the question naturally arises as to how the oxygen finds access to it? It must evidently find access to the interior of the dielectric *through the substance of the cable*—a view which is more than confirmed by the researches of Graham. That eminent chemist showed that solid india-rubber absorbed oxygen to an extent which showed the gas to be twice as soluble in it as in water at the ordinary temperature, and the comparatively greater priority of vulcanised india-rubber would [illegible] this absorption. The oxidation of unvulcanised indi[illegible] being once established, the tendency to the absorption of oxygen by the external vulcanised india-rubber, and to its passage through the latter, must be promoted by the increased tendency to chemical change of and continual assimilation of oxygen by the inner portion, which thus acts like the vacuum by which Graham caused air very rich in oxygen to filter through a stout vulcanised india-rubber tube.

The efforts made from time to time to improve the insulation of cables, served until lately to clear the ground for future experiments, but of late important success seems to have been achieved in a direction where different experimenters (including Prof. Abel himself) had failed—that direction is towards paraffin, "a substance which during the last thirty years had passed from the obscure position of a chemical curiosity to the foremost rank amongst important chemical products." In 1875 Mr. Field, F.R.S., working in conjunction with Mr. Talling, the mineralogist, produced by means of a solvent, or by masticating the substances together, a black ozokerit-product with india-rubber, which appeared quite free from the brittleness which Matthiessen, who also had been at work here, failed to get rid of. This preparation in point of insulation and inductive capacity compares very favourably with india-rubber and gutta-percha, and would seem likely to prove very valuable for telegraphic purposes in the future.

Prof. Abel could only allude to the importance of chemical science in the proper management of batteries, a subject which, after the valuable paper read before the Society by Mr. Sivewright, "On Batteries and their Employment in Telegraphy," and the instructive discussions which it elicited, needed only to be named. Amongst other matters of importance where the telegraph engineer might derive great benefit from the fruits of applied chemistry, were the decay and preservation of telegraph poles, the preservation of fibrous materials used in constructing submarine cables, the production of points and the protection of cables against the deposition of vegetable or animal growth.

Prof. Abel then concluded his address by a final illustration of the manner in which the practical electrician may unexpectedly be brought face to face with problems which can be solved by a knowledge of chemistry and by that alone. Lieut.-Col. Stotherd, R.E., having pointed out certain defects in the permanency and difficulties connected with the testing of Abel's "phosphide" fuse, he (Prof. Abel) constructed another form of high tension fuse specially designed for submarine mining. The poles of this new fuse were 0·05 of an inch apart, in an insulating column consisting of Portland cement with sufficient sulphur to allow of its being melted and cast in a mould. Fuses manufactured in this way were supplied to different military stations, and after a time it was found that the average resistance of the fuses being 15,000 ohms, that of many of them had fallen as low as 300 or 400 ohms, and one or two had gone down even below 50 ohms. The cause of this at first sight inexplicable change in the stability of the fuse was traced by Mr. E. O. Brown to the existence in many of the cement pillars of very minute hair-line cracks or fissures extending sometimes right across the space between the inclosed small copper wires. The sulphur in the cement and the copper wire in presence of the air which had penetrated with the ever-concomitant moisture had set up a galvanic action which had formed one or more complete bridges, thereby short-circuiting the copper poles. Chemical knowledge, which unravelled this mystery at once, provided the remedy; platinum, upon which sulphur and air were powerless, replaced the copper, and the permanence of the fuse was secured.

A hearty vote of thanks to Prof. Abel was carried by acclamation, and it was decided that the address should be printed and circulated amongst the members.

SCHOLARSHIPS AND EXHIBITIONS FOR NATURAL SCIENCE AT CAMBRIDGE, 1877

THE following is a list of the Scholarships and Exhibitions for proficiency in Natural Science to be offered at the several Colleges and for Non-Collegiate Students in Cambridge during the present year:—

Trinity College.—One or more Foundation Scholarships of 100*l.*, and one Exhibition of 50*l.* The examination for these will commence in the first week of April.

St. John's College.—One of the value of 50*l.* per annum. There is a separate examination in Natural Science at the time of the annual College examination at the end of the academical year, in May; and Exhibitions and Foundation Scholarships ranging in value up to 100*l.* will be awarded to students who show an amount of knowledge equivalent to that which in Classics or Mathematics usually gains an Exhibition or Scholarship n the College.

King's College.—On Wednesday, April 4, 1877, and following days an Exhibition in Natural Science will be offered for competition. The Exhibition is worth about 90*l.* a year, and is enable for three years, but not with any other Exhibition or Scholarship of the College.

Christ's College.—One or more in value from 30*l.* to 70*l.*, according to the number and merits of the candidates, tenable or three-and-a-half years, and for three years longer by those who reside during that period at the College.

Gonville and Caius College.—One of the value of 60*l.* per annum. The examination begins on the last Tuesday in the Lent erm. College examinations are held annually in the Easter erm for Medical and Natural Science Students who have passed he University previous examination, in Anatomy, Physiology, Physics, Chemistry, &c., at which prizes and Scholarships of the value of from 60*l.* to 20*l.* are awarded to members of the College of the first, second, and third year, on precisely the same conditions as those for other branches of learning. Examinations are also held, as vacancies occur, in Botany and Comparative Anatomy in its most general sense (including Zootomy and Comparative Physiology), for two Shuttleworth Scholarships, each of the value of 60*l.* per annum, and tenable for hree years. The successful candidates for the Tancred Medical Studentships are required to enter at this College; these studentships are five in number, and the annual value of each is 100*l.* nformation respecting these may be obtained from B. J. L. Frere, Esq., 28, Lincoln's Inn Fields, London.

Clare College.—One of the value of 60*l.* per annum, tenable or two years at least. The examination will be held on March 20.

Downing College.—One or more of the value of 60*l.* per annum. The examination will be on or about April 9.

Sidney College.—One of the value of 60*l.* The examination will be on March 20.

Emmanuel College.—One Foundation Scholarship of 70*l.*, enable till the holder is of standing for the degree of B.A., and our Minor Scholarships (two of 70*l.*, and two of 50*l.*), tenable or two years, will be awarded. The examination will take lace on March 20.

Non-Collegiate Students.—An Exhibition each year is given by he Clothworkers' Company, value 50*l.* per annum, tenable for hree years. Examination about Christmas, open to Non-Collegiate Students who have commenced residence in the October erm, and to any who have not commenced residence. Information to be obtained from the Rev. R. B. Somerset, Cambridge.

The subjects, it may be stated generally, are Chemistry, Physics, Geology and Mineralogy, Botany, Comparative Anatomy and Zoology, and Physiology; but for detailed information pplication must be made to the tutors of the respective Colleges.

Although several subjects for examination are in each instance iven, this is rather to afford the option of one or more to the andidates, than to induce them to present a superficial knowledge of several. Indeed, it is expressly stated by some of the Colleges that good clear knowledge of one or two subjects will e more esteemed than a general knowledge of several. In ome instances, as at Caius College, each candidate is required o furnish beforehand a list of the subjects in which he desires o be examined.

There is no restriction on the ground of religious denominaons in the case of these or any of the Scholarships or Exhibiions in the Colleges or in the University.

s 15 p of the Colleges do not restrict themselves to the number larships here mentioned, but will give additional Scholarships if candidates of superior merits present themselves; and ther Colleges than those here mentioned, though they do not ffer Scholarships, are in the habit of rewarding deserving udents of Natural Science.

It may be added that Trinity College will give a Fellowship r Natural Science, once, at least, in three years, and that such Fellowship will be given in the present year. The examinaon will take place at the end of September, and will be open o all Bachelors of Arts, Law, and Medicine of the University, f not more than three years' standing from their first degree. pplication should be made to the Rev. Coutts Trotter, Tutor of rinity. Most of the Colleges are understood to be willing to ward Fellowships for merit in Natural Science equivalent to at for which they are in the habit of giving them for Classics d Mathematics.

OUR ASTRONOMICAL COLUMN

THE COMET OF 1812.—In view of the approaching return of the comet discovered by Pons on July 20, 1812, which beyond doubt, at the time of its visibility, was moving in an elliptic orbit with a period of about seventy years, it is not without interest to inquire into the particular circumstances of its track in the heavens, and distance from the earth and sun, under different assumptions, with regard to the time of the next perihelion passage. The case is a very different one to that of Halley's comet (which has a period only five or six years longer than that of the comet in question) at its last appearance in 1835, or even at the previous one in 1759. The semi-axis major of Halley's comet was already known with considerable precision, from this body having been observed at several returns to perihelion since the year 1456, and in 1835 an exceedingly close prediction of the date of the comet's arrival at its least distance from the sun was made, it is true, after most laborious calculation. Pons' comet of 1812 is not thus situated. So far, no previous appearance has been recognised, and we are, therefore, dependent entirely upon the observations made in 1812 for the determination of the length of the revolution, and hence of the epoch of its next return. Within what limits these observations admit of the period being assigned, has not perhaps as yet been fully examined, but it appears probable they will be wider than in the case of another comet of similar length of revolution, that discovered by Olbers on March 6, 1815, the perturbations of which were calculated for the present revolution by Bessel, who fixes the return to February, 1887, though the prediction may be materially in error.

From the great inclination of the orbit of Pons' comet to the plane of the earth's annual path, it is perhaps possible that with a fairly accurate prediction of its position, it might be detected with very powerful telescopes, no matter at what time of the year the perihelion passage falls, but such prediction being impracticable, it is desirable, as we have already remarked, to trace out the apparent path of the comet amongst the stars, on different hypotheses as to date of arrival at perihelion. At present we shall confine our remarks to the more favourable conditions under which it is possible for the comet to appear.

The nearest approach of the comet's orbit to that of the earth (0·185) occurs near the passage of the descending node, about 9¾ days before the arrival at perihelion, and the longitude of the descending node being in 73° 56′ for 1880, we may assume the perihelion passage to take place on December 15·0. In this case the comet would have the following track:—

		R.A.		N.P.D.		Distance from earth.
		°		°		
Nov.	5	223·8	...	32·9	...	0·787
,,	15	228·4	...	38·3	...	0·551
,,	25	236·3	...	52·7	...	0·316
Dec.	5	252·5	...	110·1	...	0·185
,,	15	283·0	...	157·0	...	0·356
,,	25	311·4	...	164·8	...	0·629

If the perihelion passage be taken eight days later, when the earth and comet would have about the same heliocentric longitude, with the latter body in perihelion, we shall have:—

		R.A.		N.P.D.		Distance from earth.
		°		°		
Oct.	24	231·3	...	29·6	...	1·181
Nov.	13	241·8	...	34·7	...	0·760
,,	23	251·4	...	40·1	...	0·529
Dec.	3	267·8	...	56·4	...	0·308
,,	13	293·9	...	110·7	...	0·223
,,	23	320·9	...	146·2	...	0·396
Jan.	2	336·9	...	155·8	...	0·656

Under such conditions it appears very improbable that the comet could escape observation. At its discovery in 1812 it was a diffused telescopic nebulosity, but towards the end of August it became visible to the unaided eye, and about the time of nearest approach to the earth in the middle of September it exhibited a tail 2¼° in length, according to Baron de Zach; at this period, though near perihelion, its distance from the earth was 1·26. We may conclude that should the comet arrive at its least distance from the sun about the close of the year, its recovery will be almost certain.

In a future note we shall examine the conditions attending perihelion passage at other seasons.

The appearance immediately preceding that of 1812 probably occurred about the year 1742. The calculated comet of that year had very different elements, and the same remark applies to the two comets of 1743. Struyck mentions a second comet in 1742, recorded in the journals of several Dutch navigators. On the morning of April 14, the ship being (at noon) in latitude 35° 36′ S., and longitude 42° E., the comet was in the E. ¼ S.E., with a tail 30° in length; the time is not given. From this rough indication it may perhaps be inferred that its place was somewhere amongst the stars of Pisces, or bordering ones in Aries; in too small a right ascension to admit of its identity with the comet of 1812. And as already stated, an examination of earlier cometary records is not attended with more success.

During the actual revolution there may be very sensible perturbations due to the attraction of the planet Uranus.

THE ZODIACAL LIGHT.—This phenomenon was conspicuous in the neighbourhood of London on the evening of the 4th inst. At 6h. 35m. the light was very much stronger than that of the Via Lactea in the brightest part above the horizon, and totally different in colour, being a pale yellow in the more elevated portion, with a ruddy tinge nearer the horizon. It was not distinctly traceable much beyond ζ Piscium; the axis of the light passed through about R.A. 352°, N.P.D. 100°.

BIOLOGICAL NOTES

AMOUNT OF WATER IN TREES.—Farmers and gardeners have often observed, and the fact is referred to by Lindley, that during cold weather the branches of certain trees are sometimes so much bent down as to obstruct passage below the tree, but that with the advent of mild weather they return to their former positions. In investigating these phenomena, Prof. Geleznow observed that they depend not only upon temperature, but also upon the humidity of the air; and he undertook, therefore, a series of researches to ascertain the amount of water contained in different parts of the branches under various atmospheric conditions. The first part of these researches (not yet published) proved (1) that the amount of water increases in each branch from its base to its summit; (2) that the bark of the larch throughout the year contains more water than the wood; and (3) that in Coniferæ the upper part, *i.e.*, the part above the pith of a horizontal branch, contains always more water than the lower part, whilst in other trees, as, for instance, the birch, the conditions are reversed; altogether, that Coniferæ and Dicotyledones seem to possess opposite properties, as regards the distribution of water in the tree. Further researches, published now in full (*Bull. Ac. de St. Pétersb.*, vol. xxii., No. 3), introduced new elements into the inquiry, namely, the varying amount of water in the bark and the wood. It appears from these researches that humidity of the wood and dryness of bark have a constant relation; that in certain trees (fir and maple) the wood remains throughout the year drier than the bark, while in others (birch and aspen) this is the case only during a part of the year, the conditions being reversed at other times. The relations between the humidity of the bark and that of the wood are so constant, that a useful classification could be based on them. It appears, further, that the smallest amount of water contained by the branches of certain trees, as, for instance, the fir, is observed during the season when the vegetation is in fullest vigour, and that this circumstance, as well as some other important facts, is in close relation with the development of leaves. Altogether the researches, which are yet far from being completed, promise to disclose, and probably explain, a variety of very interesting facts.

THE EEL.—In the last session of the Rhenish and Westphalian Natural History Society, O. Melsheimer reported the results of observations on the habits of the eel, conducted through a series of years. The statement that the eel subsists on vegetable nourishment, probably originating from Albertus Magnus, is shown to be utterly false. Examinations of the contents of the stomach of numerous individuals show that the food of the eel is exclusively animal. It seems to be especially fond of the river lamprey (*Petromyzon fluviatilis*). The periodical movements—down stream in August and September, and up stream in April—are brought in connection with the spawning, which takes place in the sea. The bluish-black and the yellowish-green varieties are perfectly alike in their habits.

HONEYDEW IN PLANTS.—Prof. Dr. H. Hoffmann, of Giessen, has recently published the results of his observations on the formation of honeydew upon the leaves of plants, and has come to the conclusion that it is not to be attributed to the *Aphis*, or other insects. A healthy specimen of *Camellia japonica*, 1½ feet in height, without blossoms, which afforded an instance of the phenomenon, was found to be entirely free from insects. The so-called honeydew consisted of a sticky colourless liquid, which possessed a sweetish taste, and contained, principally, gum. This gradually appeared on the surface of the leaves, slowly forming drops on the under-side, which dropped down to be continually replaced. The separation of the liquid continued vigorously for some time, even after the removal of the leaves from the plant. Although showing that the appearance of the dew is not attributable to insects, Prof. Hoffmann was unable to ascertain the real method of formation. On the upper side he was able to trace the origin of spots of a clear slightly sweet liquid on the leaves of an ivy, to the presence of *Coccus sp.* This insect, as well as *Coccus abietis* and *pini*, seems to possess the power of forcibly ejecting, *per anum*, a sweetish secretion, which causes them to be sought after by bees.

RELATION OF BODY-CHANGE TO TEMPERATURE.—From exact experiments on frogs (measuring the consumption of oxygen and production of carbonic acid at different temperatures), M. Schulz arrives at the conclusion that the exchange of materials in these animals is directly dependent on the temperature (Pflüger's *Archiv*). It is specially notable, in M. Schulz's tables, that at 1° body-temperature the frog exhales so little carbonic acid that it was hardly certain whether it produced any (the amount was 0·0084 gr. per kilo. and hour). At 33° to 35°, on the other hand, the frog shows an exchange of material which comes up to that of man, and at 37° it would probably exceed this considerably, if the organism of the cold-blooded animal permitted of so rapid a replacement as the strong consumption would require. The upper limit of temperature for the frog is therefore somewhere about 35° C.

NOTES

THE city of Brunswick is making preparations to celebrate the 100th birthday of Carl Friedrich Gauss, the mathematician and astronomer, who was born there April 30, 1777. A statue is to be erected to Gauss, and it is hoped that the foundation stone will be laid on the celebration day. Contributions are requested by the Committee to be sent to the Brunswick Bank.

FROM a circular recently issued by the general committee intrusted with the duty of collecting subscriptions for the erection of a statue to Liebig, it appears that the sum total contributed up to January 1, 1877, amounts to over 7,000*l*., after the deduction of necessary expenses Russia contributed over one-half of the receipts acknowledged in this third and last report. Since the decision to provide Giessen as well as Munich with a statue, the authorities of the former place have selected a fitting locality for the memorial, and laid it out in a tasteful manner.

WE greatly regret to hear of the death of Capt. J. E. Davis, in his sixty-first year. Capt. Davis had only recently retired from the Hydrographical Department, to which he had rendered important services. He was also well known as an authority on polar matters, having himself seen service in the Antarctic regions. Capt. Davis had much to do in connection with the fitting out of the *Challenger* Expedition, and had himself made important contributions to hydrography.

LETTERS from Athens report the death of Prof. J. Papadakis, the Rector of the University, after a long period of suffering. He occupied the chair of mathematics and astronomy during a long series of years, and was a leading spirit not only in scientific circles, but also in the general society of Athens.

THE question of the erection of a great polytechnic school in Berlin is to be brought before the German Parliament. The estimated cost is eleven million marks.

THE philosophical faculty of Zürich University has conferred the degree of Doctor in Philosophy on a lady.

IN our notice last week of "Two *Challenger* Books," it was inadvertently implied that Lord George Campbell's "Log Letters from the *Challenger*," did not contain a map. That work has a map and an excellent one, taken, in fact, from the *Proceedings* of the Royal Society. Not only does it show the course of the ship, but the depths and dates of the various soundings, and by means of different colours, the varied deposits found on the ocean bed. The map adds greatly to the scientific value of the work.

M. BECQUEREL will take for the subject ot his lectures at the Paris Museum, Light and its Effects. The course of lectures will begin after Easter, and include the subject of the radiometer. Neither of the two Becquerels, for M. Leon Becquerel is his father's assistant, has ever given his opinion on the radiometer, and their joint verdict is expected with not a little curiosity.

NINE Lectures on the Osteology of Birds will be delivered in the theatre of the Royal College of Surgeons, on Mondays, Wednesdays, and Fridays, at 4 P.M., commencing on Friday, February 16, 1877, by Prof. W. K. Parker, F.R.S.

A NEW mercury rheostat, which Jacobi devised shortly before his death, is described by M. Chwolson (*Bull. Ac. de St. Pétersb.*, vol. xxii. p. 409), and its advantages and disadvantages are thoroughly discussed and illustrated by the results of some measurements. Owing to the very great precision of the new instrument, it appears to be especially useful for the measurement of very small resistances. The author concludes that this rheostat leaves far behind all former ones, and that the instrument itself, or at least its principles, will probably play an important part in future galvanometric researches.

THE Smith's prizes, Cambridge, have been adjudged as follows:—First prize, Donald MacAlister, B.A., St. John's College; second prize divided between Richard Charles Rowe, B.A., of Trinity, and James Parker Smith, B.A., of Trinity. Mr. MacAlister was senior wrangler, and Mr. Rowe and Mr. J. P. Smith third and fourth wranglers in this year's tripos.

AT a meeting of the Council of the Yorkshire College of Science, held February 2, it was resolved, "That the question of an extension of the curriculum in the direction of literature is now ripe for action on the part of the College," and a committee was appointed to confer with a delegation from the University Extension Committee, in order that a scheme might be brought before the Board of Governors. This is a step in the right direction.

THE United States Government have awarded Capt. Allen 800 dollars, and Capts. Adams, Soutar, and Walker, 300 dollars, for their kindness to the crew of the Arctic ship *Polaris*.

THE *Journal* of the Anthropological Institute will in future appear on the 1st of February, May, August, and November.

THERE will be an examination at King's College, Cambridge, on April 4 and following days, for an exhibition in natural science. The exhibition is worth about 90*l*. a year, tenable for three years, but not with any other exhibition or any scholarship of the college. Candidates must be under twenty years of age, unless already members of the college. The examination will be in physics, chemistry, and either comparative anatomy or botany, in addition to elementary classical and mathematical papers. Candidates must give a fortnight's notice of their intention to compete, sending in to the tutor certificates of character, and naming the particular subjects in which they wish to be examined.

THE following College Lectures in the Natural Sciences will be given at Cambridge during Lent Term:—Gonville and Caius College: "On the Physiology of Digestion, Absorption, and Sanguification," by Dr. Bradbury; "On Non-metallic Elements," by Mr. Apjohn. Christ's College: "On Vegetable Histology," by Mr. Vines. St. John's College: "On Chemistry," by Mr. Main; instruction in Practical Chemistry will also be given; "On Physical Geology," by Mr. Bonney; "On Palæontology," by Mr. Bonney; in the course of the term some demonstrations in Microscopic Lithology will be given; elementary course in Geology postponed to next term. Trinity College: "On Electricity," by Mr. Trotter; "Elementary Physics," by Mr. Trotter; "An Elementary Course of Practical Morphology," by Mr. Balfour; "Practical Physiology and Histology," by the Trinity Prælector in Physiology (Dr. Michael Foster), at the New Museums. Sidney Sussex College: "On Vegetable Histology and Physiology," by Mr. Hicks. Downing College: "On Chemistry," by Mr. Lewis; "On Comparative Anatomy and Physiology," by Mr. Saunders.

THE Bessemer Medal of the Iron and Steel Institute has been awarded to Dr. Percy, F.R.S.

THE King of Greece has conferred upon Mr. Edward Stanford the knighthood of the Royal Order of the Saviour for the services rendered by him to geographical science.

A BILL has been proposed to the U.S. Congress for the equipment of several Arctic expeditions.

THE sad news has been received from the African West Coast, that Baron Barth committed suicide, under an attack of fever, at Loanda, on December 7, 1876, and Dr. Mohr died at Malange on November 26, 1876, where he had only recently arrived. Baron Barth was making a botanical and geological survey of Portuguese Africa on account of the Portuguese government. Dr. Mohr will be known to our readers as the author of an interesting narrative of his journey to the Victoria Falls of the Zambesi; he was sent out by the German African Society to carry on the work of exploration from the Portuguese colony from which so many German explorers have had to return.

A FRENCH expedition under MM. Brazza and Marche is exploring the Ogowe, a large stream to the north of the Congo. News has been received by the Geographical Society of Paris from these explorers, said to be important, and will be made public at the next sitting.

THE recent discussion of the budget in the Belgian House of Representatives brought out some interesting information as to the state of primary instruction in the country. The general yearly expenses of the State for educational purposes being, in the average of many years, about 480,000*l.* (6 per cent. of the whole of the budget), from two-fifths to one-half of this sum was devoted to primary instruction. The ordinary allotments of the State for this subject were, during the years 1872 to 1876, from 188,000*l.* to 244,000*l.*; but the part taken by the communes in primary instruction is very limited. When compared for instance, with Germany, the share of these expenses which falls on the State, is as much as about 38 per cent. of the whole of the expenses of the country. The number of normal schools for primary instruction was thirty-nine, for a population of 5,250,000 souls, *i.e.*, one normal school for every 141,970 inhabitants. But the instruction, and yet more the inspection, remain still mostly in the hands of the Catholic clergy, and the general results of the efforts made by the State, though showing some improvement during the last ten years, are by no means satisfactory. Steps are being taken to introduce the teaching of natural science into primary schools. Thus, M. Couvreur ably advocated in the House the foundation of a central and some local pedagogical museums, on the plan of that of St. Petersburg, which museums would be permanent exhibitions of recent improvements made in Europe and America in the elementary teaching of natural science; he also recommended institutions where the value of the various methods and apparatus could be submitted to experiment and discussion. Such a museum is to be opened before long by the city of Brussels. The Ministry also recommends to teachers to give to their scholars some elementary notions in natural science, applied to agriculture.

THE first number of Petermann's *Mittheilungen* for 1877 contains several papers of much value. There is the first instalment of a paper on the ethnology of Russia, in which this question is gone into with the usual thoroughness, accuracy, and detail of this journal; it is accompanied by a carefully-constructed map, embracing the whole of Russia in Europe and Asia, as well as some of the neighbouring territories. Dr. Loesche describes the results of a journey by himself and Dr. Falkenstein, in 1875, up the Killoo or Kuilu river, in Loango; he gives some important notes on the natural history of the district. E. Tessier gives a *résumé* of M. J. Dupuis' travels in South China, and Dr. A. Mühry discusses the geographical conditions of some European storms. In a short paper we are informed that Clemens Denhardt has been making preparations for some time for an exploring expedition into Central Africa, the particular region which he intends to occupy being that bounded by the Indian Ocean, the east and south of the Abyssinian Mountains, the Nile and its tributaries, the great lakes, Kilimanjaro and the River Dana—a region still almost entirely unknown. A feature of great interest and the highest importance has been commenced in this number, viz., a monthly summary of geographical work in the various regions of the globe, by Dr. Behm. The first instalment embraces the last three months of 1876, and its regular continuance will make the *Mittheilungen* almost all that could be desired as a geographical journal.

M. FOUQUÉ has been appointed professor to the College of France, in room of the late M. Charles St. Claire-Deville, whose pupil and assistant he was.

AT the next meeting of the Society of Telegraph Engineers, to be held on the evening of Wednesday the 14th inst., Mr. W. H. Preece will read a paper on "Shunts and their Applications to Electrometric and Telegraphic Purposes."

WE have received the first number of a new monthly popula Norwegian scientific journal named after our own, *Naturen* The editor is Hans H. Reusch, and among the list of contributors is the well-known name of Prof. Sars.

PROF. DE BARY, of Strassburg, has declined the offer of th Botanical Chair in Tübingen rendered vacant by the death o Prof. Hofmeister.

DR. HENRY MUIRHEAD, of Cambuslang, has offered to th University of Glasgow the sum of 2,100*l.* as an endowment for a Demonstrator of Physiology in connection with the Chair of the Institutes of Medicine. The object of the endowment is the promotion of medical science by the training of young men o suitable capacity to become teachers and investigators of physiology, and as this training is best attained by actual work in th laboratory and by practical experience in the art of teaching, th demonstrator will be regarded as a teaching assistant to the professor, while he will also be encouraged to pursue independen original investigation, and will be aided by the use of all the laboratory appliances.

THE third edition of "L'Homme Fossile en Europe," b the late H. Le Hon, being out of print, a fourth edition, jus appeared in Brussels, will be the more welcomed as it contains besides a short biography of the author, numerous additions b M. Ed. Dupont, referring to the recent discoveries in this department, and bringing this most valuable work to the presen level of our knowledge as to the origin of man.

WE are glad to see that a second edition of Dr. Fran Clowes's "Elementary Treatise on Practical Chemistry" (J. an A. Churchill) has been published, with some useful additions We noticed the first edition in vol. xi. p. 107.

IN the *South Australian Register*, of November 28, 1876, is a interesting lecture by the Rev. S. J. Whitmee, on the Ethnology and Philology of Polynesia. He contends that over all Polynesia there are two distinct types of people, a brown rac connected with the Malays, and a black, or negro race, connected with the Papuans. There is also a third and very much mixed race, to which Mr. Whitmee could not venture to give a name or assign an origin.

WE have received a separate reprint from the *Philosophica Magazine*, of Capt. Abney's paper "On the Alkaline Development of the Photographic Image."

PROF. DIETERICI, of Berlin, sought to show in a public lecture, delivered a few days since, that the theories of Darwin wer by no means novel, having been essentially published by learne Arabs in the tenth century.

WE have received several numbers of the *Bulletin* of th Torrey Botanical Club of New York, containing interestin papers which relate chiefly to botanical subjects of local interest.

THE additions to the Zoological Society's Gardens during th past week include a Pig-tailed Monkey (*Macacus nemestrinus* from Java, presented by Dr. Broadbent; a Brazilian Tree Porcupine (*Cercolabes prehensilis*) from Trinidad, presented by Mr Eliot S. Currey; three Amherst Pheasants (*Thaumalea amherstiæ*) from China, presented by Dr. A. P. Reid; a Yellow-fronted Amazon (*Chrysotis ochrocephala*) from U. S. Columbia, presented by Mr. F. A. B. Geneste; three Rhomb-marke Snakes (*Psammophylax rhombeatus*) from South Africa, presente by the Rev. P. H. R. Fisk; an Ocelot (*Felis pardalis*) from South America, three Andrean Geese (*Bernicla melanoptera*) from Peru, purchased; two Double-striped Thicknees (*Œdicnemus bistriatus*) from Central America, purchased.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, January 25.—"Description of the Living and Extinct Races of Gigantic Land Tortoises, Parts iii. and iv. The Races of the Aldabra Group and Mascarene Islands" (conclusion), by Dr. Albert Günther, F.R.S.

In continuation of, and concluding, the researches into the history of the Gigantic Land-Tortoises, read before the Royal Society on June 20, 1874, and published in the 165th volume of the "Philosophical Transactions," the author treats n Parts iii. and iv. of the Tortoises of the Aldabra Group and Mascarenes.

By the addition of the valuable materials obtained by one of the naturalists of the Transit of Venus Expedition to Rodriguez, and by the Hon. Edward Newton in Mauritius, as well as by the aid of supplementary information received from other sources, the author has been enabled to show in the present parts of his paper that the round-headed division of Tortoises is confined to Aldabra and never extended to the Mascarenes proper; and that the Tortoises from the latter islands can be externally, though not osteologically, distinguished *as a whole* from the Galapagos Tortoises, as will be seen from the following synopsis:—

Nuchal plate absent. Frontal portion of the skull flat. Fourth cervical vertebra biconvex. Pelvis with broad symphysial bridge.

A. Gular plate double; sternum of moderate extent ... ... GALAPAGOS TORTOISES.

B. Gular plate single; sternum short ... . MASCARENE TORTOISES.

a. Carapace thin, thickened towards the margins; centre of the last vertebral plate raised into a hump, which is separated from the penultimate vertebral by a transverse depression: *Tortoises of Mauritius* (*T. triserrata*, *T. inepta*, *T. indica*, *T. leptocnemis*).

b. The entire carapace extremely thin and fragile, all the bones very slender: *Tortoise of Rodriguez* (*T. vosmæri*).

II. Nuchal plate present. Frontal portion of the skull convex. Third cervical vertebra biconvex. Pelvis with narrow symphysial bridge. Gular plate double. Carapace thick. ALDABRA TORTOISES (*T. elephantina*, *T. daudinii*, *T. ponderosa*, *T. hololissa*).

Linnean Society, January 18.—Prof. Allman, president, in the chair.—Three new Fellows were elected, viz., Dr. W. Miller Ord, Thos. Routledge, and S. D. Titmas.—An interesting and scientific memento of the ill-fated *Polaris* Expedition was exhibited by Mr. R. Irwin Lynch. This consisted of a pot of growing wheat which had been sown from the grain left in Polaris Bay, 81° 38′ N., by the American Expedition. Capt. Sir George Nares, in a letter to Dr. Hooker, says that the grain in question had been exposed to the winter frosts, 1872-76; notwithstanding the intense cold it had been subjected to, the above sample grown at Kew gave 64 per cent. as capable of germination. A grain of maize, among the wheat, which also sprouted, possessed even greater interest, inasmuch as being a truly tropical plant.—The amphibious and migratory fishes of India formed the subject of a paper by Dr. Francis Day. He first instanced many forms which respire air direct, can live for long periods after their removal from water, and are but little affected by a bandage being placed round their gills, preventing the use of that organ. The *Saccobranchus* was shown to have a distinctly amphibious circulation, venous blood being sent by the pulmonary artery to the respiratory sac, and arterial blood being returned from it to the aorta. He questioned the accuracy of the swim-bladder of fishes, being the homologue of the respiratory bladder of amphibia, and observed that in the *Saccobranchus* both a respiratory sac and a swim-bladder co-existed; the one along the muscles of the back, the other more or less inclosed in bone but possessing a pneumatic duct.—Mr. G. J. Romanes read a second notice on varieties and monstrous forms of Medusæ. He expressed surprise that among the jelly fish—at least the naked-eyed group, with their lowly grade of organisation and proneness to exhibit the phenomena of gemmation—examples of monstrous and misshapen forms are comparatively rare. In those cases met with, especially in *Aurelia aurita*, the deviations from the normal type nearly always occur in a multiplication or in an abortion or suppression of *entire segments*. This affects the segments of the umbrella in a symmetrical manner, whilst the ovaries and manubrium, to a certain extent, may or may not be implicated.

Chemical Society, February 1.—Prof. Abel, F.R.S., president, in the chair.—Dr. H. E. Armstrong read a paper on Kekulé's and Ladenburg's benzene symbols, in which he discussed the relative value of the two symbols as a means of expressing the known reactions of benzene and its derivatives, expressly pointing out how Ladenburg's prism symbol was more in accordance with our knowledge of the quinones; but that up to the present time, although it might be considered proved that in benzene six carbon atoms were linked together in a closed chain, we had no evidence to show the manner in which the atoms were united. Subsequently Mr. W. H. Perkin read a paper on the formation of coumarine and of cinnamic, and of other analogous acids from the aromatic aldehydes. These acids, of which twenty are described in the paper, were obtained by the action of a metallic salt and acid anhydride, such as sodic acetate and acetic anhydride on an aromatic aldehyde; the latter part of the paper contained an account of the acids obtained from coumarin.

Anthropological Institute, January 30.—Annual meeting.—Col. A. Lane Fox, F.R.S., president, in the chair.—The Treasurer presented his Report, which showed that the finances of the Society were in a satisfactory condition. The President delivered his anniversary address. It gave a short *résumé* of the papers that had been read during the past year. From the Report of the Council it appeared that there had been an increase of members in 1876 over deaths and retirements. The following Officers and Council were elected to serve for 1877:—President, John Evans, F.R.S. Vice-presidents: Prof. George Busk, F.R.S., Hyde Clarke, Col. Lane Fox, F.R.S., A. W. Franks, F.R.S., Francis Galton, F.R.S., E. Burnet Tylor, F.R.S. Directors and Hon. Secs.: E. W. Brabrook, F.S.A., Capt. Harold Dillon, F.S.A. Treasurer, J. Park-Harrison, M.A. Council: J. Beddoe, F.R.S., J. Barnard Davis, F.R.S., W. Boyd Dawkins, F.R.S., W. L. Distant, Robert Dunn, F.R.C.S., Charles Harrison, F.S.A., H. H. Howorth, F.S.A., Prof. T. McK. Hughes, F.G.S., Prof. Huxley, F.R.S., A. L. Lewis, Sir John Lubbock, Bart, M.P., F.R.S., R. Biddulph Martin, F. G. H. Price, F.R.G.S., J. E. Price, F.S.A., Prof. Rolleston, F.R.S., F. W. Rudler, F.G.S., C. R. Des Ruffières, F.R.S.L., Lord Arthur Russell, M.P., Rev. Prof. Sayce, M.R.A.S., M. J. Walhouse, F.R.A.S.

Victoria Institute, January 5.—Dr. C. Brooke, F.R.S., in the chair. Mr. David Howard, F.C.S., read a paper upon the structure of geological formations as an evidence of design. After which, a paper by Principal Dawson, F.R.S., on the recent discovery of numerous flint agricultural implements in America was read.

Institution of Civil Engineers, January 30.—Mr. George Robert Stephenson, president, in the chair.—The paper read was on the combustion of refuse vegetable substances for raising steam, by Mr. John Head, Assoc. Inst. C.E.

BERLIN

German Chemical Society, January 15.—A. W. Hofmann, vice-president, in the chair. E. Mulder wishes to substitute the following expression, $M = d$, for the usual expression of the law of Arvogadro, $M = 2d$, by accepting as the atomic weight of hydrogen not 1, but 0·5.—I. Boguski and N. Kagander, in continuing their researches on the quantity of carbonic acid evolved in a given time by the action on marble of acids of different strength, arrives at the conclusion: that the velocities of the evolution of carbonic acid are inversely proportional to the molecular weights of the acids employed.—A. Christomanos recommended several modifications of the usual methods of analysis of chrome-iron-ore.—A. Basarow described for lecture purposes a miniature torpedo, containing only three grams of gunpowder, and sufficing to throw up water from a pail to the height of twenty or thirty feet.—F. Frerichs proposed, for organic analysis, to heat the compound in sealed tubes with oxide of mercury, and to determine the volumes of CO_2 and of O.—C. Göttig has found that the ordinary method of forming aldehydes from acids by distilling their calcium-salts with formiate of lime, holds good for the production of ethyl-salycylic aldehyde, but not of salicylic aldehyde.—A. Ladenburg has observed slight differences in the two bodies, $N(C_2H_5)_3.C_7H_7I$ (iodo-benzyl-tri-ethylamine) and $N(C_2H_5)_2C_7H_7.C_2H_5I$ (iodo-ethyl-diethyl-benzylamine), the former, treated with HI yielding iodide of benzyl, while the second does not yield this product. He thinks, therefore, that these two compounds are isomeric, that nitrogen is triatomic, and $NH_3.HCl$ a molecular combination. The same chemist states oxythymochinone to have the melting-point, 173°–174°, and not 187°, as formerly observed. He upholds the views regarding the constitution of this body lately published by him in a separate form.—R. Anschutz and G. Schultz obtained phenanthrenchinonimide by the action of alcoholic ammonia on phenanthrenchinone,

$$C_{14}H_8O_2 + NH_3 = C_{14}H_9NO + H_2O.$$

—H. Schwanert reported on several derivatives of dinitrotoluolsulphonic acids.—A. Berndtsen described the aldehyde of thiobenzoic acid obtained from thiobenzamide by the action of nascent hydrogen :—

$$\underset{\text{thiobenzide}}{C_6H_5 . CS . NH_2} + 2H = \underset{\text{thiobenzaldehyde}}{C_6H_5 . CS . H} + NH_3.$$

A second body formed simultaneously forms the subject of further investigations. The same chemist has succeeded in transforming acetonitrile into acetothiamide, colourless prisms fusing at 108° :—

$$CH_3 . CN + SH_2 = CH_3CS . NH_2.$$

C. Seuberlich, by the action ot sulphuric acid on a mixture of gallic and benzoic acids, has obtained black metallic needles of anthragallol, $C_{14}H_8O_5$.—C. Liebermann communicated that H. E. Armstrong has transformed nitrosothymol into amidothymol and into thymochinone by oxidation, and that R. Schiff has proved that nitrosothymol can be transformed into ordinary dinitrothymochinone. These facts prove the relative position of the constituent groups to be different than supposed by Ladenburg. F. Tiemann described a new acid, $C_9H_{10}O_4$, homovanillinic acid, obtained from acetyl-eugenol by oxidation, which, treated with alkali, yields homoprotocatechic acid, $C_8H_8O_4$. The relations of these substances are :—

$$\underset{\text{Vanillinic.}}{C_6H_3\left\{\begin{array}{l}COOH\\OCH_3\\OH\end{array}\right.} \qquad \underset{\text{Protocatechic acid.}}{C_6H_3\left\{\begin{array}{l}COOH\\OH\\OH\end{array}\right.}$$

$$\underset{\text{Homovanillinic.}}{C_6H_3\left\{\begin{array}{l}CH_2COOH\\OCH_3\\OH\end{array}\right.} \qquad \underset{\text{Homoprotocatechic acid.}}{C_6H_3\left\{\begin{array}{l}CH_2COOH\\OH\\OH\end{array}\right.}$$

Conjointly with A. Herzberg, the same chemist has obtained cinnamic acid by the action of acetic anhydride on benzaldehyde. The reaction gives a better yield than chloride of acetyl, and is also applicable to salicylic aldehyde and to vanilline.—C. Vogel communicated spectroscopic reactions of magnesia with purpurine and with cochineal.—The chairman read a letter of Prof. F. Wöhler, in Göttingen, in which he accepts the office of president of the Society for the ensuing year, with thanks for this acknowledgment of his past services to science.

PARIS

Academy of Sciences, January 29.—M. Peligot in the chair.—The following papers were read :—Note on the stability of arches, by M. Resal. He gives an analytical demonstration of the theorem, that when the thrust at the key-stone of an arch is minimum the curve of pressures is tangent to the intrados at the joint of rupture.—Reply to Dr. Bastian, by M. Pasteur. He defies Dr. Bastian to obtain the result he got with sterile urine, provided only the solution of potash used be pure, water pure, and potash pure, both exempt from organic matters. If Dr. Bastian takes impure potash, M. Pasteur authorises him to take it or anything else in the English pharmacopœia, if only it be heated previously to 110 degrees for twenty minutes or 130 degrees for five minutes.—On the germs of bacteria in suspension in the atmosphere and in water, by MM. Pasteur and Joubert. An inquiry suggested by the discussion with Dr. Bastian. The germs are shown to be very numerous in water, like that of the Seine; they occur in the distilled water of our laboratories, and can traverse all filters. They are absent from water of springs in the interior of the ground that has not been reached by dust from the atmosphere nor by water circulating above ground.—Researches on the irisation of glass, by MM. Frémy and Clemandot. They reproduce at will the irisation sometimes observed in glass (from some old tombs, &c.), by subjecting glass under heat and pressure, to the action of water containing about 15 per cent. of hydrochloric acid. The chemical composition and the conditions of annealing and tempering, influence the phenomenon. (Particulars later). Bottle glass for holding an acid liquid like wine should not irisate under action of acids; if it does the liquid is quickly altered. The author's method enables him to test the quality of a glass beforehand, by submitting it to dilute hydrochloric acid.—Report on a memoir by M. Henri Becquerel, entitled "Experimental Researches on Magnetic Rotatory Polarisation." He studies the relation between this property and the index of refraction, examining bodies with a high index; and these he finds to have a high rotatory power. In solutions of salts the rotatory power increases rapidly with the concentration. He demonstrates also an anomalous rotatory dispersion accompanying negative magnetic rotation.—On the products obtained by calcination, in a closed vessel, of the wash (*vinasses*) of molasses of beet, by M. Camille Vincent.—On a new arrangement of the rods of lightning conductors, by M. Janiant. The rods are generally six metres long, weigh not less than 120 kilogrammes (involving much strain), and cost, with their copper point, some 300 francs. The author arranges four iron corner channels in form of a quadrangular pyramid connected at the base by iron sockets attached to the timber work. At the top the channels are thinned to the prescribed diameter of 2 cm. for the copper point, and this is screwed on an iron rod, which traverses the system from top to bottom, and ensures metallic communication with all the parts. The system weighs only 20 kilogrammes, and is half the price of the other.—On the effects produced by introduction of foreign substances into carbon, in preparation of carbon points for the electric light, by M. Gauduin. These experiments were made in 1875, with phosphate of bone, lime, chloride of calcium, borate and silicate of lime, pure precipitated silicon, magnesia, borate and phosphate and magnesia, alumina, and silicate of alumina. The salts of lime gave the greatest increase of light; with the first substance, the intensity was doubled. Silicon diminished the light.—Treatment of phylloxerised vines by sulphide of carbon fixed in pulverulent matters, by M. Fournet.—On the necessity of abandoning the Baumé areometer and replacing it by Gay Lussac's densimeter, by M. Maumené.—On the development of the ellipse, by M. Laguerre.—On the two theorems of M. Clebsch relative to curves quarrable by elliptic functions or by circular functions, by M. Maric.—Researches on the spectra of metals at the base of flames, by M. Gouy. The base of the flame gives, up to a very small height, a spectrum resembling the electric spectrum of the metal examined.—On the preparation of alkaline nitrites, by M. Etard.—Researches on the formation of natural sulphurous waters, by M. Plauchud. Sulphurous mineral waters owe their formation to the reduction of various sulphates produced under the influence of living beings acting like ferments. It is possible that not every sulphuration of water is attributable to ferments, as acetic acid may be produced by spongy platinum as well as *mycoderma aceti*.

DARWIN ON FERTILISATION

The Effects of Cross- and Self-Fertilisation in the Vegetable Kingdom. By Charles Darwin, M.A., F.R.S., &c. (London: John Murray, 1876.)

FEW as are the students of vegetable physiology in this country, it is very far from a mere boast to say that, with Mr. Darwin's aid, we have no reason to shrink from comparing English work in this subject with that done abroad. Mr. Darwin has sometimes lamented that he is not a botanist, yet it would be difficult to name any scientific man with an accepted claim to that description who could point to more valuable botanical work than his studies of heterostyled plants, the fertilisation of orchids, and the habits of climbing and insectivorous plants. As to the present volume, there is no risk whatever in stating that it at once takes and will always retain a classical position in botanical literature. And when one considers that these are not the only things which have come during late years from the same apparently inexhaustible treasury, and when one remembers also that the great student who has filled it has throughout struggled with difficulties which would have effectually quenched the energy of most men, one may allow oneself to wonder whether Mr. Darwin's own scientific activity is not itself a more than remarkable biological problem.

There can be no doubt that the publication of the present work is extremely opportune. An enormous body of observations, of which a great part have been brought together by Dr. Hermann Müller, have solidly confirmed the well-known induction stated by Mr. Darwin in 1862, that "nature abhors perpetual self-fertilisation." Most persons who have studied the subject have been satisfied that the facts safely covered the conclusion that the varied adaptive contrivances in flowers really had for their object the prevention of self- and the promotion of cross-fertilisation, even if nature chose to preserve an impregnable silence as to the reason of her abhorrence of the former process. There have not, however, been wanting those who have attempted to explain away the significance of all that had been stated. Not seeing the mischief of self-fertilisation, they have hastily assumed that it had none, and thence have arrived at the conclusion that the cause of the adaptive modification of flowers must be sought for elsewhere.

At any one period the area of knowledge is always bounded by a wall too high to see over, and against which it is easy but not profitable to bruise one's head. It is difficult to say whether it requires more genius to scale the wall at one dash or to pass out by the doors which are everywhere provided for those with eyes to see them. And though no one would have the rashness to suggest that there was anything defective in Mr. Darwin's scientific vision, yet there is some comfort to be derived from the fact that he gives from his own experience a most instructive instance of the real difficulty that even the greatest of investigators may feel in emancipating himself from the limits which prepossession—conscious or unconscious—constantly opposes to the progress of research. Without, of course, having a shadow of doubt that nature had some need to satisfy in so laboriously struggling to prevent self-fertilisation in plants, Mr. Darwin was content to suppose that it might be injurious in the long run, in some way difficult, at present—if ever—to be analysed, and, to use his own words:—

> "That it would be necessary, at the sacrifice of too much time, to self-fertilise and intercross plants during several successive generations in order to arrive at any result. I ought [he continues] to have reflected that such elaborate provisions favouring cross-fertilisation, as we see in innumerable plants, would not have been acquired for the sake of gaining a distant and slight advantage, or of avoiding a distant and slight evil" (p. 8).

In fact an observation almost accidental led the way to the remarkable discoveries recorded in the present volume. Of these an article in the *Academy* (August 28, 1875) by Mr. George Darwin gave, I believe, the first intimation, and raised in the highest degree our expectations. "My father," he stated, "has now been carrying on experiments for about nine years on the crossing of plants, and his results appear to him absolutely conclusive as to the advantages of cross-fertilisation to plants." Mr. Darwin informs us that he was led to the investigation by the manifest contrast presented by "two large beds of self-fertilised and crossed seedlings from the same plant of *Linaria vulgaris*" (p. 9), in which he found to his surprise that "the crossed plants when fully grown were plainly taller and more vigorous than the self-fertilised ones." His "attention was now thoroughly aroused," and two-thirds of the present volume are devoted to the very extended course of experimentation, the results of which Mr. Darwin puts forward in confirmation of the conclusion which his first and accidental observation suggested. These results deserve and will receive the most careful study at the hands of botanists, but it would be scarcely useful within the limits of this notice to examine them in any detail. They appear, however, to me, to demonstrate completely the advantage which cross-fertilised plants obtain in all that concerns their struggle for life—in increase of size, of bulk (as measured by weight), and of fertility, as well as in precocity of flowering and capacity of resisting adverse external influences.

The remainder of the volume is, however, occupied with general discussions, upon which it may be interesting to make some remarks. The process of gamogenesis essentially consists in "the physical admixture of protoplasm derived from two sources." Mr. Darwin's investigations have left no room for even a shadow of a doubt that the object of nature in bringing about this result is to secure for the starting-point of the new organism a protoplasmic mass made up of elements which have been independently individualised or differentiated by exposure to different external conditions. Mr. Herbert Spencer explains this by the need which the manifestation of life involves for continually disturbing the condition of molecular equilibrium to which all things in nature gradually tend. But as Mr. Darwin hints, this mode of explanation scarcely does more than restate the empirical facts which we may now sum up by saying that for gamogenesis to give the best result a certain *mean* differentiation—varying much for different organisms—in the sexual elements which take part in it is necessary. And in so far as Mr. Spencer's theory suggests an analogy to chemical change, it is perhaps leading us away from the direction of real explanation altogether.

The use of the phrase "mean differentiation" perhaps conveniently expresses Mr. Darwin's ingenious and most probable correlation of the facts of hybridisation with those of self-fertilisation.

"It is an extraordinary fact that with many species, flowers fertilised with their own pollen are either absolutely, or in some degree, sterile; if fertilised with pollen from another flower on the same plant they are sometimes, though rarely, a little more fertile; if fertilised with pollen from another individual or variety of the same species, they are fully fertile; but if with pollen from a distinct species, they are sterile in all possible degrees until utter sterility is reached. We thus have a long series with absolute sterility at the two ends; at one end due to the sexual elements not having been sufficiently differentiated, and at the other end to their having been differentiated in too great a degree, or in some peculiar manner" (pp. 455, 456).

In this mode of regarding phenomena which at first hardly seem to have anything in common, and embracing them under a single "expression," there is a neatness quite mathematical. Mr. Darwin admits, however, with characteristic frankness that in thus breaking down the fundamental difference between species and varieties, he traverses a prejudice which "it will take many years to remove" (p. 467).

But it is possible to go even further and regard gamogenesis and agamogenesis themselves as particular cases of a generalised process. Every organism, whether sexually produced or not, may be regarded as an aggregate of cells derived from a single mass of protoplasm which has undergone repeated division. Fertilisation, as Prof. Huxley has remarked,[1] is only "one of the many conditions which may determine or affect that process." And this remark probably supplies the explanation of the undoubted fact that amongst flowering plants as in every other part of the vegetable kingdom, there is every gradation between plants which are simply incapable of self-fertilisation and therefore would die out if they were not perpetually crossed, and others in which self-fertilisation is the rule.

"Some few plants, for instance, *Ophrys apifera*, have almost certainly been propagated in a state of nature for thousands of generations without having once been intercrossed; and whether they would profit by a cross with a fresh stock is not known. But such cases ought not to make us doubt that, as a general rule, crossing is beneficial, any more than the existence of plants which in a state of nature are propagated exclusively by rhizomes, stolons, &c. (their flowers never producing seeds), should make us doubt that seminal generation must have some great advantage, as it is the common plan followed by nature" (p. 439).

Still there is room for believing that nature may be able to give more or less freely to plants, but in some other way, those benefits which gamogenesis, especially in its more differentiated forms, undoubtedly confers. It may be one of nature's favourite expedients, and yet not the only one. It is highly important to bear this in mind and to keep clearly in view what it is exactly that Mr. Darwin has done. He has explored, and in a manner which had never been attempted, much less accomplished before, the precise utility of cross-fertilisation, and has consequently given enormously increased force to all arguments drawn from the adaptive arrangements that promote it by demonstrating their extreme urgency. But he has not tied nature's hands to doing her work with this implement alone, and therefore he is not open to the objection which some persons will probably urge, that cross-fertilisation cannot be so important, seeing that many plants get on apparently very well without it. This is, indeed, as if one were to argue that the printing-press cannot have had the influence attributed to it, seeing that there have been those who expressed their meaning excellently well with the help of the fore-finger and some sandy soil.

The evidence which Mr. Darwin has collected leads almost irresistibly to the conclusion that the benefit derived from gamogenesis does not depend upon any mysterious property inherent in the process itself, but that "change" is to be regarded as at the bottom of the benefit derived from it; intercrossing, in fact, ceases to be beneficial if the plants crossed have been for many generations exposed to the same conditions. The advantage is, in fact, of the same kind as that which all organisms seem to derive from "an occasional and slight change in the conditions of life." "But the offspring from a cross between organisms which have been exposed to different conditions [and therefore differentiated] profit in an incomparably higher degree than do young or old beings from a mere change in their conditions" (pp. 454, 455), and the reason is that "the blending together of the sexual elements of two differentiated beings will affect the whole constitution at a very early period of life, whilst the organisation is highly flexible." But as change may be of the most variable amount, the corresponding differentiation may be equally variable. In some cases it must be exceedingly small; amongst the *Conjugatæ*, for example, in *Rhynchonema*, two adjacent cells of a filament unite by small lateral processes which bridge over the intervening septum. And the bridge being very narrow, one cell is forced to become the recipient of the contents of the other and the sexual differentiation of the two conjugating cells is thereby established. In *Vaucheria*, where the protoplasm is continuous through the whole vegetative portion of the filamentous organism, the sexual organs are formed by small adjacent processes which are merely parted off from the common protoplasm of the filament which bears them. This must also be an extremely close case of self-fertilisation, but as fertilisation is effected by motile antherozoids, there is a remote possibility of an occasional cross. The hermaphrodite condition in such cases may easily be conceived to have been developed from a stage in which conjugation alone obtains.

It would not be difficult to show that all through the vegetable kingdom the hermaphrodite condition precedes the diœcious. Thus in ferns where the sexual organs are developments of epidermal processes on the peculiar intermediate generation known as the prothallium, there is almost every condition which is met with in flowering plants. The female organs (archegonia), however, require more than one layer of cells for their ultimate development, and are consequently matured later than the male organs (antheridia). Hence ferns tend to be proterandrous and therefore functionally diœcious; and as it frequently happens that the young prothallium gets arrested in its development without reaching the stage in which archegonia are produced, such prothallia will be exclusively male by arrest of development. It can hardly be doubted that in an analogous manner male flowers have arisen in diclinous flowering plants. In *Osmunda* amongst ferns the complete diœcious condition is reached. There can, in fact, be no doubt that ferns are habitually cross-fertilised, and there is also good reason to believe that they are even hybridised. It is further noteworthy that whilst in *Osmunda* there is an agamic reproduction of the prothallial generation, in a few rare cases, as pointed out first by Dr. Farlow, the process of gamogenesis is wholly in abeyance and the prothallium gives rise to the spore-bearing stage agamogenetically. One might remark here that the probable absence of true gamogenesis amongst the larger fungi might be compared with this abnormal occurrence in ferns. But another explanation suggests itself. Amongst the *Myxomycetes* the continuous masses of protoplasm which constitute the plant in its active state, segregate into spores which eventually set free zoospores. These swim about to again coalesce into a plasmodium. Sachs has suggested that this coalescence is of a sexual character, and in fact a kind of multi-conjugation; and no doubt the zoospores, in their motile condition, will undergo a certain amount—inconceivably minute it may be—of differentiation, due to slight differences in exposure to external conditions such as heat and light, and thus the end of a more regular sexual process may be attained. In the higher fungi there is nothing exactly comparable with this unless we compare with the fusion of zoospores in the *Myxomycetes* the habitual inosculation and intergrafting of the mycelial threads, the result of which must be to bring about an intermixture of somewhat differentiated protoplasm.

---

[1] "Encyclopædia Britannica," Art. Biology, p. 687.

Perhaps, therefore, on a review of Mr. Darwin's remarks on the subject of hermaphroditism (pp. 409, 410), one may demur to his conclusion that the monœcious condition "is probably the first step towards hermaphroditism." It seems not improbable that precisely the converse may be the more true. Mr. Darwin thinks "that as plants became more highly developed and affixed to the ground they would be compelled to become anemophilous in order to intercross. Therefore all plants which have not since been greatly modified would tend still to be both diclinous and anemophilous." But it does not appear that it is intended to limit this statement to flowering plants; yet it would certainly require some modification amongst *Pterido-phyta* for example. As we have seen, ferns, at any rate, are not diclinous, nor are they anemophilous, yet they escape all the evil results possibly attending the hermaphrodite condition. The fact is that as long as plants possess motile antherozoids, and their sexual processes take place not in mid-air, but on damp soil, there is no need for the intervention of agencies like the wind or insects to bring about cross-fertilisation. The natural locomotive powers possessed by the antherozoids are sufficient to secure that. The difficulty began when the very limited mobility of the pollen tube was substituted for the amazing activity of the antherozoid. And it will throw a great deal of light on the question as to whether the primordial flower was diclinous or not if one considers the manner in which it probably originated.

In the first place, it must be remembered that the processes which take place in a "flower" are, in a vascular cryptogam, spread over two distinct generations. The drama which once had two acts is now compressed into one. Bearing this in mind, we shall find little difficulty in seeing in the sporangiiferous cone or spike of *Selaginella* the homologue of the flower. For, like that, it is composed essentially of an axis bearing modified lateral appendages, some of which, in this case the upper ones, produce male structures—microspores—and the lower—female ones—macrospores. These bodies fall to the ground, and those from adjacent plants are more or less commingled by the wind before sexual interaction begins to take place. Now, comparing a flower, we find that it also consists of an axis with modified lateral appendages, and if we call the embryo-sac a macrospore and the pollen-grain a microspore, as we are thoroughly justified in doing, then the only important difference between a "*Selaginella*-fructification" and a "flower" is that the position on the axis of microspore- and macrospore-producing structures is inverted.

How, then, do we proceed from one to the other? Simply by prolonging the period during which microspores and macrospores remain attached to the parent plant. Instead of fertilisation being effected on soil moist enough to allow the antherozoids to move, suppose it take place on the parent plant in a comparatively dry atmosphere. Antherozoids are no longer set free by the microspore, which simply puts out processes (of which those from the microspore of *Salvinia*—forming the very rudimentary male prothallia—are a kind of foreshadowing) towards the female organs developed from the macrospore. And there is precedent, for example, amongst the *Saprolegnieæ*, for such a reversion to a mode of fertilisation resembling conjugation (which fertilisation by a pollen tube really is) from a phase of motile antherozoids.

There is a probability, then, that a flower originated by the retention of macrospores (more especially) within the structures of some plant-form not distantly related to *Selaginella*—such a flower would be extremely inconspicuous, destitute of colour—these modifications being only subsequently acquired—and, what is more important, hermaphrodite. Diclinous flowers would arise simply by the arrest of development of either the male or female organs, and this arrest would be only one of the several modes by which nature determines the cross-fertilisation which we now know to be beneficial, and therefore likely to be secured by the self-adjusting process of natural selection. This view, by which flowers are regarded as originally hermaphrodite, instead of, as Mr. Darwin suggests, monœcious, further supplies a very simple explanation of the otherwise almost inexplicable nature of cleistogene flowers. These being inconspicuous and self-fertilising—are probably survivals of the original type.

I am happy to be able to support what I have urged by the following passages from Mr. Bentham's presidential address to the Linnean Society in 1873. Criticising Strasburger's views as to the pedigree of phanerogams (which derived them from the diclinous Conifers), he remarks that if we accept them,

"We must suppose that races, after having once secured the advantages of a total separation of the two sexes and undergone modifications suited to their separate requirements, have again returned to their primitive state of sexual proximity, and commenced a totally different series of modifications destined to counteract the evil effects of that proximity. A much more simple hypothesis would be that Conifers separated from the parent stock before the development of floral envelopes, *the higher Dicotyledons before the separation of the sexes.*"

The anemophilous fertilisation of the arborescent plants of cool countries is perhaps rather a climatic adaptation than a survival of a primitive condition, while the cases, of which many have been recorded, in which diclinous plants have produced hermaphrodite flowers—such as the papaw and pitcher-plant in the Glasnevin Botanic Garden described by Dr. Moore—would be easily explicable as the results of atavism, *i.e.*, of reversion to a former hermaphrodite condition. On the other hand Mr. Darwin's suggestion (p. 410) that "if very simple male and female flowers on the same stock each consisting of a single stamen or pistil, were brought close together and surrounded by a common envelope, in nearly the same manner as with the florets of the *Compositæ*, we should have an hermaphrodite flower," offers very considerable morphological difficulties. As a further argument that the flower originates like the fructification of *Selaginella*, by the sexual specialisation of adjacent lateral appendages, one may point out that the early stages in the development of macrospores and microspores are indistinguishable, while in flowering plants there is a reminiscence of this in the case of ovules occasionally being polleniferous.

Difficult as it is to resist discussing the suggestions which everywhere present themselves in this most interesting book, the limits of a review compel me to stop. I will merely point out that here; as in so many cases, investigations undertaken from a purely scientific point of view are not without their practical utility. The precise conditions which Mr. Darwin has ascertained as sufficient to fix in a fleeting variety any particular quality, will be of the last importance in the hands of cultivators.

Just two centuries before the date of this book Sir Thomas Millington, at Oxford (1676), laid the foundation of this branch of investigation by assigning to pollen on theoretical grounds its hitherto unknown function. This it only remained for Bobart, in the Oxford Physick Garden, to experimentally verify (1681). Science is the property of no nation, nevertheless one may feel some pride that the first and the last of the capital discoveries that have been made in respect to plant fertilisation belong to Englishmen.

W. T. THISELTON DYER

OUR BOOK SHELF

Bulletin des Sciences Mathématiques et Astronomiques. Tome dixième. Mars-Juin, 1876. (Paris: Gauthier-Villars.)

WE have no mathematical publication in this country covering quite the same ground as this admirable *Bulletin.* Indeed we hardly think such a journal could survive the issue of half-a-dozen numbers here. The late Mr. T. T. Wilkinson, in an interesting series of notices of "Mathematical Periodicals," points out that such periodicals have "formed a distinguishing feature in our scientific literature for upwards of a century and a half," and quotes a remark of Prof. Playfair (*Edinb. Rev.*, vol. xi.) to the effect that "a certain degree of mathematical science, and, indeed, no inconsiderable degree, is, perhaps, more widely diffused in England than in any other country of the world." These observations have reference principally to such journals as the *Lady's and Gentleman's Diary.*

A very limited circulation, we fear, rewards the editors of the *Quarterly Journal of Mathematics* and the *Messenger of Mathematics.* Nor do we think the state of things would be greatly altered if such a publication as the one before us were started here. The division is mostly a triple one— a review, or reviews, of new mathematical works, followed by an analysis of the contents of current mathematical publications, occasionally supplemented by an original paper.

In the March number we have a long account of Dr. Lindemann's edition of Clebsch's "Vorlesungen über Geometrie" (ersten Bandes erster Theil), a review of Rear-Admiral Sands's "Astronomical and Meteorological Observations" (1871, 1872), an analysis of Dr. Günther's "Lehrbuch der Determinanten—Theorie für Studirende." We have also in this and the other numbers descriptions of the contents of Bellavitis' *Rivista di Giornali*, Catalan and Mansion's *Nouvelle Correspondance Mathématique*, *Mathematische Annalen*, *Giornale di Matematiche*, *Monatsberichte*, and like periodicals. Just noticing the interesting discovery that the Gaussian logarithms (logarithmes d'addition et de soustraction) were first treated of by Leonelli (Avril No., p. 164), his work having been translated into German in 1806, and Gauss having published his table in Zach's *Monatliche Correspondenz* in 1812, we pass on to two notices of mathematical histories. M. E. Hoefer's "Histoire des Mathématiques, depuis leurs Origines jusq'au Commencement du XIX^{e} Siècle" (Mars No.), comes in for strong condemnation. At the end of the critique we read "nous terminerons cette analyse en exprimant le désir de voir bientôt paraître dans notre langue un ouvrage sur l'histoire des mathématiques, écrit par un mathématicien avec tout le soin que réclame une tâche aussi difficile, et s'adressant, non à *tout le monde*, mais à ceux qui ont intérêt à connaître cette histoire et que leurs études mettent à même de la comprendre." The importance of Hankel's "Zur Geschichte der Mathematik im Alterthum und Mittelalter" in the eyes of the editor may be gathered from the fact that the notice of it takes up thirty-four pages out of the forty-eight. Judging by the extracts and comments the work is one of much research, originality, and interest. "Tel est le résumé bien incomplet du remarquable volume dont nous avons cherché à rendre compte. Nous espérons que ce que nous venons de dire suffira pour engager tous ceux qui s'intéressent à la science à lire le livre de Hankel, et pour en faire désirer une traduction dans notre langue." Is it too much to hope that now we have living amongst us a mathematician whose "great historical treatises are so suggestive of research and so full of its spirit" this country will produce a work to rival M. Hankel's? If it is too much to expect then we hope some one will do for us what the writer in the *Bulletin* desires for his own country.

LETTERS TO THE EDITOR

The Obsidian Cutlers of Melos

DURING a tour in Greece in the past summer I obtained a small number of stone implements chiefly from the Island of Kythera (cerigo) and the Isthmus of Corinth, consisting of a few corn-crushers or pounders, and some celts. The latter are particularly clumsy and very thick in section, and are usually a beach or torrent pebble of suitable form ground to a cutting edge, and sometimes roughened by pecking at the other extremity, as if to afford a firmer grasp for the hand. Their shape makes them unsuitable for insertion into a handle except where the implement is small, and here the roughening is absent. I also obtained a large number of the obsidian cores and flakes from the Island of Melos, which are familiar to most collectors. It is on these latter objects that I shall make some observations.

On examining a series of these flakes I found a small number of them which presented a singular wavy pattern down the back ridge, which has evidently been produced by alternate pressure, or a series of taps administered by some small instrument like a punch.[1] I have since procured some more cores and flakes with the view of examining the question more carefully, and have been fortunate in securing some interesting evidence from them. Out of a total of 230 obsidian flakes examined I have found 39 which have this marking with more or less distinctness. In many cases the working is extremely rude, the alternate chipping wide, straggling, and uneven, and the depth of the depression and general character of the fracture such as to suggest considerable violence in the blows which produced it. In other cases the chipping is flatter and shallower, but still not very even. But in a very few choice specimens the chipping is so even and regular as to produce a pattern not unworthy of the manufactures of some of the "crimped" Danish daggers.

On examining a series of small cores I was delighted to find on a few of them traces which leave no doubt that this curious marking was produced *before* the flake was detached from the core. In addition to the beautiful parallel fluting for which the Greek cores are remarkable, I have found one ridge in some of the cores (in 22 out of 125) worked up into the serrated edge and ready for the blow which should have detached the flake. I have only had the good fortune to find in one instance a flake still *in situ* on its core whose chipping will compare with the best specimens in my possession of detached flakes. Indeed on some of the cores the working is so rude as to form merely a jagged and irregular line instead of the beautifully clean ridge of the ordinary flaking; and without the evidence of the other flakes and cores, I should not have been able to interpret the intention of these ruder specimens.

There is another form of working to be observed on a certain number of the obsidian flakes. They have in many cases, by a series of very delicate and flat chippings, had their back ridge so modified or removed as to present a blade-like surface. In some cases this extends over the whole of the back of the flake, in others (where it has been a double-ridged flake) the chipping is merely enough to remove one ridge, making a blade like one of our own dinner knives, thinner at the cutting edge than on the blunt back. The intention in this case is very evident, being merely to increase the cutting powers of the flake by removing all impediments. Here again the chipping was effected while the flake was still *in situ*. I have two or three cores with one side flattened by the removal of several ridges, and awaiting conversion into a knife-blade by a blow which never descended.

The use, however, of the flakes with the serrated back ridge, is more questionable. It is, I think, not possible to suppose that the working in this case was put there as a mere piece of ornamental cutlery, although the similar crimping on the Danish daggers was certainly so. In the best Melian flakes the working is certainly highly ornamental, but such specimens are somewhat exceptional, and in the majority of instances the working cannot be considered ornamental at all, and evidently does not aim at nicety and symmetry. Hence we may reasonably conclude that the purpose of the working was utility in the first instance, and ornament only incidentally. I think there is little doubt that these serrated flakes were manufactured to serve the double purpose of a knife and a saw (rasp, or file), and they would be by no means inefficient tools in experienced hands.

I am not aware that attention has been called to these peculiarities of the Greek obsidian flakes—or indeed that they have been hitherto observed at all: and I have therefore thought it worth while to offer some account of this interesting instance of obsidian manufacture. I am not aware that any similarly worked flakes have been discovered in Mexico; and I should be much interested if any of your readers could correct me on this point.

It is worth remarking that there are several qualities of Greek obsidian. The blackest and most beautiful is glossy and lustrous, but will by no means compare with the obsidian of Mexico in these particulars. Greek obsidian has nearly always an undertone of opaque green. There is, however, a quality which is a dull leaden grey, slightly lustrous only, and less vitreous in its composition. It breaks with the same fracture as the more lustrous qualities.

When the flake is trimmed very fine, it is frequently transparent, and if held to a strong light presents a beautiful grey and black "brindled" texture.

The Greek cores are all of small size, the longest which I have seen being just under three inches; but I have one flake which measures $3\frac{3}{8}$, and a few which vary between that and three inches. One most exceptional specimen, however, which is quite unlike any of the others, and is weathered on both sides, measures $4\frac{3}{8}$ inches by $1\frac{3}{8}$ broad, has a rough central ridge, a large bulb of percussion, and is in sectional thickness $\frac{3}{4}$ inch. I have some shorter fragments approaching the same character.

It will not have escaped the notice of many readers that Dr. Schliemann found a number of obsidian "blades" (flakes, no doubt) in one of the last opened of his tombs at Mykenæ, together with twenty-five arrow-heads of flint. Future discoveries in Greece will furnish additional proofs of the general use of this material in early times, and I have little doubt that Melos served as the "Sheffield" of Greece, in the obsidian trade. I had myself the fortune to pick up a small fragment of the substance amongst the ruins of Tiryns.

I have placed the series of flakes, cores, &c., in Charterhouse Museum, where they can be seen by anyone who is interested in them.

GERALD S. DAVIES

Charterhouse, Godalming

---

[1] Mr. John Evans, to whom I showed one of these, is of opinion that the marking has been produced in the second of the two ways suggested, viz., by blows administered by a small set or punch.

Ocean and Atmospheric Currents

IN a clever article in the *Quarterly Review*, on the geographical and scientific results of the Arctic expedition, which I have read with great interest, the following passage occurs:—"The polar streams flow southward as surface-currents as long as they remain under the influence of northerly winds. When they reach the region of south-westerly winds they disappear under the warm waters of the Gulf Stream. And this for the simple reason that in each instance the stream, as Sir George Nares says, will take the line of least resistance. In the case of a stream going before the wind, this will be on the surface; when going against the wind, the line of least resistance will be some distance below it."

It is certainly very clever of ocean currents to dip below the surface, when they meet with a foul wind, but that they do so requires proof, especially as the warm current in the North Atlantic, bound presumably from the equatorial to the North Polar regions, makes a detour all along the north coast of South America, deflected by the north-east trade when it might apparently have accomplished its purpose so much more directly by the simple expedient of dipping beneath the surface. I would beg to suggest that the disappearance of the polar streams under the warm waters of the Gulf Stream, as indicated by the writer in the *Quarterly*, is to be accounted for in a far simpler manner, viz., because owing to the high temperature of the Gulf Stream in the latitude where this particular phenomenon takes place, it is lighter than the fresher but far colder water of the polar stream.

While I regret to differ from Sir Geo. Nares, backed by so great an authority as Mr. Croll, I must question the possibility of wind piling up water to any great extent either on the surface of the open ocean, or even in more confined water, of either great or uniform depth, as the water will, under those circumstances, re-establish its equilibrium by running off below the surface.

We know that in both the polar and equatorial basins, we have large volumes of water constantly running in at the bottom, or in case some of my readers may disagree with me, with reference to the polar basins, I will put it more guardedly, and say at some distance below the surface; these currents must displace on the surface a body of water exactly equal to their own volume, and this body of water must necessarily run off in that direction in which it meets the least resistance. For the sake of brevity I leave out the consideration of evaporation and precipitation, which bear a very small proportion to the large volume of these currents.

I have in a previous paper pointed out that "Heavier water flowing continuously from a higher level (*i.e.*, in the case of the ocean from the surface) into the bottom of any basin of lighter water must displace and raise a body of water equal to its own volume. The lighter water will just as surely be lifted and buoyed upwards by the heavier water as a ship, a piece of cork, or any other substance having a less specific gravity than water, and when this lighter water is raised above the level of its own basin it will naturally flow off in the direction in which it meets the least resistance."

To conclude, I argue that while the wind undoubtedly influences the direction taken by ocean currents, difference of gravity, and not wind, is the principal promoter of them. The perfect agreement between the two systems of ocean and atmospheric currents alluded to in the *Quarterly* is, in my opinion, to be accounted for from similar causes producing similar effects.

How can the winds influence ocean currents running for thousands of miles below the surface, or how can they influence the direction of the lower strata of surface currents ranging say from 50 to 600 feet in depth, the latter being the depth of the Gulf Stream off Hatteras? DIGBY MURRAY

January 25

MR. DIGBY MURRAY (vol. xv. p. 294), in common with a great number of meteorologists, maintains that the surface-trades have come, as upper-currents, from the Arctic and Antarctic regions, and that the prevailing westerlies of the extra-tropical regions have come, as upper-currents, from the equator, without intermingling their volume in the district of the tropical calms.

He argues that this *must* be the case, because the surface-trades on the interior borders of the tropical calms differ from the westerlies on the exterior borders in their degrees of electricity, and of saturation, and in other particulars.

I regard this argument as incontestably sound, provided always that no objection can be taken to the assumption on which it rests. That assumption may thus, as I conceive, be fairly stated: "Atmospheric currents differing greatly in character must have travelled from widely distant regions of the globe."

This premise is plausible, and the objection which I have to offer to it rests upon a fact which is, unfortunately, obscure, and which has received very little attention.

Some light is frequently thrown on the more general and permanent atmospheric circulation of our globe by the analogy of the local and temporary systems of circulation which we examine in our own latitudes. Now the *most local* currents often differ very remarkably in character according to the direction in which they move: *e.g.*, the easterly winds felt on the south border of a small anticyclone, if pursued for a very limited distance into the district in which they begin to travel from the south, are often found to have undergone complete change in their electrical conditions, in the aspect of the clouds which they carry, in their humidity, in their amount of ozone, and finally even in their effects on the animal frame. Still more extraordinary are the alterations often noticeable in the different segments of very local cyclonic circulations. In the case of the smallest secondary depressions I have, very frequently indeed, been struck by the wonderful alteration in the several atmospheric conditions, and especially by the reversal of the electrical conditions, which immediately attends the springing up of a northerly breeze, when the barometric minimum has passed to the east. This breeze, in many of these examples, occupies a very short as well as very narrow belt, and is only of a few hours' duration. What is more important, it is usually *of very limited depth*. The synchronous upper-current observations at which I have been for some years at work, prove that in many instances of very local depressions the cirrus travels from southerly or westerly points for many hundred miles on all sides of the small depression, as well as immediately over it, in some cases very slightly affected, in others absolutely unaffected, by the limited circulation at the earth's surface.

Until therefore it can be shown (in contradiction to what is indicated by this fact) that our most local currents, if differing in character, have travelled to us at a great elevation from very high and very low latitudes respectively, I cannot hitherto regard Mr. Digby Murray's reasoning as furnishing an "absolute proof" of the soundness of his position.

From Mr. Murphy's criticisms on my former argument I do not retire, as Mr. Digby Murray may possibly complain that I have done from my discussion with himself, behind a veil of cirrus, after the convenient fashion of the Homeric heroes. But as I have already stated, my agreement with his view that "the imperfection of the Arctic as compared with the Antarctic depression is due to the amount of land in the northern hemisphere" (though differing from him as to the nature of the relation between the cause and the effect), it is perhaps hardly necessary for me to say that from his proposition in NATURE (vol. xv. p. 312) I am bound to dissent. I do not think that on Mr. Murphy's hypothetical globe, possessed of an atmosphere containing no aqueous vapour, the currents would "act as in our actual atmosphere," or in a manner at all analogous to that which he describes. On this point I am afraid we must agree to differ for the present. W. CLEMENT LEY

February 7

Auroric Lights

HAVE the auroric lights been studied in regard to their relations with changes in the weather? From casual observations made during the last twenty years it would appear that there are at least two distinct kinds of light so classed. One is brilliant and transparent, of a white, yellowish, bluish, or yellowish-red colour: while the other is semi-opaque and of a bloody red colour. The latter generally seems to be considered in Ireland a forerunner of bad weather, or, to quote a Connemara shepherd, "Them bloody lights are bad." The first kind generally appear as intermittent pencils of light, that suddenly appear and suddenly disappear. Usually they proceed or radiate from some place near the north of the horizon; but I have often seen them break from a point in the heavens, this point not being stationary but jumping about within certain limits. The brilliant aurora of September, 1870, was one of the latter class, except that the centre of dispersion was not a point, but an irregular figure, sometimes with three sides, but changing to four and five-sided. It began as rays near the north horizon and proceeded up into the heavens in a south-south-east direction. Sometimes, however, these lights occur as suddenly flashing clouds of light, like those of July 16 last, which were of a white colour; but at other times I have seen them of blue and reddish yellow. If this class of lights are watched into daylight they appear somewhat like faint rays of a rising sun. One morning while travelling in West Galway, in the twilight, they were very brilliant, and quite frightened the driver of the car, who thought the sun was going to rise to the north instead of at the east.

The second, or bloody-red light, usually occurs in clouds floating in one direction up into the heavens, but often depressed over a portion of the sky. I have never seen them coming from the eastward, and only on a few occasions from the southward, they generally proceeding from the west, north-west, or north. If both kinds of light occur at the same time, the second, while passing over the first, dim them. If the second class are watched into daylight they appear as dirty misty clouds that suddenly form and disappear without your being able to say where they came from or where they went to, or as a queer hazy mist over a portion of the sky that suddenly appears and disappears, or as misty rays proceeding from a point in the horizon. Generally when these clouds occur there is a bank of black clouds to the westward.

This season has been very prolific in auroric light, as there have been few nights since the 1st of October last in which they did not appear, sometimes, however, very faint. Generally they were lights of the second class, but on a few occasions there were a few rays of the first associated with them; on wet nights they made the rain-clouds or mist of a reddish purplish colour; tints of which could be seen in some of the excessively dark nights we had in November. On many occasions they were late in the night, being very common and brilliant during the "dark days" of December a few hours before dawn (about five o'clock). I have watched them carefully this season to see if we had a chance of fine weather, but each time we had a fine clear day they appeared also and the weather broke again. Last week I only saw white lights of the first class, very faint on two nights, but the weather has not cleared yet. It has, however, become seasonable, as we have had showers of sleet and snow, while previously it was like spring weather, the trees all budding out, innumerable birds singing morning and evening, and flies and wasps flying about. G. HENRY KINAHAN

Ovoca, January 27

On the Sense of Hearing in Birds

THE sense of hearing is doubtless of much assistance in discovering the food of such birds as the scansores—to wit, woodpeckers, creepers, wrynecks and the like, which feed on insects.

On one occasion, in a Canadian forest, whilst seated close to a rotting pine trunk, I heard distinct scratchings in the interior, as if mice were nibbling the wood, and on splitting open the trunk, numerous large white larvæ of *Hylesinidæ* "woodworms" were found busily employed in making their tunnellings throughout the soft substance of the decayed wood.

Now, while these sounds were audible to human ears, it may be fairly believed that they would have been readily detected by the woodpecker, which may be often observed to halt suddenly on its way up a pine trunk. This *trait* in the mode of climbing is noticeable more or less in all the insectivorous climbers, and appears to me to be caused partly by the bird listening for the sounds produced by insects either in the bark or in the wood. I noticed this particularly in the case of the great black woodpecker (*P. pileatus*) or "log-cock," as it is named in Canada. It would suddenly stop on its way up a tree trunk, and after remaining perfectly motionless for a short time, commence to attack the bark and wood with great vehemence. Every one who has travelled in North American forests will have observed how the excavations made by woodpeckers are often confined to one side of a tree, or to particular situations. And not only on decayed parts, but, as in the case of the extremely tough cedar (*T. occidentalis*), where openings of several inches in circumference have been made through several inches of perfectly fresh wood in order to reach the decaying central layers where wood-eating beetles deposit their eggs and the animal is matured. Admitting that it may have been induced to dig out the insect by tracing the external opening inwards, still in the case of the larvæ the wandering from its birth-place, and the sounds consequent on the tunnelling process, would assuredly be heard by a bird whose ears had been trained to such delicate noises through the necessities of its mode of life. I can therefore well believe that auscultation is of great service to such birds, and also to nocturnal species in discovering their prey. A. LEITH ADAMS

Royal College of Science, Stephen's Green, Dublin

Tapeworm in Rabbits

I WOULD suggest that the tapeworm referred to by Mr. G. J. Romanes is like the Bothriocephalus of man—perhaps a species of the same genus. This is not supposed to have a cystic state, but to be developed from a ciliated embryo taken into the system on raw or badly-cooked vegetables, which have been watered by sewage from cesspools, in which the eggs will remain alive for months.

In the same way the eggs of the rabbit's tape-worm probably remain in the animal's droppings till set free in rain as ciliated embryos. As the rabbit feeds on the vegetation watered by such rain, there is no difficulty in understanding how the embryos would reach his alimentary canal. R. D. TURNER

Meteor of January 7, 10.31 P.M.

THE fine meteor mentioned in NATURE, vol. xv. p. 244, and also seen by Mr. W. H. Wood, p. 295, was observed by many other persons; and as your correspondent asks for another observation of it, the following may be useful:—"J. L. M'C.," writing from Putney Hill, London, says: "As near as I could judge, it appeared between the stars Castor and Pollux (α and β Geminorum), and its course lay almost due north-east, passing over the stars λ and ψ Ursæ Majoris, and disappearing a little beyond the latter star. It was of great brightness, left a tail of fire in its wake about two degrees in length, and was visible some ten seconds." This account, compared with the other two referred to, stands as follows:—

Place.	Meteor.					Duration in seconds.
	Begun		Ended		Length of path.	
	R.A.	Decl.	R.A.	Decl.		
	°	°	°	°	°	
London	... 153	+ 43	... 200	+ 31	... 39	... Very slow.

From these paths the radiant point comes out near γ Eridani, R.A. 58°, Decl. S., 12°, and I can confirm this position from other meteors seen in January, including one as bright as Venus, on the 4th, 8.51 P.M., which exhibited the same slow, halting motion as that noted in regard to the fine one seen on the 7th. I have read other accounts of the latter, but they are mostly vague. At Bermondsey it was seen at 10.30, and described as large and remarkably brilliant, closely resembling in size and colour the meteor which appeared on September 24, 1876. It was of a bluish colour, left a long tail or streak of light in its wake, and its course in the heavens was from south-west to north-east. At 10.37 on the same evening a very large, brilliant meteor was seen at Lower Clapton, and this, no doubt, refers to the same object.

Mr. Barrington (NATURE, vol. xv. p. 275) notes another bright meteor, at 6 P.M., on January 19, but its apparent path shows it to have been different to the one seen by a correspondent at Wolverhampton, at 6.27, January 19, who writes that he witnessed a meteor of "unusual magnitude and brilliancy. It moved almost perpendicularly, in a southerly direction, very slowly, the time occupied in its passage being about seven or eight seconds."

Ashley Down, Bristol W. F. DENNING

THE UNITED STATES GEOGRAPHICAL AND GEOLOGICAL SURVEY OF THE WESTERN TERRITORIES UNDER DR. F. V. HAYDEN

Explorations in 1876.

WE have been furnished with some early notes upon the results of the work of Dr. Hayden's survey during the past year, from which we make the following extracts:—

"For reasons beyond the control of the geologist in charge, the various parties composing the United States Geological and Geographical Survey of the Territories did not commence their field-work until August. Owing to the evidences of hostility among the northern tribes of Indians, it was deemed most prudent to confine the labours of the survey to the completion of the Atlas of Colorado. Therefore the work of the season of 1876 was a continuation of the labours of the three preceding years, westward, finishing the entire mountainous portion of Colorado, with a belt of fifteen miles in width of northern New Mexico, and a belt twenty-five miles in breadth of Eastern Utah. Six sheets of the Physical Atlas are now nearly ready to be issued from the press. Each sheet embraces an area of over 11,500 square miles, or a total of 70,000 square miles. The maps are constructed on a scale of four miles to one inch, with contours of two hundred feet, which will form the basis on which will be represented the geology, mines, grass, and timber lands, and all lands that can be rendered available for agriculture by irrigation. The areas of exploration of the past season are located in the interior of the continent, far remote from settlements, and among the hostile bands of Ute Indians that attacked two of the parties the previous year."

The force was divided by Dr. Hayden into four parties. The first, for primary triangulation, under Mr. A. D. Wilson, with Mr. Holmes as artist and geologist, accomplished the survey of an area of about 1,000 square miles. The second, or Grand River party, under Mr. Garnett as topographer, and Dr. Peale as geologist, surveyed about 3,500 square miles. The third, or White River Division, with Mr. Chittenden as topographer, and Dr. Endlich as geologist, spent forty-eight days in absolute field-work, and reports a surveyed area of 3,800 square miles, in the accomplishment of which 1,000 miles of traverse were made, while forty-one main topographical stations and sixteen auxiliary ones were established. The fourth, or Yampah party, conducted by Mr. Bechler, topographer, assisted by Dr. White, geologist, surveyed about 3,000 square miles. Thus, during the two months of last autumn, these active explorers surveyed about 11,300 square miles of territory (that is more than the whole of the southern or lowland part of Scotland) with sufficient accuracy and detail to permit of the construction of a general map on this scale of four miles to an inch, and with contour lines at successive elevations of 200 feet to mark the main topographical features. Fortunately the geological structure is of extreme simplicity, otherwise such rapid and useful work would be impossible. Dr. Hayden and his associates are doing good service by making known in this way the main features of those vast territories, leaving the details to be worked out at a later time.

Among the most interesting geological results obtained last year are some additional particulars regarding the brackish water-beds lying at the base of the tertiary rocks of these western territories. Three new species of

Unio were found, making six in all, now known to occur in these strata.

"They are all of either distinctively American types or closely related to species now living in American fresh waters. They represent by their affinities the following living species :—*Unio clavus*, Lamarck ; *U. securis*, Lea ; *U. gibbosus*, Barnes ; *U. metaneorus*, Rafinesque ; and *U. complanatus*, Solander. They are associated in the same stratum with species of the genera *Corbula*, *Corbicula*, *Neritina*, *Viviparus*, &c., and which stratum alternates with layers containing *Ostrea* and *Anomia*. The close affinity of these fossil *Unios* with species now living in the Mississippi river and its tributaries, seems plainly suggestive of the fact that they represent the ancestry of the living ones. An interesting series of facts has also been collected, showing that some of the so-called American types of *Unio* were introduced in what is now the great Rocky Mountain region as early as the Jurassic period, and that their differentiation had become great and clearly defined as early as late Cretaceous and early Tertiary times. Other observations suggest the probable lines of geographical distribution, during the late geological periods of their evolutional descent, by one or more of which they have probably reached the Mississippi river system, and culminated in the numerous and diverse forms that now exist there.

"The work of the past season shows very clearly the harmonious relations of the various groups of strata over vast areas, that although there may be a thickening or a thinning out of beds at different points, they can all be correlated from the Missouri river to the Sierra Nevada basin. The fact also that there is no physical or palæontological break in these groups over large areas from the Cretaceous to the Middle Tertiary, is fully established. The transition from marine to brackish water forms of life commences at the close of the Cretaceous epoch, and without any line of separation that can yet be detected, continues on upward until only purely fresh-water forms are to be found. Dr. White, an eminent palæontologist and geologist, says that the line must be drawn somewhere between the Cretaceous and Tertiary epochs, but that it will be strictly arbitrary, as there is no well-marked physical break to the summit of the Bridger group." A. G.

ALLOY OF PLATINUM AND IRIDIUM FOR A NEW METRIC STANDARD OF LENGTH

THE Warden of the Standards has, in his valuable annual reports, described the steps which have been taken to secure new International Metric Standards, and Mr. Chisholm has also given abundant information as to the various points of interest connected with their preparation and preservation. The advantage of employing an alloy of platinum and iridium appears to have been so conclusively demonstrated that the French Chamber granted, in November, 1875, 260,000 francs (10,400*l.*) for the expenses of constructing the new International Prototype Standards, and, of this sum, 257,500 francs were required for the cost of an alloy containing 90 per cent. of platinum, and 10 per cent. of iridium, of which they were to be made.[1]

The preparation of a bar for a standard of length has been undertaken for the Association Géodésique Internationale by Messrs. Johnson, Matthey and Co., who presented the results of their labours to the Academie des Sciences on December 4 last.[2] The platinum and iridium used were prepared by the processes of MM. St. Claire Deville and Debray, and they were analysed in their laboratory before fusion. Mr. George Matthey thus describes the method by which this difficult task was accomplished. Five ingots were prepared by melting together in each case 450 ounces of platinum and 55 ounces of iridium. These were then cut in small pieces by the aid of an hydraulic press, and the fragments melted together and kept fluid by a flame of coal gas and oxygen. The ingot obtained was laminated, cut into strips, and again melted into an ingot, which appeared to be very homogeneous and free from roughness or visible flaws. This ingot was forged into a bar 35 cm. long, 7·5 cm. wide, and 2·5 cm. thick. The greater part of this was repeatedly annealed and rolled between polished cylinders of steel until it was 4·10 metres long, 21 mm. wide, and 5 mm. thick, which were very nearly the required dimensions. Then a perfectly rectangular form was imparted to the rule by means of a "drag-bench," and the finishing was effected by a planing machine, as the alloy, owing to its extreme hardness, removed iron from the plates through which it was drawn.

After Mr. Matthey's communication had been read, M. St. Claire Deville gave the result of a careful examination to which he had submitted the bar. He found that the alloy in the form of an ingot has a density 21·508 at 0° C., an oblong mass cut from the bar, was found to be, after annealing, of the density 21·516, which showed that when annealed, at a high temperature, the metal assumes very nearly the density of the fused metal. It was proved by analysis to contain—

	I.		II.
Platinum	89·40	...	89·42
Iridium	10·16	...	10·22
Rhodium	·18	...	·16
Ruthenium	·10	...	·10
Iron	·06	...	·06
	99·90	...	99·96

From which the following figures were deduced :—

	Proportion.	Density at 0 C.	Volume.
Platinum Iridium at 10 per cent.	99·33	21·575	4·603
Iridium in excess	0·23	22·380	0·010
Rhodium	0·18	12·000	0·015
Ruthenium	0·10	12·261	0·008
Iron	0·06	7·700	0·008
	99·90		4·644

Density at 0° C. calculated from analysis No. I. = 21·510
" " " " No. II. = 21·515

which agree perfectly with the results of the analyses, and with regard to them it should be pointed out, that it is very difficult to purify platinum and iridium, and that the smallness of the amounts of rhodium and ruthenium present affords additional evidence of the care with which the refining was performed. It is well known that all substances capable of being tempered, such as glass and steel, change their dimensions in time, others which become crystalline with changes of temperature, as zinc does, are in the same case. The researches of Mr. Wild have shown that hyalite, a variety of opal, appears to be free from this mobility of form, and consequently of density. With facts such as these in view, M. St. Claire Deville proposes to make certain experiments in conjunction with M. Mascart, to determine whether platinum-iridium is subject to a permanent change of volume or not.

The work upon which the accuracy of standards depends is of the highest importance, and Mr. Matthey has well sustained the reputation of this country for technical skill. Metallurgists will appreciate his success, for they can recognise the difficulty he has had to contend with in the fusion and working of such an alloy, but for those who are less familiar with the conditions which had to be met, we would quote the graceful words of MM. Dumas and Deville. The former observed : "Il a exécuté ce travail avec un succès complet sous le double rapport de la composition exacte de l'alliage et de la forme de la règle . . . . l'intérêt actuel est évident, et la production enrichit l'outillage scientifique d'un alliage doué de propriétés précieuses." M. Deville said : "Qu'il me soit permis, en terminant, de remercier le métallurgiste habile, le savant distingué, M. G. Matthey, qui a accompli son œuvre avec un talent et un désintéressement qui ne seront pas perdus pour la science."

W. CHANDLER ROBERTS

[1] Tenth Annual Report of the Warden of the Standards, 1876, p. xxxiv.

[2] [illegible]

THE UPPER COLORADO[1]

AMONG the most eminent services rendered by American geologists to the cause of science, there can be little hesitation in placing the labours of Lieut. Ives and Dr. Newberry as given to the world in their well-known Report on the Colorado country of the West. By pen and pencil they brought vividly before the eye and the imagination the structure and scenery of a region so singular and so stupendous in its memorials of slow prolonged subaerial erosion as not only to throw every other known district of the kind far into the shade, but to furnish proofs of the potency of river-excavation, which even the keenest advocates for the power of rain and rivers at first hesitated to believe. Since that Report appeared, however, additional and confirmatory illustrations of the same marvellous scenery have been published by other observers, notably by Hayden and Powell. The gorges of the Colorado, with walls sometimes more than a mile high and running for nearly five hundred miles across the tableland, are now more or less familiar, from descriptions and sketches, to the geologists of all countries. They are admitted, too, to be due, as Dr. Newberry first contended, to the gradual erosive action of the rivers by which they are traversed. The whole of this Colorado basin or plateau is justly regarded as the most magnificent example on the face of the globe of how much the land may have its features altered by the agency of running water.

In the present Report Dr. Newberry gives the results of a second exploration to the Colorado, but to a more northern or higher tract than that embraced in his previous journey. The Expedition took place as far back as 1859, and this Report was written and sent to the authorities by the beginning of May, 1860. At that time, however, the Civil War was impending, by which not only this publication but many others of importance were arrested. The recent surveys of the Department of the Interior and the Bureau of Engineers having called renewed attention to the Colorado region, Col. Macomb and Dr. Newberry have succeeded, at last, in inducing the authorities to print and circulate their account of the observations made by them seventeen years ago. It is a welcome contribution to the literature of the subject. Dr. Newberry, by his summary and his narrative of detail, combined with his clever lithographic sketches, presents us with so vivid a picture of the landscapes through which he has wandered and of the geological structure which has given them their character, that nothing further can be desired save a personal visit to the marvels themselves under his experienced guidance. Four of the most characteristic views are here reproduced as woodcuts.

Westwards from the Rocky Mountain ranges to the head of the Gulf of California the basin of the Colorado stretches as a vast plateau, broken by the transverse gorge of the Great Cañon, at the bottom of which, from 3,000 to 6,000 feet below the level of the plain, the river wanders to and fro for nearly 500 miles. The plateau is further marked by a succession of terraces ending in steep walls sometimes 1,000 feet or more in height, and by occasional isolated mountain areas which rise above the general level like islands from the sea. These various inequalities, however, when seen from any of the eminences bordering the plateau are almost lost in the vast sweep of the level plain. On all sides the table-land is surrounded with mountain-ranges which seem on the whole to have a meridional direction, so that the table-land itself would appear to be a tract which has somehow escaped plication during the movements by which the encircling ridges were formed. The isolated mountains on this plain, however, indicate the same north and south trend, are composed like these bounding ridges, and may be referred to the same series and to a similar mode of origin.

In that upper part of the Colorado plateau now described by Dr. Newberry we recognise the same geological formations as well as the same striking features of colour which have given its name to the chief river. The oldest rocks belong to the Carboniferous system. Thence up to strata believed to represent the earlier Tertiary series of Europe there is a continuous conformable development of stratified deposits. These strata spread out in horizontal sheets over the plateau. On the eastern and western margins they have been heaved up along the flanks of the mountain ridges, and here and there, where an isolated axis of elevation or a dislocation occurs on the plain, they have likewise been upturned. But for the most part they retain their horizontality, so that the lower formations are not seen, except where they have been cut into at the bottoms of the cañons. The Carboniferous limestones contain such characteristic brachiopods as *Productus semireticulatus*, *P. scabriculus*, *P. punctatus*, *Spirifer*, and *Athyris*. The earliest records of that region, therefore, are those of a sea-floor, which must have stretched eastwards across what is now the range of the Rocky Mountains towards the land which then lay over the site of the Eastern States. The thickening out of the marine limestones towards the west establishes this point in the ancient physical geography of the American continent. Above the Carboniferous limestones and shales lie a conformable series of bright red, green, and yellow sandstones, shales, and marls, which are regarded by Dr. Newberry as Triassic, and perhaps partly Jurassic, and which pass conformably upward into massive yellow and grey sandstones and green shales, which are placed on the horizon of the Lower Cretaceous rocks. These latter strata, containing many cycads and ferns, with other traces of terrestrial conditions, form the surface over an enormous area of the table-land. As they approach the broader valleys they end off in a steep cliff or bluff like a sea-wall, often cut along the edges into numerous detached tables, pinnacles, and quaintly-shaped outliers. The red strata underneath form the platform out of which the deep gorges have been eroded and their bright colours running in parallel stripes along the walls of the cañons and the faces of the isolated fragments and pillars give an extraordinary character to the fantastic forms into which the rocks have been worn.

The want of any evidence of disturbance from palæozoic up into older Tertiary time is dwelt upon by Dr. Newberry in this Report as showing the simplicity of the structure of this part of the continent. The facts which he brings forward help to make our ideas still clearer of the stages by which the present physiography of America has been reached. He demonstrates the truth of his previous conclusion that the region of the Colorado is one of vast erosion, and he gives some interesting indications of the extent of this denudation. He shows that the great plain with its surface of firm Lower Cretaceous sandstone was once covered by a continuous sheet of soft Middle and Upper Cretaceous shales, of which scattered mounds and millions of loose fossils are strewn over the plain, and which rise along its margin into an upper plateau overlooking the great tableland and presenting a steep escarpment towards it. These overlying strata are at least 2,000 feet thick. There cannot be any doubt, therefore, that previous to the erosion of the profound gorges the tableland was buried under 2,000 feet of soft strata, all of which have been removed except these fragmentary relics. Dr. Newberry satisfactorily disproves the notion that this denudation could have been effected by any violent current like those waves of translation which used to be called in to account for the existence and distribution of the glacial drift and erratic blocks. No one can read his pages without a conviction that he correctly regards the whole erosion of the Colorado region as one vast continuous process in which air, rain, frosts, and rivers have been the main agents.

---

[1] Geological Report, by J. S. Newberry, M.D., of the United States Exploring Expedition under Captain J. N. Macomb, from Santa Fé, New Mexico, to the Junction of the Grand and Green Rivers of the Great Colorado of the West. (Washington, 1876.)

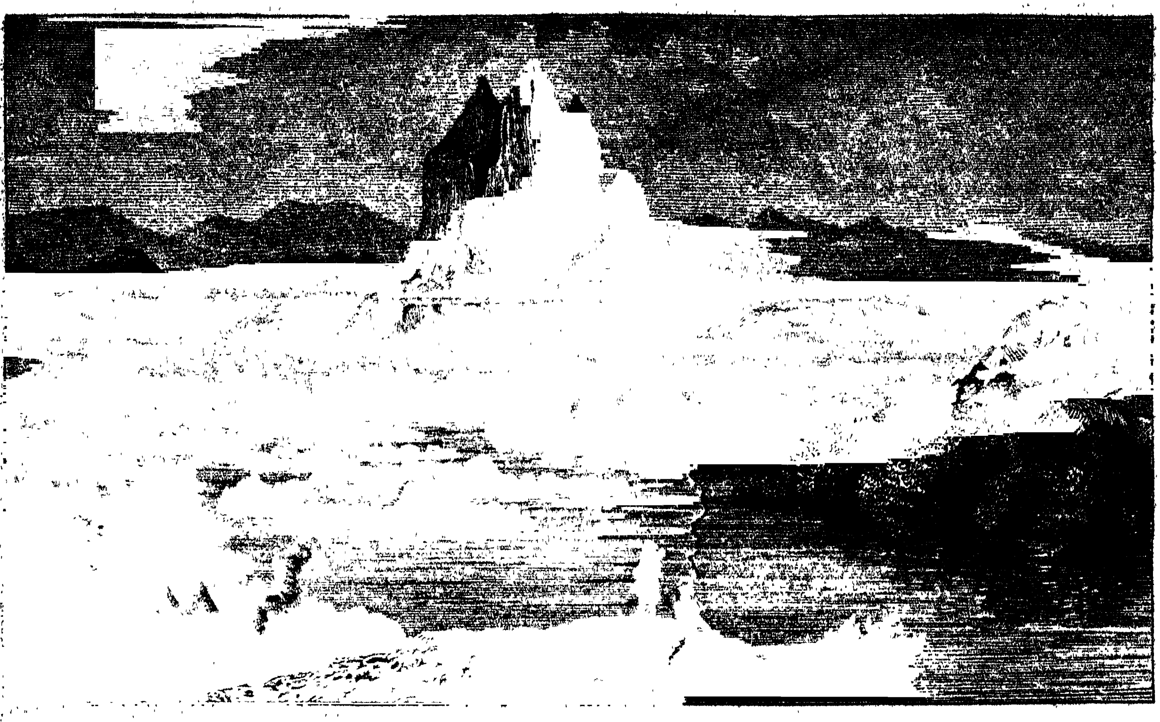

FIG. 1.—The Needles, looking South-westerly.

FIG. 2.—Lower San Juan, looking West.

The observations contained in this Report upon the structure of the isolated ridges which now and then disturb the horizontality of the stratified formations of the great plain are of considerable interest and importance. They show that the elevation of these ridges did not take place until after the deposition of the older Tertiary rocks, and that this elevation was not merely due to the protrusion of hypogene masses, but was part of a general and prolonged movement of plication by which the present axis of the North American continent was determined. The whole of the sedimentary formations of the plain are found bent up against the granitic nucleus, which, like a wedge, has

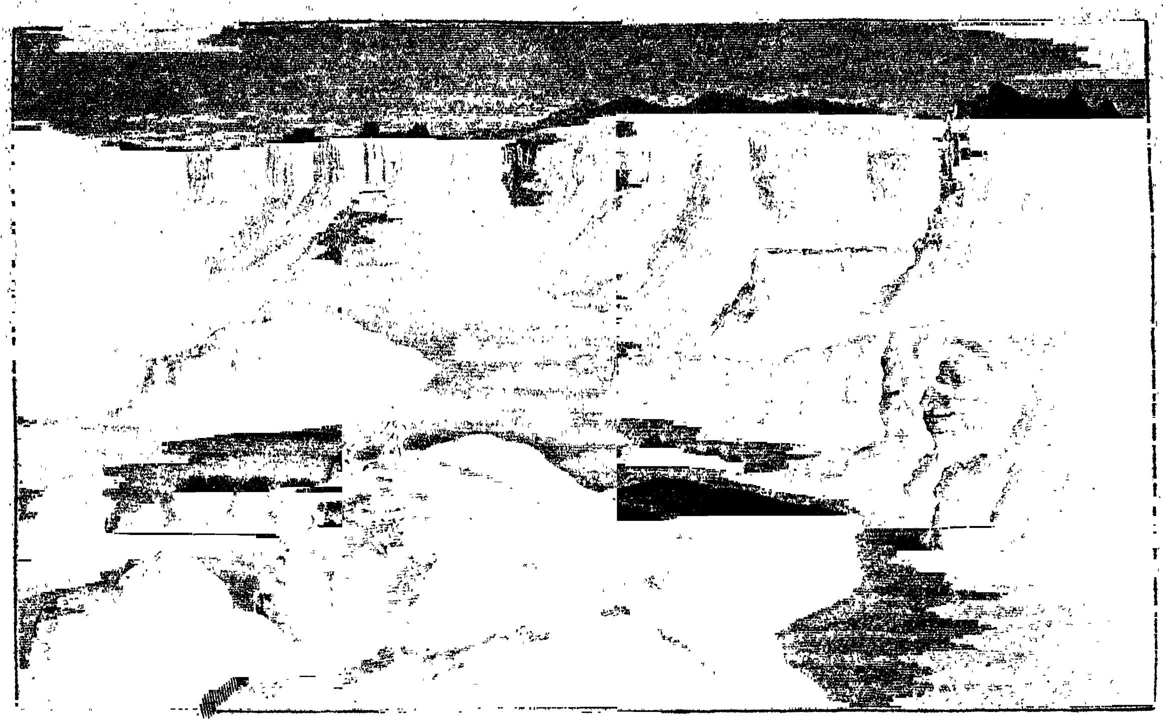

Fig. [illegible].—Head of Labyrinth Creek, looking South-easterly.

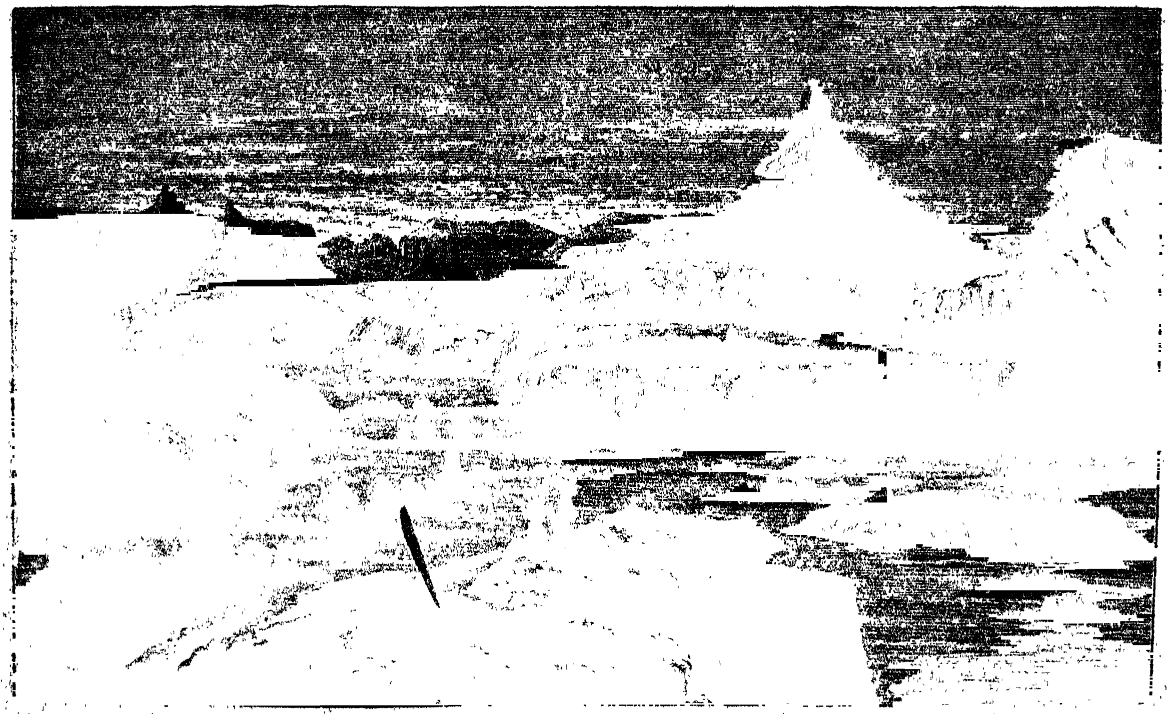

Fig. 4.—Head of Cañon, Colorado. Erosion of Triassic Series.[1]

been driven through them. No proof of any such movement or of any volcanic action older in date than the Eocene, or Upper Cretaceous rocks, was obtained in this Expedition. So that we have here, apparently, an area where any subterranean movements which occurred never disturbed the conformable succession of deposits during that vast section of geological time from the Carboniferous (or even from the Silurian) up to the Eocene period. Whether the traces of terrestrial surfaces indicated by the plants and lignite beds of the Lower Cretaceous series, occurring as they do with marine strata below and above them, are to be regarded as marking oscillations of the crust, or as due merely to the gradual up-filling of the old sea-basin and its conversion into lagoons and terrestrial surfaces which were subsequently gently submerged again beneath the Middle and Upper Cretaceous seas, may be a question for discussion. It would seem that coincident with or subsequent to the pre-Miocene plication and upheaval, volcanic action began in the Western States. Dr. Newberry gives a drawing and a description of a singular basaltic rock called the Needles (Fig. 1) rising to a height of 1,700 feet above the Cretaceous floor of one of the tributary valleys of the San Juan, and regards this mass as having been intruded among the strata and as now left visible owing to its superior hardness, while the surrounding and overlying softer rocks have been washed away. But in his former Report in conjunction with Lieut. Ives, he showed the existence of a group of large extinct volcanoes in the San Francisco mountain group in Arizona, lying on the south side of the Colorado basin. The lava-streams are yet so fresh there that he supposes that the last eruption can hardly have taken place more than a comparatively few years ago. Considerably further to the east in New Mexico, San Mateo rises as another important extinct volcanic cone 11,000 or 12,000 feet high, whose most recent lavas are so fresh that "it is difficult to believe that they have been exposed to the action of the atmosphere even for so much as a hundred years." Dr. Newberry remarks that similar but smaller volcanic vents equally recent in appearance, but equally inactive now, are scattered over the entire area of the central tablelands from Mexico far up into the British possessions.

The author, who is an accomplished palæontologist as well as an active and gifted geologist, has added a valuable Appendix, in which he gives descriptions of the Carboniferous and Triassic fossils obtained by him in the course of the Expedition, and to which Mr. F. B. Meek[1] contributes an account of the Cretaceous fossils collected. It should be added, that besides the lithographic sketches the Report is enriched by some excellent plates of fossils. ARCHIBALD GEIKIE

DEEP SEA MUDS[2]

II.

Peroxide of Manganese.

PEROXIDE of manganese occurs widely in ocean deposits, either as nodules, incrustations, or as depositions on the bottom itself. It has been found most frequently in the nodular form in the deep sea clays far from land. It also occurs in the organic oozes, when these contain much volcanic *débris*, or are near volcanic centres.

In shallow water, near some volcanic islands, it covers shells and pieces of coral or pumice with a light brown incrustation. It has been met with very sparingly, if at all, in shore deposits removed from volcanic centres.

In my preliminary report above referred to, I stated that further investigation might show that manganese nodules and depositions abound in these regions where we have much of the *débris* of augitic or heavy lavas.

A re examination of specimens since our return confirms this view. Wherever we have pumice containing much magnetite, olivine, augite, or hornblende, and these apparently undergoing decomposition and alteration, or where we have evidence of great showers of volcanic ash, there we find the manganese in greatest abundance. This correspondence between the distribution of the manganese and volcanic *débris* appears to me very significant of the origin of the former. I regard the manganese, as we find it, as one of the secondary products arising from the decomposition of volcanic minerals.

Manganese is as frequent as iron in lavas, being usually associated with it though in very much smaller amount. In magnetite and in some varieties of augite and hornblende the protoxide of iron is at times partially replaced by that of manganese.

In the manganese of these minerals and in the carbonic acid and oxygen of ocean waters we have the requisite conditions for the decomposition of the minerals, the solution of the manganese, and its subsequent deposition as a peroxide.

The carbonic acid converts the silicates of the protoxides of manganese, and the protoxides of manganese into carbonate of manganese, and thus prepares the way for oxidation by the oxygen of the water.

It is probable that the action of the carbonic acid is not apparent, and that the manganese is at once deposited as a high oxide if not as the peroxide. This theory is essentially the same as that which Bischof gives for manganese ores generally. I have laid a series of these manganese depositions on the table. An inspection of these and their localities will show that in the clays and oozes the depositions are nodular in form. If a section be made of one of these, a number of concentric layers will be observed arranged around a central nucleus—the same as in a urinary calculus. When the peroxide of manganese is removed by strong hydrochloric acid, there remains a clayey skeleton which still more strongly resembles a urinary calculus.

This skeleton contains crystals of olivine, quartz, augite, magnetite, or any other materials which were contained in the clay from which the nodule was taken. In the process of its deposition around a nucleus, the peroxide of manganese has inclosed and incorporated in the nodule the clay and crystals and other materials in which the nucleus was imbedded. The clayey skeleton thus varies with the clay or ooze in which it was formed. Those from a fine clay usually adhere well together; those from a globigerina ooze have an areolar appearance; those from a clay with many fine sandy particles usually fall to pieces. Mr. Buchanan informs me that the purest portions of these nodules, that is those portions made up of closely-packed concentric layers, contain from 30 to 34 per cent. of the peroxide.

Taking the nodule as a whole, it will of course contain very much less than this. The nucleus varies in each nodule, and that part of a nodule which is made up of concentric layers will vary with each locality and with the depth from which it comes. We may expect, therefore, that analysis will show considerable variations in the amount of alumina, silica, and metals, lime, &c., in the nodules from different stations. At some places in the Pacific the nodules show periods of deposition very distinctly. We have first a very compact nodule which may have a shark's tooth for a nucleus, and which appears to have been formed slowly. Then there would seem to have been a shower of ashes. After a time manganese was again deposited, inclosing in the nodule a layer of these ashes. The most frequent nucleus in the nodules is a piece of pumice or other volcanic fragment.

In deep sea clays, far from land, sharks' teeth, ear-bones of whales, and fragments of other bones are very often the nucleus around which the manganese is deposited. In one instance a piece of siliceous sponge forms the nucleus. In a globigerina ooze a portion of the deposit has apparently formed the nucleus. In these we have perfect casts of the foraminifera, but all the carbonate of lime has been removed. The volcanic fragments which have formed the nuclei of nodules appear frequently to have undergone peculiar alterations. For instance, obsidian is usually surrounded by beautiful agate bands.

When we found the bottom composed almost entirely of volcanic ashes, or so hard from other reasons that the sounding tube did not penetrate it, the manganese was deposited in layers over the bottom itself. Large pieces of this nature were taken several

---

[1] Since this article was written, the announcement of Mr. Meek's death has reached this country. A more disastrous blow could not have been inflicted upon the progress of palæontology in the United States. It is much to be desired that amid the universal regret with which the death of this able palæontologist is received, some record shall be published of the services he has done. His numerous papers are scattered through so many publications (for he seems to have been ever at the call of any one who needed his assistance), that probably a comparatively small number even of palæontologists are aware of them all.

[2] "On the Distribution of Volcanic Débris over the Floor of the Ocean; its Character, Source, and some of the Products of its Disintegration and Decomposition," by Mr. John Murray. Read at the Royal Society, Edinburgh. Continued from p. [illegible]

The escape of carbonic acid through the floor of the ocean near volcanic islands may in these regions greatly accelerate the processes which end in the deposition of the peroxide of manganese, and account for the great abundance of it in some such localities where we found it.

Native Iron and Cosmic Dust.

While examining the deposits during the cruise I frequently observed among the magnetic particles from our deep sea clays small round black-coloured particles which were attracted by and I found it difficult to account for the origin of these.

On our return home I entered into a more careful examination of the magnetic particles. By means of a magnet carefully covered with paper I extracted these particles from the deposits, from the pumice-stones, and from the manganese nodules of many regions. The great majority of these magnetic particles are magnetic iron ore and titaniferous iron, either in the form of crystals or as fine dust. In the clays and in the manganese nodules from stations far from land and in deep water there were again noticed many small round spheres among the magnetic particles.

On mentioning this to Prof. Geikie he suggested that I should try the method employed by Prof. Andrews, of Belfast, for detecting minute particles of native iron.

This process consists in moistening the magnetic particles, which have been extracted by means of the magnet, with an acid solution of sulphate of copper, when copper is at once deposited on any native particles which may be present. In this way I have detected native iron in many of our deposits, in the powdered portions of manganese nodules, and in pumice-stones.

Prof. Andrews tells me that there can be little doubt that the particles on which copper is deposited are native iron, as he has found that it is not deposited on nickel, and the chances of cobalt being present are very slight. Prof. Andrews warned me on the extreme precautions necessary in conducting these observations, that no iron from a hammer or other instrument should get at the specimen under observation.

It is true that all specimens of our deposits have been obtained by means of dredges and iron gear, and some of these particles may be from this source.

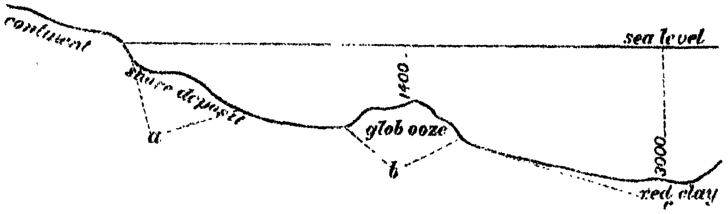
Many of the particles must have another origin. I have taken two of our manganese nodules, and washing them carefully, taking care to let no iron instrument come near them, have broken them by rapping them together. Then taking only the interior parts of these nodules I have pulverised them in a porcelain mortar. The magnetic particles were afterwards extracted by a magnet covered with paper. Now, on a glass slide under the microscope, and adding the sulphate of copper solution, there was in a few moments a deposit of copper on several small perfect spherules, varying in size from the $\frac{1}{1000}$ to the $\frac{1}{300}$ of an inch in diameter. I have placed some of these spherules under the microscope and now show them to the Society. It will be noticed that on one the copper is not deposited all over the sphere, but in ramified spider-like lines. On the cut surface of a meteorite, from Prof. Sir Wyville Thomson's collection, which I also exhibit, the copper is precipitated in precisely the same manner as on the little sphere on the manganese nodule. Besides the spherules on which the copper is deposited, there are others generally of a larger size and dark colour. These are, so far as microscopic examination shows, quite like the particles on the mammilated outer surface of this Cape meteorite, also from Sir Wyville's collection.

These spherules have hitherto only been noticed in those deposits in deep water far from land, and where for many reasons we believe the rate of formation of deposits to be very slow.

They occur also only in those manganese nodules which come from the same deep sea clays or deposits far from land.

The particles of native iron found in pumice-stones are not numerous, and never take the form of spherules so far as observed. Some of these particles of native iron may then come from the dredge. Other particles come from the pumice and the volcanic materials. Prof. Andrews long since showed that minute particles of native iron existed in basalt and other rocks. And lastly, the spherules of which I have been speaking, appear to have a cosmic origin.

The reason for these spherules occurring only in deposits far from land and in deep water, may be more apparent by reference to the annexed diagram, which might represent a section from the west coast of South America out into the Pacific 500 miles. Along the shores of the continent, as at *a*, we have an accumulation of river and coast detritus. At *b* in depths from 1,400 to 2,200 fathoms we have a globigerina ooze mostly made up of surface shells. At *c*, in a depth of 2,300 to 3,000 fathoms, all the surface shells are removed from the bottom. No coast detritus reaches this area, and we find in the deposit pumice stones, some volcanic ashes, manganese nodules, sharks' teeth, and ear-bones of whales. It is only in areas like this that we find sharks' teeth and ear-bones of cetaceans in any numbers. Some of them from the same haul are deeply surrounded with manganese deposit, and contain little animal matter, while others have no deposit on them, and seem quite recent. These, and other facts which might be mentioned, all argue for an exceedingly slow rate of deposition. Now it is in these same areas that the spherules of native iron and other magnetic spherules are found, both in the deposits and in the manganese nodules from them.



Finding them in this situation favours the idea that they are of cosmic origin, for in such places they are least likely to be covered up or washed away. It is certainly difficult to understand why the spherules on which the copper is precipated have not become oxidised. If nickel be present in them, this may retard oxidation to some extent.

The manganese depositions in our ocean deposits are very different in structure and composition from any of the ores of I have had an opportunity of examining, and the the deep sea far from land have not, so far as I know, any equivalents in the geological series of rocks.

All the subjects treated of in this paper are still under investigation, and at some future time I hope to present a much more detailed account.

These observations seem to me to give ground for the follow-

volcanic *débris*, either in the form of pumice or ejected fragments, are universally distributed in ean deposits.

pumice stones are continually being carried into the sea by rivers and rains, and are constantly floating on the surface of the ocean far from land.

Third.—That the clayey matter in deposits far from land is principally derived from the decomposition of the feldspar in fragmental volcanic rocks, though in the trade wind region of the North Atlantic the dust of the Sahara contributes much material for clay.

.—That the red earth of Bermuda, Bahamas, Jamaica, and other limestone countries, is most probably originally derived from the decomposition of pumice stone, while these limestones were in the process of formation.

Fifth.—That the peroxide of manganese is probably a secondary product of the decomposition of the volcanic rocks and minerals present in the areas where the nodules of manganese are found.

Sixth.—That there are many minute particles of native iron in deposits far from land; that some of these particles are little spherules; that these last, as well as some other spherules which are magnetic, have probably a cosmic origin.

the peroxide of manganese depositions in the deep sea are different in structure and composition from known ores of manganese.

Eighth.—That we do not appear to have equivalents of the rocks now forming in the deep sea far from land, in the geological series.

In conclusion, I have to acknowledge much assistance in these investigations from all my colleagues, especially my indebtedness to Sir Wyville Thomson and Mr. Buchanan.

Since my return I have received many hints from Profs. Tait, Geikie, Turner, Dr. Purves, Mr. Morrison, and other gentlemen.

In much of the mechanical work which an examination of these deposits has entailed, I have, both during the cruise and since my return, had the assistance of Frederick Pearcey.

OUR ASTRONOMICAL COLUMN

NEW COMET.—M. Stephan, Director of the Observatory at Marseilles, announces the discovery of a new comet by M. Borrelly on the morning of the 9th inst. It is described as bright, round, with a well-defined nucleus, and 3½ minutes in diameter. The first complete observation gave for its position—

February 8 at 16h. 57m. 58s. M.T. at Marseilles.
Apparent Right Ascension ... ... 17h. 13m. 22·7s.
" North Polar distance ... ... 91° 28′ 20″
Diurnal motion in R.A. + 1m. 44s. ; in N.P.D. − 3° 7′.

M. Borrelly was also the discoverer of the last unpredicted comet, on December 6, 1874, in which year six comets were observed ; in 1875 only two were observed, both known comets of short period ; in 1876 none.

THE OCCULTATION OF REGULUS ON FEBRUARY 26.—The occultation of a star of the first, or between the first and second magnitudes, is a sufficiently uncommon phenomenon to attract attention. Regulus will be occulted on the 26th instant while the moon is at a considerable altitude, and to facilitate the calculation of the times of immersion and emersion at any place in this country we will apply the very convenient method given by the late Prof. Littrow for distributing such predictions over a limited area.

Putting the latitude of the place = 50° + *l*, and expressing *l* in degrees, and the longitude from Greenwich = L, and expressing L in minutes of time, + if east, − if west, and founding the equations upon direct computations for Greenwich, Edinburgh, and Dublin, we find with the *Nautical Almanac* elements,

Time of Immersion = 12h. 47m·2 − [0·0095]*l* + [9·5191] L
" Emersion = 13h. 53m·5 − [0·2188]*l* + [9·3209] L
Angle at Emersion from N. Point } = 232°·8 − [0·185]*l* − [9·468] L

The quantities within brackets being logarithms and the resulting times for the meridian of Greenwich.

The following are the circumstances of the occultation at a few of our observatories; Greenwich time throughout :—

	Immersion.		Emersion.		Ang'e at Emersion.
	h.	m.	h.	m.	°
Cambridge	12	45·1	13	49·9	229
Dublin	12	35·4	13	42·5	235
Edinburgh	12	36·9	13	40·9	227
Greenwich	12	45·7	13	51·0	231
Liverpool	12	39·7	13	45·2	231
Oxford	12	43·7	13	49·5	232

No other occultation of so bright a star, visible in this country, will take place until July 28, 1879, when Antares will be occulted.

Amongst the Chinese observations collected by the Jesuit missionary, Gaubil, are a number of occultations of Regulus, the earliest of which is dated March 16, A.D. 501. While referring to this star, we may mention a remarkable approximation of several planets near it, which is also recorded in the Chinese annals, and which, so far as we know, has never been examined. As interpreted by Gaubil, the observation runs thus :—

In B.C. 27, second year Ho-ping, in the tenth moon, between the 20th and last day of the moon, Saturn distant from Regulus 1° (Chinese measure), Jupiter to the north-west 1°, Mars to north-west 2°.

The Chinese commenced their year at the new moon immediately preceding the sun's entry into the sign Pisces, and their months were lunar. Accordingly in B.C. 27 the first moon commenced soon after midnight on February 10, Greenwich time, and the tenth moon on the evening of November 2 ; the time indicated by the Chinese record is therefore probably between November 23 and December 2. Perhaps some one may have the curiosity to examine this reported conjunction of Mars, Jupiter, Saturn, and Regulus. We can state positively that an occultation recorded about forty years earlier, observed under the same dynasty, Han, and at the same station, that of the Chinese court at Si-gnan-fou, in the province of Chen-sy, actually occurred, according to our latest tables, and at the hour recorded in the Chinese annals.

THE SOLAR ECLIPSE OF 1567, APRIL 9.—Prof. Grant, in his valuable "History of Physical Astronomy," remarks that "the earliest eclipse which was unequivocally asserted to have been annular was one which occurred in the year 1567." It was observed at Rome by Clavius, of Calendar celebrity, who has recorded that when the obscuration was greatest there still remained round the moon's limb a very narrow ring of the solar light. Kepler ("Ad Vitellionem") found from his tables the sun would have entirely covered the moon, and hence considered that the luminous ring, mentioned by Clavius, was in reality the *corona*, visible during total eclipses of the sun.

The elements of the eclipse of 1567 obtained upon a similar system of calculation to that applied to other modern solar eclipses in this column are as follow :—

Conjunction in R.A. 1567, April 8d. at 23h. 17m. 10s. G.M.T.

	°	′	″
R.A.	26	30	57
Moon's hourly motion in R.A. ...		33	8
Sun's " " " ...		2	19
Moon's declination	11	27	45 N.
Sun's "	10	58	57 N.
Moon's hourly motion in decl. ...		9	6 N.
Sun's " " " ...		0	52 N.
Moon's horizontal parallax		57	36
Sun's " "		0	9
Moon's true semi-diameter		15	54·0
Sun's " "		15	41·7

The sidereal time at Greenwich mean noon, April 9, was 1h. 47m. 8s. If with the above elements we make a direct calculation of the circumstances of the eclipse at Rome we find a very great eclipse little short of totality ; began at 10h. 41m. os A.M., ended at 1h. 42m. 23s. P.M. mean times at Rome, magnitude 0·9972, so that the breadth of the crescent was about 2½ seconds. The eclipse would be total for a few seconds on the central line in this longitude, the augmented semi-diameter of the moon exceeding the sun's semi-diameter only 1″·5 ; but our result as it stands may very well explain the words of Clavius, the extremely narrow crescent of the solar disc still remaining, added to the probable visibility of the brighter part of the *corona*, giving to the naked eye the appearance of a narrow uniform ring of light.

NEW MINOR PLANET.—No. 172 of the group of small planets was detected by M. Borrelly at Marseilles on the 5th inst. ; at 12h. 8m. its R.A. was 10h. 35m. 36s., N.P.D. 80° 30′·9, twelfth magnitude. On the following night at 9h. 58m. its R.A. was 10h. 34m. 46s., N.P.D. 80° 29′·3.

METEOROLOGICAL NOTES

METEOROLOGY OF THE LIBYAN DESERT.—A second volume of Gerhard Rohlfs' great expedition into the Libyan desert has been recently published at Cassel, under the editorship of Dr.

W. Jordan of Karlsruhe, giving the detailed results of the researches of the expedition into the physical geography and meteorology of this region during the winter of 1873–74. Though the observations extended only over a comparatively brief period, yet from their evidently high quality, the ability with which they have been discussed, and the physical characteristics of the region, the results thereby obtained form an exceedingly valuable contribution to meteorology. The results of the two-hourly observations show, as regards the daily maxima and minima of atmospheric pressure that the forenoon maximum and afternoon minimum are very greatly in excess of the others, and that the difference between them indicates an amplitude of range in accordance with that given for this region in Buchan's recently published charts of diurnal barometric range. The temperature has a daily range of 24°·5, the maximum occurring about 3 P.M., and the minimum a little before 6 A.M. The lowest observed temperature was 23° in the earlier part of February. The minimum of vapour tension occurs about 6 A.M., and the maximum about 11 A.M. While the mean relative humidity at Cairo in winter is 65, it is only 51 in the desert, falling to 35, the minimum at 2 P.M., the dryness of the climate being thus very great. A humidity of only 17 was observed at Sandheim on February 12, at 2 P.M. Rain fell from February 1 to 4, thunder was heard on the second, and during next night 0·48 inch of rain fell, soaking the sand of the desert to a depth of about five inches—an amount of rain of rare occurrence in the district. The prevailing winds are north-westerly, those having the highest percentages being W. 16, N.W. 34, and N. 27, or 77 per cent. Warm springs occur in several of the oases, the highest observed being at Dachel, the temperature of which ranged from 92°·3 to 96°·8, or about 15° above the annual mean temperature of the locality. The magnetic declination was observed on January 1, at ten places variously situated between 25° 11′, and 29° 12′ lat. N., and 25° 31′ and 32° 34′ long. E. of Greenwich, the results of which, when compared with the observations of declination made in 1819-20 by Cailliaud indicates an annual variation of 6′·4, being closely approximate to that of Central Europe.

HEIGHT OF THE SEINE AT PARIS DURING 1876.—In the *Bulletin International* of the Paris Observatory for January 13, the height of the Seine is given for each day of 1876, as observed at Pont de la Tournelle and Pont Royal. The zero of the scale at Pont de la Tournelle is the lowest point to which the river fell during the great drought of 1719. The highest flood hitherto recorded measured 27 feet in 1658, and the greatest dryness 3·28 feet below the zero of the scale on September 29, 1865. During 1876 the greatest flood was 21 feet on January 17, the greatest dryness 0·89 foot, and the mean for the year 3·15 feet, being 0·82 foot below the mean calculated by Delalande.

OSCILLATIONS OF TIDES.—The meteorological *Bulletin* of the Brussels Observatory for January 26 calls the attention of meteorologists and physicists to a remarkable perturbation in the state of the sea, shown by the *marégraphe* of Ostende. "The low-tide level on January 25," the *Bulletin* says, "was by thirty-five centimetres lower than it should have been, and the high-tide level in the evening was lower by sixty centimetres, as if the tide were stopped in the last part of its ascending motion. These depressions of the sea-level took place under quite the same circumstances of wind at Ostend, as those which were observed during an elevation of the level, on January 2. The local direction of the wind, in the report, cannot be the cause of these oscillations, and the true cause remains thus unknown, and well deserving the full attention of meteorologists and physicists."

HURRICANE OF JANUARY 31, IN BELGIUM AND HOLLAND.—The hurricane which, accompanied by an unusally high tide, visited the shores of the North Sea during the night of January 30–31, is reported to have done very great damage. The height reached by the tide at Ostend was 7·5 metres above the mean level of the sea, and the height of the waves during the hurricane was about 12 metres (40 feet), the mareograph showing fluctuations from 1·5 to 1·5 metres above zero. The tide thus exceeded by about 4 feet the highest tides remembered at Ostend. The embankment of the town was destroyed for a length of more than 700 feet, and stones 14 feet long were thrown by the waves to distances of about 40 feet. Large parts of the town were inundated. At Antwerp the tide which swept along the Scheldt was higher by 1 foot than the highest tides remembered. The shores of the river were therefore inundated, as well as some of the polders, which appear now as immense lakes. The streets of Antwerp were covered with water 1 metre deep; Mechlin, Termonde, and many other places, were also flooded. In Holland the ravages were not less. Rotterdam was inundated, the Maas reaching a level only 6 centimetres lower than that reached in 1825. Various other places in Holland suffered. Numerous accounts received at the Brussels Observatory from various points of the kingdom will enable the path of the hurricane to be traced with great accuracy. It is worthy of notice that it took one hour and a half to go from Ostend to Brussels.

WEATHER NOTES.—Letters received from the United States on Saturday last state that the weather on the Atlantic seaboard has been intensely cold; temperatures from −35° to −40° have been recorded. At Baltimore, on the 26th ult., the temperature was the lowest known for many years, and the ice extended fully sixty miles down Chesapeake Bay, effectually blocking the harbour. Several steamers were compelled to put back, being unable to force their way through the ice-fields. Seventy vessels were locked in the ice twelve miles down the bay and the crews were in great distress. Very heavy snow-storms are reported from the west of the State of New York, by which railway travelling was all but stopped. Australian letters report exceedingly intense heat in Victoria during the month of December, the temperature in the shade rising on the 15th to 110°·7 at the Melbourne Observatory, and at some places in the interior, 116°·0 was recorded.

INTERNATIONAL WEATHER MAPS.—We have the greatest pleasure in noting that the system of simultaneous observations of atmospheric changes for the construction of the valuable weather maps issued under the direction of Gen. Myer, of Washington, U.S., which is already carried practically around the northern hemisphere on land, has recently received a large and important expansion. A general order was issued by the Navy Department, on December 25, to the commandants of naval stations and commanding officers of vessels of war, directing meteorological observations to be taken, recorded, and forwarded to the Bureau of Navigation, a particular officer being designated as responsible for the duty. The observations are to be of such a character as to be suitable for the preparation of synoptic charts, and to embrace, whenever practicable, at least atmospheric pressure, temperature, wind, rain, wet-bulb thermometer, sea-swell, and weather daily, on board every vessel in commission, and at every naval station of the United States at 7.35 A.M. Washington mean time (0.43 P.M. Greenwich mean time). The Secretary of the Navy enjoins the greatest care and promptitude in the taking and recording of these observations, which thus form part of the system of international meteorological observations taken simultaneously, upon which the United States have entered. We very earnestly hope that the navies and the mercantile vessels of all civilised countries will soon join in carrying out this magnificent scheme of observations originated by the Americans in 1873, and since then further developed and carried on by them with the highest ability and success.

NOTES

ACCORDING to arrangements made since the death of Prof. J. C. Poggendorff, the *Annalen der Physik und Chemie* will in future be edited by Prof. Dr. G. Wiedemann, of Leipzig, assisted by Prof. Helmholtz and the Physical Society of Berlin. Prof. Wiedemann possesses admirable qualities for the new position, and under his supervision this well-known scientific journal will at least lose none of its former valuable features. The first number of the *Beiblätter*, the newly-founded adjunct to the *Annalen*, has already been issued. It will not only offer a review of contemporary physical research, but will seek to replace the supplementary volumes of the *Annalen*.

THE Council of the Royal Society of Edinburgh has awarded the Macdougall-Brisbane Gold Medal to Mr. Buchan for his paper on the diurnal oscillation of the barometer, as forming one of an important series of contributions by him to the advancement of meteorological science.

THE great Von Baer medal, worth over 1,000 roubles, and bestowed but once in three years, has been given by the St. Petersburg Academy of Sciences, to Dr. A. Götte, Professor of Zoology at Strasburg, in recognition of his remarkable work "Die Entwickelungsgeschichte der Unke."

A MEDAL to commemorate the part taken by the Institute of France in the observation of the transit of Venus has been struck at the national mint. It bears the representation of a female passing before the car of Apollo, with the motto in Latin, "Quo distent spatio, sidera juncta docent." Each member of the Institute has received a silver medal, as well as the heads of the mission; the assistants received a bronze one. A medal has been cast in gold and presented to M. Dumas, the President of the Transit Commission. The expenses were defrayed by subscription among the members of the Institute.

DR. STRAUDBERG, the president of the Swedish Academy of Sciences, died suddenly in Stockholm on February 5.

THE Norwegian Government proposes to send out a vessel during this year for the purpose of deep-sea exploration in the Atlantic. A credit of 103,000 kronen has been sought from the national Parliament to cover the expense of the expedition.

BARON BARTH, whose sad end at Loanda we mentioned last week, belonged to one of the oldest families of the Bavarian nobility. Although but thirty-one at the time of his death, he had already won a name by valuable researches on the nature of the Swiss glaciers, and by geological investigations in various parts of Europe.

FOR a number of years the University of Jena has been unable from lack of funds to meet the demands of modern university education, by the increase of professorships, establishment of scientific collections, &c. So severe has been the check upon the growth of the institution, that its friends have finally set on foot energetic measures to obtain a large increase in the annual grants from the various grand ducal governments upon which it depends for support. Saxe-Weimar has already promised an addition of 40,000 marks, and it is probable that this historic university will soon be relieved from its embarrassments.

WE regret to announce the death of the eminent surgeon, Sir William Fergusson, Bart., on Saturday last, in his sixty-ninth year.

WORK is about to be commenced on the new buildings for the University of Strasburg. They will be situated to the north-east of the City, with which they will be connected by a broad promenade, and will provide accommodation for about 1,500 students. The Government grant for the purpose amounts to millions of marks.

THE Hunterian Oration at the Royal College of Surgeons was delivered on Tuesday by Sir James Paget, in presence of the Prince of Wales, and a large and brilliant company. Sir James sketched the career, and pointed out the quantity, the wide range, and importance of the work done by Hunter.

AS Prof. Kirchoff refused the directorship of the Sun Observatory at Berlin, a Committee of Direction has been appointed, consisting of Professors Kirchhoff, Förster, and Awers.

AMONG the Bills to be brought before Parliament this session is one by Mr. Hardy "to make further provision respecting the Universities of Oxford and Cambridge, and the colleges therein."

ON Thursday last, Prof. Alexander Agassiz, who has been on a visit to this country for the purpose of investigating the results of the *Challenger* Expedition, embarked at Liverpool on board the White Star steamer *Britannic* on his return home. On the Wednesday evening he was entertained at dinner by the members of the Liverpool Art Club, and on Thursday, after visiting the Library and Museum of this town he was invited by the Mayor to lunch with the members of the library and museum committee at the town hall.

DR. N. V. KONKOLY, the director of the O. Gyalla Observatory in Hungary, is at present engaged in an extensive series of observations upon the spectra of the fixed stars. In the February session of the Hungarian Academy of Sciences he gave the results obtained with 160 stars. Vogel's division into three typical classes, white, yellow, and red, is followed. An interesting observation was made upon β Lyræ. The bright bands in its spectrum detected by Vogel in 1871 have now entirely disappeared, and were probably due to an astral protuberance. The same astronomer laid also before the Academy a carefully prepared record of all shooting stars observed in Hungary during the past six years. Their number amounts to about 2,000.

LORD NORTHBROOK has presented to Oxford University a valuable collection of skins of the game birds of India, collected for him by Mr. A. O. Hume, C.B., a distinguished Indian ornithologist. Lord Northbrook, in a letter to Dr. Acland, assures him that the collection is very perfect, if not unique.

A SINGULAR case has been tried at Paris. A manufacturer of gelatine complained that the water supplied by the new city waterworks was too good for him, and that he could not continue the manufacture of his gelatine. He claimed about 3,000*l.* damages, but his suit was dismissed with costs.

AT the next session of the French Association for the Advancement of Science, in August, the Geological Society of Normandy will organise an exhibition of all the geological and palæontological products of the five departments which compose that old province.

WE have received the first two numbers of a new monthly Italian journal, *Elettricita*. It is published at Florence.

WE regret that our space only admits of our acknowledging the receipt of the *Proceedings* of the Liverpool Literary and Philosophical Society for 1875-6. This volume, like many of its predecessors, contains a considerable number of papers of real value in various departments of science. Messrs. Longmans and Co., are the London publishers.

THE Report of the Committee of the East Kent Natural History Society contains some forcible remarks on the condition of provincial museums in the same direction as those of Prof. Boyd Dawkins, which we reported some weeks ago. It is shown that the rates now squandered in support of those miscellaneous and motley gatherings, and incoherent medleys vaguely called museums, would suffice for the formation and maintenance of museums worthily so named, and admirably adapted by judicious selection and arrangement to forward the education of our youth, and the direction of all classes of the people in the study of natural science. But, so far from promoting this worthy end, the managers of many provincial museums seem to understand nothing more than the establishment of unmeaning curiosity shops, better fitted to amaze the eyes and puzzle the brains of the groundlings, than to convey rational amusement and instruction to the people. Thus the study of the sciences of natural history is rather retarded than advanced, and the prevailing ignorance maintained and confirmed. Local museums should be adapted to the best mental culture. They ought to have a few good preparations, whether exotic or native, to exhibit plainly the general principles of nature, and systematic sets of many specimens to display particularly the natural history of the district; while the needless and grievous expense of room and money, caused by the acquisition and preservation of a gallimaufry of unsuitable objects, should be most strictly avoided. The rapid spread of knowledge, the report states, will soon convince the rate-paying public that their rates should be expended with at least some regard to the instruction of the rising generation. We sincerely hope so.

UNDER the heading, "Can Birds Count?" Mr. C. W. Wade, of Magdalen College, Oxford, writes as follows:—"I have often noticed that crows crowded on Sundays to a certain place, where, on the seventh day a friend of mine was in the habit of amusing himself by placing a quantity of broken biscuit on his windowsill; he had time for this only on the Sunday morning, and during the week no food was so presented. We noticed that on the Sundays a crowd of the birds came about the window, whereas on other days no special sign of excitement was visible among them. The opinion I formed of their power to count the days as they passed has been strengthened by hearing the following story." Mr. Wade then states that a gentleman much troubled by the depredation of crows built a shed at a distance from his house, where he took up position with gun and ammunition. After the first shot the crows would not return, so the gentleman took a friend with him to the shed and then sent him away, he himself remaining; but the crows kept out of range. Taking others with him up to the number of twelve, and sending them off separately, the result was the same. At thirteen, however, the crows seem to have lost count, and returned. To be fully credible the account ought to be first-hand, as it is not, and based on a regular series of experiments.

ANY information on the prospects of the future supplies to this country of Russian boxwood is a matter of some importance, therefore it is interesting, if not entirely satisfactory, to read in a recent report from Poti, the port from whence the bulk of the boxwood is shipped, that, though considerable quantities are still exported, it becomes annually worse in quality, and the supply for shipment at Poti must soon be exhausted. The export from the Abkassian forests is still prohibited by the Russian Government, but it is said that this restriction will shortly be removed. The writer of the report referred to describes a journey he made in 1873, through splendid forests of Normandy pine, birch, beech, oak, chestnut, walnut, and boxwood. With the opening of these forests it is estimated there will be a plentiful supply of prime boxwood for about fifteen years, after which that of inferior quality must be resorted to, as in Mingrelia. Boxwood, it seems, has also become quite recently an article of commerce from Taganrog to France and England; about 4,000 tons were shipped to these two countries during the year 1875, at a cost of from 8*l*. to 10*l*. per ton, free on board. This boxwood is drawn from Persian territory, on the southern coast of the Caspian Sea, across which it is conveyed to Astrachan, thence up the Volga to Tzaritzin, whence it passed over to Kalatch, on the Don, for Rostoff and Taganrog.

NO. 7, concluding vol. ii. series ii. (Science) of the *Proceedings of the Royal Irish Academy*, has just been published. It contains a report on Irish Hepaticæ, by Dr. David Moore; a revision of the species of Abies of Endlicher and Parlatore, and Pseudotsuga of Carrière and Bertrand, by Prof. M'Nab; contribution to the history of Dolomite, by Mr. E. Hardman; on Glucinum, by Prof. E. Reynolds; on the chemical changes in potato disease, by Rev. Prof. Jellett; on remains of *Cervus megaceros*, by G. Porte; on the detection and precipitation of phosphoric acid by ammonic molybdate, by A. N. M'Alpine; on the product of the squares of the differences of the roots of a cubic equation, by Prof. Young; and on a new genus and species of sponge, by Prof. E. P. Wright.

THE February session of the Berlin Geographical Society was devoted to detailed reports from the lately-returned African explorers, Dr. Pogge and Dr. Lenz. The former described his journey from Angola to Mossumbu, the chief town of the Watajombas, whose existence has hitherto been regarded as mythical. The difficulties of the route were few, and the climate in the interior healthful. Dr. Pogge's experience would seem to point out his route as one of the most desirable for future expeditions to use in attempting to reach the interior of the continent. Dr. Pogge stated his belief that the Casai or Casabi is the Upper Congo, and that the Lualaba flows into the Ogovai. A letter in Tuesday's *Times*, from an Angola paper, written by a Portuguese merchant, is of the same tenor. It states that a Portuguese, whose name is not given, has found the source of the Zaire, twenty days' march east from Malange, and one day's march from the capital of Dumbo Tembo. The river is known as Casai or Casabi till it crosses the country of Lunda, when it gets the name of Nzare. Livingstone, in a letter dated Cassangé, February 13, 1855, mentions the common belief there that the Casai and Quango join to the north of Cassangé, and form the Zaire or Congo. We seem to be getting near the solution of the problem. Dr. Lenz, at the same meeting, sketched rapidly the results of his three years' wanderings among the Oskebas of the Ogowai district, by whose assistance he was also able, although with the greatest difficulty, to penetrate to the Adooma land, and touch his farthest point to the east, Banjska. The interesting results of his anthropological and ethnological studies among the Oskebas, we hope to give more fully.

ON Monday evening, Gen. R. Strachey gave the first of a series of lectures on Scientific Geography at the Geographical Society. He traced the progress of Geographical Science, pointed out the wide field embraced by it at the present day, and showed its aims and its importance.

THE annual meeting of the American Geographical Society was held on January 16, Rev. H. W. Bellows, D.D., in the chair. The annual election of officers and members of the Council was held. Chief-Justice Daly was re-elected president, and delivered his annual address on the Geographical Work of the World for 1876. The address, of which an early copy has been forwarded to us, is one of great interest, and contains a comprehensive view of geographical work during 1876 in all departments and in all parts of the world. Mr. Daly criticises with some severity various statements as to previous explorers in the Report of Sir George Nares. He commends the plan proposed by Dr. Hayes some years ago, of carrying on polar exploration by establishing a station at Port Ffoulke, a plan substantially the same as that proposed by Capt. Howgate of the U.S. Signal Service, to which we referred in a recent number. Mr. Daly mentions the interesting fact that the first Geographical Society was probably that founded in Venice in 1688, under the name of "Society of Argonauts," followed a few years later by an association of the same kind established at Nuremberg. For English readers one of the most valuable parts of this address is the account of the work of the various U.S. Surveys for 1876. We regret that space prevents us doing more than referring to this interesting address.

AT the last session of the Berlin Academy a letter was read from Dr. J. M. Hildebrandt, travelling under the auspices of the Academy, who on December 10 was preparing to leave Mombassa, in Zanzibar, for an extensive expedition in the Kibuyn land. The chief aim of the undertaking will be to study the snowy regions of the lofty chain of mountains bordering on the coast-land. One of the first efforts will be directed to scaling the lofty summit of the Kenia.

Die Natur for February 12 contains a paper by Karl Emil Jung, "On the Family Conditions of the Australian Natives," in which he states some facts with regard to their marriage customs that deserve the attention of ethnologists.

NO. 3 of the *Bulletin Trimestriel* of the Cairo Geographical Society contains a paper by Dr. Güssfeld on his exploration in West Africa, and a paper of great value by Col. Colston giving the results of his observations among the Bedouins of Sudan and Kordofan. Accompanying letters from Col. Gordon, which have been referred to by us already, are four maps of the course of the Nile in the region of the great lakes.

WE have received a copy of a lecture on the English Arctic Expedition given at the Scientific Club, Vienna, by Dr. Chavanne, forming one of a series of cheap popular scientific lectures which are being published by A. Hartleben, of Vienna.

SEVEN weekly meetings of the Cambridge University Natural Science Club were held during the last (October) term, when the following papers were read:—"On Analogies between the Senses in Man," by J. Allen (St. John's); "The Pectoral and Pelvic Girdles," by T. W. Bridge, B.A. (Trinity); "The Probable Age of the Earth," by E. B. Sargant (Trinity); "Caves," by J. E. Marr (St. John's); "The General Anatomy and Functions of the Cerebrum," by O. A. Browne, B.A. (Trinity); "Fermentation," by A. Hill (Downing); "The Chemical Composition of the Albumenoids," by S. H. Vines, B.A. (Christ's). Seven meetings are arranged to take place during the present (Lent) term. There are nineteen members in residence.

PROF. OGDEN ROOD has called attention (*Am. Journ. of Sci. and Arts*) to some cases in his own experience, which, along with an experience described by Tait, seem to prove that our retinal apparatus for reception of waves of light of medium length is more liable to be strained by nervous shocks or by prolonged excitation, than that designed for reception of waves of greater or less length. Thus nervous derangement and prolonged excitation may produce temporary green colour blindness. The effects Prof. Rood observed were in recovering from effects of chloroform, exposure to bright white light out of doors (when white objects seemed at first purplish red), and convalescence from typhoid fever (when white objects appeared of a weak orange yellow).

THE works in connection with the Paris Exhibition of 1878 are progressing with surprising activity. The buildings, which must be ready in the end of March by contract, will be completed before the appointed time.

IN the February Session of the Wurtemberg Anthropological Society, a somewhat novel communication was presented by Prof. v. Zech, the statistician of the Society. He instituted a careful comparison between the returns of the late parliamentary election and the anthropological statistics of the kingdom collected during the past year. The majorities of the government party were invariably obtained in districts where light-coloured hair and eyes predominate. The *Schwarzen*, the Ultramontanes, formed a medium class with regard to complexion, &c., and were not recruited from among the black-haired and the black-eyed, who seemed on the contrary to be the champions of social democracy.

THE *American Naturalist* for February contains an Account of the Natural History of the Fanning Group of Islands, by Dr. T. H. Streets. These are four coral islands in the Pacific, stretching from 1° 57′ N. to 5° 49′ N., and from 157° 27′ to 162° 11′ W. They do not seem to have been yet grouped on any chart.

A SECOND edition, revised to December 31, 1876, has been published of the "Catalogue of the Publications of the United States Geological and Geographical Survey of the Territories." Since 1867, forty-one publications have been issued, besides twenty-five maps. A considerable list of works in process of publication and in preparation is also given.

AT the meeting of the Brighton and Sussex Natural History Society, held on the 8th inst., an interesting paper by Miss Crane was read, "On Certain Genera of Living Fish and their Fossil Affinities." It is reported in full in the *Sussex Daily News* of February 10.

THE additions to the Zoological Society's Gardens during the past week include a Macaque Monkey (*Macacus cynomolgus*) from India, presented by Master R. Wallace; two Chinese Geese (*Anser cygnoides*) from China, presented by Mr. A. H. Medhurst; a Common Raven (*Corvus corax*), European, presented by Mrs. Nathan; a Common Magpie (*Pica caudata*), European, presented by Miss Jessie Bovill; a Rough-legged Buzzard (*Archibuteo lagopus*), European, presented by Mr. W. R. Paxton; a Common Marmoset (*Hapale jacchus*) from Brazil, a Common Paradoxure (*Paradoxurus typus*) from India, deposited; two Maned Geese (*Bernicla jubata*) from Australia, a Red-vented Cockatoo (*Cacatua philippinarum*) from the Philippine Isles, purchased.

SCIENTIFIC SERIALS

IN the January number of the *Quarterly Journal of Microscopical Science* we find that Dr. Klein has superseded Dr. Payne, as one of the editors. Mr. H. N. Moseley has two valuable papers, the first on the colouring matter of various animals, and especially of deep sea forms dredged by H.M.S. *Challenger*, in which a large number of fresh band-producing colours from sponges, Coelenterata, Echinoderms, Annulosa, and Mollusca are described with figures of their spectra. In the second, *Stylochus pelagicus*, a new species of Pelagic Planarian, is described, with notes on other pelagic species, together with the larval forms of Thysanzoon, and of a gymnostomatous Pteropod.—Dr. Klein, in a note on a method of preparing the cornea by the employment of caustic potash and lunar caustic.—Mr. Kidd describes Schiefferdecker's Microtome, and gives an epitome of a paper by Engelmann on "Contractility and Double Refraction."—Mr. Peek has an important paper on the minute structure of the gills of Lamellibranch molluscs, the investigation having been undertaken in the Histological Laboratory of Exeter College, Oxford, at the instigation of Prof. Lankester. The filamentary gills of *Arca* and *Mytilus* are shown to explain the nature of the more complicated organ in *Anodon*, the most simple type being filaments bent on themselves at their middle points, outwards for the outer gills, and inwards for the inner, so that in section they form a W.—The last paper is a *résumé*, by Mr. Archer, of recent contributions to our knowledge of freshwater Rhizopoda.

Journal de Physique, January.—On the phenomena of induction, by M. Mouton.—Chromatic polarisation of tufts in biaxial crystals, by M. Marc.—Note on the experiment of the Franklin portrait; a new glass breaker, by M. Barat.—On absorption of radiant heat by aqueous vapour, by M. Hagu.—Note on the employment and choice of spectacles designed to correct bad vision, by M. Dubois.

SOCIETIES AND ACADEMIES

LONDON

Mathematical Society, February 8.—Mr. C. W. Merrifield, F.R.S., vice-president, in the chair.—The following communications were made to the Society:—On the area of the quadrangle formed by the four points of intersection of two conics, by C. Leudesdorf.—A certain series, by Mr. J. W. L. Glaisher, F.R.S.—The differential equation $\frac{dx}{\sqrt{X}} + \frac{dy}{\sqrt{Y}} = 0$, by Prof. Cayley, F.R.S.—On the classification of loci, and a theorem in residuation, by Prof. Clifford, F.R.S.

Zoological Society, February 6.—Osbert Salvin, F.R.S., in the chair.—Mr. Sclater exhibited and made remarks on some unnoticed characters in the original and unique specimen of Comrie's Manucode (*Manucodia comrii*, P.Z.S., 1876, p. 459).—Mr. Howard Saunders exhibited a specimen of the Panay Sooty Tern (*Sterna anæstheta*), which had been obtained on the English Coast, and was the first recorded occurrence of this bird in the British Islands.—Dr. A. Günther, F.R.S., read a memoir on the tortoises collected by Commander Cookson, R.N., during the visit of H.M.S. *Peterel* to the Galapagos Islands. The main results of Commander Cookson's visit consisted in giving us a knowledge of the tortoise of Abingdon Island (*Testudo abingdoni*) and of the tortoise of the north of Albemarle Island (*T. microphyes*).—A communication was read from Mr. Robert Collett containing an account of his observations on *Phylloscopus borealis*, as met with on the coast of the Varanger Fjord and adjacent parts of Finmark.—Mr. Sclater read a note on an apparently new species of spur-winged goose of the genus *Plectropterus*, proposed to be called *P. niger*, founded on two examples living in the Society's Gardens, which had been presented to the Society by Lieut.-Gen. A. V. Cunningham.—Prof. A. H. Garrod read a paper on the mechanism of the intervertebral substance and on some effects resulting from the erect position of man.—A communication was read from Sir Victor Brooke, containing notes on the small rusine deer of the Philippine Islands, and giving the description of a new species proposed to be called *Cervus nigricans*, of which a female example was recently living in the Society's Gardens.—A paper by Mr. O. Salvin and Mr. Ducane Godman was read giving the description of twelve new species and a new genus of butterflies from Central America.—Dr. Günther gave an account of the zoological collection made during the visit of H.M.S. *Peterel* to the Galapagos Islands, which had been worked out by himself and his assistants in the Zoological Department of the British Museum.—Mr. R. B. Sharpe communicated the description of a new species of pheasant of the genus *Lobiophasis* and of a new species of *Pitta* from the Lawas River, North-west Borneo. Mr. Sharpe proposed to call the former *L. castaneicaudatus*, and the Pitta, *Pitta ussheri*.

Geological Society, January 10.—Prof. P. Martin Duncan, F.R.S., president, in the chair.—Frederick Tendron and David Thomas were elected Fellows, and Dr. J. F. Brandt, of St. Petersburg, Dr. C. W. Gümbel, of Munich, and Prof. Eduard Suess, of Vienna, Foreign Members of the Society.—On gigantic land-tortoises and a small fresh-water species from the ossiferous caverns of Malta, together with a list of the fossil fauna, and a note on Chelonian remains from the rock-cavities of Gibraltar, by A. Leith Adams, F.R.S., Professor of Zoology in the Royal College of Science, Dublin. The author described three distinct species of tortoises from the Maltese rock-cavities, one of which was of gigantic proportions, and equalled in size any of the living or extinct land Chelonians from the Indian or Pacific Islands. The characteristic peculiarity in the two larger species is a greater robustness of the long bones as compared with the denizens of the Mascarene and Galapagos Islands, with which he had been enabled to contrast them. The largest, on that account, he had named *T. robusta*; it rivalled the gigantic *Testudo ephippium* (Günther) in size, showing affinities to it in a few minor characters. A smaller species, *T. Sprattii*, and a small *Lutremys*, not distinguishable, as far as the few remains extend, from the recent *L. europæa*, besides many fragments of shields of tortoises of various dimensions, had been obtained. These Chelonians were found in conjunction with the remains of the dwarf elephants and other members of the remarkable fauna, collected by Admiral Spratt and the author in the ossiferous rock-cavities of Zebbug, Mnaidra, Benghisa, &c. The paper contained a list of the animal remains hitherto recorded from the Maltese fissure caverns, including three species of dwarf elephants, two species of *Hippopotamus*, two gigantic species of *Myoxus*, a gigantic swan, and other animal remains; and further, a Note on some Chelonian remains from the rock-fissures of Gibraltar.—On the Corallian rocks of England," by the Rev. J. F. Blake, F.G.S., and W. H. Hudleston, F.G.S. The object of the paper was to describe the rock masses existing between the Oxford and Kimmeridge clays as exhibited throughout England. They occur in five distinct areas which were treated separately. Where best developed, as in Yorkshire and at Weymouth, the series is much more varied than the usual nomenclature indicates; in both instances a lower mass of limestone, distinct from that representing the "coral rag" of Central England, is present. In Yorkshire, especially, this limestone is of great importance, and is separated by a "middle calc. grit" from the upper limestone series. These upper limestones were also shown to be separable into two very distinct divisions, especially by their fauna, viz., the "coralline oolite" and "coral rag," which last term is here applied in a restricted sense only to true coral-bearing or inter-coralline beds. The upper beds, called "supra-coralline," were shown, where present, to be of great interest and importance—and their fauna was for the first time indicated—and the iron-ores of Abbotsbury and Westbury were proved to belong to this portion of the series. The fauna of the Corallian rocks was shown to be very markedly Oxfordian in the lower portions, and equally Kimmeridgian in the upper, while but a limited portion only could be said to have a fauna of its own. The whole series was deposited in lenticular masses of traceable size.

Physical Society, February 3.—Prof. G. C. Foster, president, in the chair.—The following candidate was elected a member of the Society:—Mr. J. Norman Lockyer, F.R.S.—Prof. Osborne Reynolds exhibited a number of experiments in relation to vortex motion in fluids. They have been gradually developed during the last few years, but are still in a very incomplete state, and he hopes that others will join him in the inquiry. Probably one reason why so little progress has been made in the determination of the elementary laws of fluid-motion is that mathematicians have been without experimental data on which to found their calculations. The well-known rings formed by puffs of smoke have been studied by many high authorities, but not with a view to their general bearing on this subject. Prof. Reynolds first showed smoke rings and their interference by means of the apparatus devised by Prof. Tait, and added that although the theory of smoke rings does not imply that vortex motion is peculiar to vapours, their existence in liquids was only pointed out by Mr. H. Deacon at a comparatively recent date. In studying the action of the screw-propeller, Prof. Reynolds noticed the systematic manner in which the form of a disc moved obliquely through water is retained by the track of air which it produces. If a flat disc be supported on a light frame and caused to move rapidly through water the motion ceases on withdrawing the hand suddenly; but if this be done gradually the motion continues. By passing a coloured liquid down a fine tube to the back of the disc, he found that a vortex ring is always formed, which passes to the rear of the disc, and the same effect is produced by dropping water from a height into water covered with a coloured liquid. In a trough about six feet long and at one end of which was a horizontal tube closed with sheet india-rubber, air rings were formed by introducing air into the tube and then striking the india-rubber externally by means of a flat board, and it was shown that a ring is capable of propelling a vane placed in its course, to the front of which it never advances. If the air be replaced by a coloured liquid the ring travels with considerable velocity and the motion of a solid body of the density of water is in no degree comparable. If a ring travels through a part of a liquid which has previously been coloured, it causes no motion of translation, and Prof. Reynolds concludes that no resistance is offered to their motion. Nevertheless the motion is gradually stopped, but the ring is constantly enlarging by gathering water as it travels, and its momentum remains nearly constant. After adverting to the methods adopted to ascertain the direction and velocity of motion, the initial form of the rings was shown to be a spheroid. A solid of this form, however, is very slow in its passage through water, and he considers this to be due to friction. He has succeeded in imitating the form of the ring by causing a disc, surrounded by pieces of ribbon, to move through water. Finally, Prof. Reynolds referred to Sir William Thomson's researches on the interference of two rings, and showed that the oscillating rings so produced can be formed in liquids or gases by employing an oval in place of a circular aperture.—The Annual General Meeting of the Society was then held.—The president read the report of the Council, of which the following is a brief abstract:—The Council points with satisfaction to the number and interest of the papers read before the Society, and a brief summary is given of the more important. The Society has to regret the loss of three of its members, Mr. David Forbes, F.R.S., Mr. A. S. Hobson, and Mr. Arthur Pinn. The publication of a new edition of Prof. Everett's work and of a complete edition of Sir Charles Wheatstone's writings is announced, and the Council hopes shortly to undertake the translation of scientific papers from foreign sources to be published in its proceedings.—The following Officers and Council were elected for the ensuing year:—President, Prof. G. C. Foster, F.R.S. Vice-Presidents: Profs. W. G. Adams, F.R.S., and J. H. Gladstone, F.R.S, Mr. W. Spottiswoode, LL.D., F.R.S., Sir W. Thomson, LL.D., F.R.S., and Dr. W. H. Stone. Secretaries: Prof. A. W. Reinold and W. C. Roberts, F.R.S. Treasurer, Dr. E. Atkinson. Demonstrator, Prof. F. Guthrie, F.R.S. Other Members of Council: Prof. W. F. Barrett, Latimer Clark, Major Festing, W. Huggins, D.C.L., F.R.S., Prof. Kennedy, O. J. Lodge, Prof. H. MacLeod, Prof. B. Stewart, LL.D., F.R.S., Prof. Unwin, and E. O. W. Whitehouse.—The proceedings terminated with votes of thanks to the Lords of the Committee of Council on Education for the use of the Physical Laboratory at South Kensington and to the several officers of the Society.

Royal Microscopical Society, February 7.—Anniversary meeting.—H. C. Sorby, F.R.S., president, in the chair.—The president delivered the annual address, in which, after reference to the memory of those of their number deceased during the past year, he gave an interesting account of his recent researches into the composition and origin of the loose materials which form the sands and clays of this country, and also of those composing the sandstones and stratified rocks.—The result of the ballot for officers and council for the ensuing year was as follows:—President, Mr. H. C. Sorby. Vice-presidents: Dr. L. S. Beale, Sir John Lubbock, Bart., Rev. W. H. Dallinger, and Mr. H. Powell. Treasurer, Mr. John W. Stephenson. Hon. Secretaries: Mr. H. J. Slack and Mr. Chas. Stewart. Council: Dr. Robert Braithwaite, Dr. Lawson, Dr. Millar, Messrs. Bevington, Brooke, F. Crisp, Ingpen, E. W. Jones, Loy, M'Intyre, Thos. Palmer, and F. H. Ward. Assistant Secretary, Mr. Walter W. Reeves.

Institution of Civil Engineers, February 6.—Mr. George Robert Stephenson, president, in the chair.—The paper read was on "The Sewage Question," by Mr. C. Norman Bazalgette.

ROME

R. Accademia dei Lincei, January 7.—Second appendix to memoir on the construction, properties, and applications of a constant inductor, by M. Volpicelli.—On complete elliptic integrals, by Prof. Smith.—On the small oscillations of an entirely free rigid body, by M. Cerruti.—On the anatomy and physiology of the retina (continued), by M. Franz Boll.—On the spinal medulla and the electric lobe of the torpedo, by M. Reichenheim.—Geological studies on the group of the Gran Paradiso.—Rational catalogue of the rocks of Friuli, by M. Taramelli.

PARIS

Academy of Sciences, February 5.—M. Peligot in the chair.—M. Duchartre presented the second and last part of the second edition of his "Éléments de Botanique." The following papers were read:—On the fundamental invariants of the binary form of the eighth degree, by Prof. Sylvester.—Preliminaries of a comparative study of living and fossil European oaks; definition of present races, by M. De Saporta.—On monochlorised oxide of methyl, by M. Friedel.—Composition and origin of diamantiferous sand of Du Toit's Pan, in South Africa, by M. Meunier. Geologists have assigned a deep origin, representing them as the residue of alteration of pyrogenous rocks emitted like lava. The author's analysis gives, besides minerals proper, a number of complex rocks which cannot have been formed at once in the state of mixture by the same causes. Each of them must have been removed from a special deposit, then carried to the point where mixture took place. These sands belong to the so-called *vertical alluvia*, and are related in formation to the Kaolinic sands in the environs of Paris.—On the preparation and use of the liquid for washing vines attacked by Phylloxera, by M. Boiteau.—MM. André and Angot expressed a Mercury on May 5, 1878. They hope thus to render the study of the next Venus transit more fruitful.—Diathermaneity of metals and of paper, by M. Aymonnet. They are not athermanous, as generally thought. They are more diathermanous for dark heat from metallic bodies raised to a temperature under 100° than for luminous calorific radiations or those near red. They have weaker absorbent powers than water. It is possible to find a mathematical relation between the absorbent power of a body and its coefficient of conductivity.—Note on the presence of ammonia in cast steel, by M. Regnard. Ingots of steel newly broken gave a distinct smell of ammonia, with perceptible noise in escape of the gas, and bubbles in soapy water if applied. The appearance of the fracture in all such cases was crystalline, varying slightly from periphery to centre; the liberation was greatest at centre. Soft steels in general did not give the phenomenon, nor did ingots previously annealed. Analysis of the gas showed it to be nearly pure hydrogen, with perhaps a few traces of acetylene.—On the active principle of *Strophantus hispidus*, or Inee, by MM. Hardy and Gallois. This is the plant used by the Pahonias in poisoning their arrows. The isolated body, called *ineine*, has not the same physiological properties as *Strophantine* (so-called by Fraser). Injected in considerable quantity under the skin of a frog's foot, it does not stop the heart's movements.—Immediate disorders produced by injections of pure fuchsine into the blood, by MM. Feltz and Ritter. The nervous disorders, like those of drunkenness, cannot, the authors now think, be due to embolic lesion (in the capillaries), but to direct impression of the nervous system by the fuchsine itself.—Structure and mineralogical composition of variolite of Durance, by M. Michel Levy. The globules of variolite are not petro-silicious. By its petrographic affinities it seems to be a compact term of the series of euphotides. It presents an interesting association of several varieties of amphibole and pyroxene; also a new example of spherolites entirely crystallised.—On the intestinal anguillule (*Anguillula intestinalis*), a new nematoid worm found by Dr. Normand in persons attacked by diarrhœa of Cochin China, by M. Bavay. It is distinct from, and much less abundant than, the *Anguillula stercoralis*.—On the minute phenomena of fecundation, by M. Fol. All the phenomena are reduced to two typical cases.—On *Filaria hematica* (Hæmatozoa), by MM. Galeb and Pourquier. The authors found filaria in the blood of the fœtus of a bitch whose heart was teeming with them; the embryos doubtless passed through from mother to offspring. This explanation destroys the idea of verminous diathesis, and of spontaneous generation, called in to explain the genesis of such hæmatozoa. The authors also verify M. Davaine's view that the nematoid worms circulating in the vessels of certain dogs are larvæ of the hæmatic filaria.—Determination of ammonia in the air and in meteoric waters at Montsouris, by M. Levy.—On two new species of Ibis, from Cambodge, by M. Oustalet.—On a new sounding-line, by M. Tardieu.

A WORKING NATURALIST

Life of a Scottish Naturalist: Thomas Edward, Associate of the Linnean Society. By Samuel Smiles. Portrait and Illustrations by George Reid, A.R.S.A. (London: John Murray, 1876.)

IT is rather a delicate thing and seldom advisable to publish a full and formal biography of a man with an account and attempted estimate of his work while he himself is still alive and in comparative vigour. There are many sound reasons, however, to justify Mr. Smiles in telling the wonderful story of the still living Thomas Edward, the Banff shoemaker and naturalist; not the least weighty of these is that it will bring to Edward some of that *kudos* and cash which he has earned long ago, and which it would have been well for himself and for science had they, or at least the latter, reached him years since.

Thomas Edward, born 1814, is the son of very humble but thoroughly respectable Scotch parents, who were able to bestow upon him the scantiest schooling. He was brought up in Aberdeen, where he was in rapid succession expelled from three schools on account of his intense inborn passion for "everything that hath life." He used to take all sorts of birds and beasts and creeping things to school with him, in his pockets, in boxes, or in bottles. Tom's specimens would often escape, and the scene may be imagined when some unconscious urchin realised that a snail, or a horse-leech, or a "Maggie-mony-feet" (centipede), was crawling up his bare legs. Poor Edward meant no harm, but it was too much to expect that an ordinary dame or dominie would, in that remote and unscientific age, at least, take the trouble to understand the boy's nature and tendencies and aspirations. The consequence was severe thrashings and expulsion.

When Edward left school finally he was only six years old, could read with difficulty, and could hardly be said to be able either to write or count. After serving for some time in a mill he was apprenticed to a shoemaker, Begg, "a low-class Cockney," Mr. Smiles calls him, and certainly a regular brute, who treated the poor boy and his birds and beasts in a most cruel fashion. However Edward managed with this man and a subsequent master to pick up a fair knowledge of the shoemaking trade, and after vainly trying to emigrate as a stowaway, removed to Banff when about twenty years old, where he has lived ever since working as a journeyman for wages, and devoting every moment of his leisure to the gratification of his passion for natural history. It is common enough for working men, and especially for shoemakers, to take an interest in certain animals, especially in birds; but Edward's fondness for animals was no fancy of this sort. From almost his infancy he was devoured with a passion for the observation and possession of animals of all kinds; to him no living creature was unclean or loathsome, and he feared to face or handle nothing from a centipede or an adder to a polecat. While yet a baby in his mother's arms he nearly put a premature end to his career by springing to clutch at a passing insect; and while being drilled as a militiaman in Aberdeen he made himself liable to severe punishment by rushing like a madman from the ranks in chase of a passing butterfly.

As a journeyman shoemaker Edward had to work from six in the morning till nine at night. Shortly after settling in Banff he married, luckily for his love of nature, a prudent and considerate woman, who, instead of thwarting his eccentricities, did what she could to help him and enable him to indulge them. "Weel," she said once, when asked what she thought of his habits, "he took such an interest in beasts that I didna compleen. Shoemakers were then a very drucken set, but his beasts keepit him frae them. My man's been a sober man all his life; and he never negleckit his wark. Sae I let him be." "Wise woman!" justly adds Mr. Smiles. Shoemakers' wages in Banff were very low—only a few shillings a week. For many years Edward earned only about 10*s.* a week, and yet on this he managed to rear, without incurring debt, a thoroughly respectable and honest family of about a dozen children, who have repaid their parents' care by doing what they could to comfort their old age. Edward being a man who had a proper sense of his duty to his family, seldom thought of allowing his favourite pursuit to encroach on his long working hours. As his consuming passion must be satisfied, he took the only course legitimately open to him; he gave up his nights to it. As soon as he got home from work, unless indeed the weather was unusually bad, he shouldered his gun, equipped himself in his eight-pocket coat, four-pocket vest, double-storied hat, and other traps of a rude but efficient enough kind, and putting his supper of oatmeal cakes in his pocket, set out to watch and catch the denizens of the woods, heaths, air, and sea-shore of the region around Banff. He would prowl about as long as the light permitted, lie down for an hour or two in a hole, under the lee of a bush, inside some old ruin, or underneath a flat tombstone in some eerie churchyard, snatch an hour or two's sleep, and be up again with the first streak of dawn. Even when thus resting, however, he would frequently be kept awake watching the doings of any night animals that might be near him. Frequently also his rest was a very broken one. He might be wakened by a weasel or a pair of rats or some other inquisitive or hungry creature tugging at his coat-pockets or trying to make their way underneath his hat, always well filled with insects, birds, or eggs. He gives a most exciting description of a two hours' struggle with a pole-cat that attacked him while resting in darkness in the ruins of Boyne Castle. He was dreadfully lacerated by the claws of the animal, but this he did not mind, so long as he succeeded in keeping the skin of the pole-cat whole. Once he spent two days and a night, without sleep or food, in watching a Little Stint (*Tringa minuta*), which he sighted on the shore near Banff, and thought himself amply rewarded by being able at last to capture it. As might be expected, in his unconscious eagerness to follow out his pursuit, he met with frequent accidents, and was once or twice within very little of losing his life by falling down high precipices. All this, however, he took as "in the bond"—as no more than might be looked for by one in his circumstances persisting in gratifying a passion of the kind that consumed him.

When compelled to stay at home Edward occupied himself with the preparation of his collections and the making of cases for holding them. In no long time every corner of his house was filled with cases, and he wisely determined to turn an honest penny by exhibiting his treasures. This he did on two or three occasions in Banff on fair days when the town was filled with country people. These exhibitions were so successful that he resolved, by the advice of his friends—it was all the help they ever gave him—to try a wider sphere, and he rented a room in Aberdeen, where he arranged his collection. Many of the groups of animals were most artistically put together, and as a mere sight, not to speak of its scientific value, the exhibition was well worth visiting. But it proved a complete failure; only a few people dropped in. It was a serious matter to Edward, for of course he had to leave his work and necessarily incur what were for him considerable liabilities. The prospect was so gloomy that he was driven to think of the last resort of despair, suicide. He went down to the mouth of the Dee, and had divested himself of his outer garments preparatory to taking a last plunge, when a strange bird hopping about on the sand caught his eye. His ruling passion asserted its sway, and off he set on a long and exciting chase to discover the nature of the bird; in this he failed, but the chase left him a more cheerful and a wiser man. He was compelled to sell his collection for about 20*l*, returned to Banff and resumed his work and gradually his old habits, and ere long had the pleasure of seeing another collection gradually accumulating. More than once afterwards had he to sell his collections, which he regarded as his savings' bank to fall back upon in time of need. But his ardour was never damped, and until prevented from wandering far by rheumatism and other results of his hard life, he never ceased adding to his store.

Edward's collections not only included quadrupeds, birds, and insects; plants of all kinds came in for a share of his attention, and, latterly, marine animals of all kinds; in the last field, especially, he did work of the highest value. Except one or two clergymen of similar tastes, the dreadfully respectable people in and about Banff took no notice of Edward, whom they seem rather to have shunned as eccentric, if not crazy. But gradually naturalists in various parts of England came to know of him, and thus he got into correspondence with well-known workers in various parts of England. One of his principal correspondents was Mr. Spence Bate, who, during the preparation of the "History of the British Sessile-eyed Crustacea," obtained important help from Edward. The latter collected for and sent Mr. Bate a very large number of specimens. Of 294 Crustaceans found in the Moray Firth, no fewer than twenty-six new species were added by Edward himself. A new Isopod which he discovered was named after himself *Praniza* (*Anceus*) *Edwardii*, and one of his most notable discoveries was one of the little fishes known as midges, which he sent to Mr. Couch, who pronounced it new to science, and named it Edward's Midge (*Couchia Edwardii*). By and by he was induced to send descriptions of his observations first to the local journal and latterly to such scientific journals as the *Linnean Society's Journal*, the *Zoologist*, *Naturalist*, and *Ibis*. No one reading Edward's accounts of his experiences would ever dream that their author had had no schooling after his sixth year, and had worked nearly all his life from 6 A.M. till 9 P.M. at a common handicraft. They have been compared without any exaggeration to the classical descriptions of Wilson and Audubon.

How Edward, with no dredging apparatus whatever, but only with old pots, pans, rags, from seaweed cast ashore, from the inside of fishes obtained from the fishermen, and by other similar methods, collected his marine specimens, many of the greatest rarity, is well told in Mr. Smiles's narrative. It is quite amazing how much is yet to be learned about the commonest objects of our land and sea; and how much of new Edward managed to discover of the nature and habits of animals about which one would have thought no more was to be learned. In an appendix of forty-eight pages Mr. Smiles gives a descriptive list of a portion of the Fauna of Banffshire observed or found by Edward; had all that he has found been thus catalogued it would have filled the volume.

It is to the credit of the Linnean Society that years ago they conferred upon Edward the rare honour of Associate. Doubtless had the numerous correspondents whom he was so ready to help with specimens and the result of his observations known of his real condition, they would have done something to put him in a position in which he could have helped science with less hardship to himself. Here, surely, if ever there was one, was a fair case for the endowment of unremunerative research, and had the fund now being allotted been in existence even ten years ago, Edward would have had a prime claim upon it. How these things are managed in Norway may be learned from the following extract from a letter from Mr. A. Archer, Laurvig, Norway, to the *Times*, called forth by reading Edward's Life:—

> "Some years ago there lived on the wild west coast of Norway a clergyman, with his wife, a large family, and a small income. He, too, employed every leisure hour in the study of nature, but being a graduate of Christiania University, and being obliged to take many a journey over the large fiords in visiting distant parts of his parish, he possessed two great advantages over Edward - a good education and larger opportunities of observation. He, too, had the seeing eye without which all opportunities are useless, and shortly it was known that science was being enriched with discoveries in zoology made by the hard-worked parish priest. The action of the Norwegian Storthing was prompt. Though the great majority of that body are poor peasants, with little more education than they have picked up in the parish school, and though in all ordinary cases they hold the purse-strings with a grip that would have pleased Joseph Hume, they have the virtue of being liberal when good cause can be shown for it. At the request of the Governing Body of the Christiania University they created a new unattached Professorship of Zoology, endowed it with a salary of 333*l*., equal to 1,000*l*. in England; and, relieving the clergyman from his parish duties, which could be as well performed by another, appointed him to the professorship, but without requiring from him either residence or teaching. How the Professor, in these favourable circumstances, went on enriching science with his discoveries till his name became famous over the world, how he trained up his sons to follow in his footsteps, how two of them, though yet young men, are professors in Christiania University, one of them in his own favourite science, all this is known to the scientific men of Europe, nor, should any of them read this, will they require to be told that the name of the clergyman was Sars. It would, of course, be absurd to ask the enlightened Parliament of Great Britain to take in the case of Edward a hint from the Norwegian Storthing in the case of Sars, and the

Scotch Universities are, we all know, too poor to create unattached professorships and endow them, standing as they do rather in need of endowment. Is it equally absurd to ask if one of the wealthy English Universities would not consider it an honour to rank Edward among its professors, and assist him to publish the observations he may yet have time to make, or does it merely show gross ignorance of the spirit in which they are governed to suppose that either of them could so far depart from the usual routine? I suppose I am not the only countryman of Edward who, having lived here long enough to learn how poor Norway treats her great men, will regret—not so much on account of Thomas Edward, for his has been a great life and example, but in the cause of science—that his lines have not fallen in pleasanter places."

But Edward never complained of his lot, and had Mr. Smiles not written the present work, he would have had to stick to his stool to the end. All Edward ever wanted was some way of earning a living that would have enabled him to give more time and attention to his scientific pursuits, and no one will deny that it would have been immensely to the gain of science could his services have been devoted entirely to it, for he was too passionately fond of nature ever to have been spoiled by prosperity. But regrets are now useless; happily Edward is not beyond the reach of consolation and well-merited reward, and happily he is receiving them. He will be mentioned in the annals of science as an observer of the highest accuracy and originality, who gave up to a parish a genius fitted for an immensely wider sphere. The obvious moral of the work to those who have to spend most of their time in earning their daily bread, as well as to others, we need not point here. Mr. Smiles's work is one of the most interesting biographies ever written, and the illustrations gratuitously contributed by Mr. Reid are a great pleasure. Our readers by buying the book will not only become possessed of a rare treat, but will at the same time help to confer a substantial benefit upon Thomas Edward, the Scottish Naturalist.

BLAKE'S "ASTRONOMICAL MYTHS"

Astronomical Myths. Based on Flammarion's "History of the Heavens." By John F. Blake. (London: Macmillan and Co., 1877.)

IN the continual turmoil of daily life, when each one is looking forward to new methods and new discoveries, we seldom or never look back into the doings of our early predecessors, and even when we do we are somewhat inclined to pity their ignorance and their, to us, absurd notions. We ought rather to call to mind the difficulties under which the great men of old laboured, difficulties under which our present leaders in astronomy would probably have been equally sorely tried. We must remember that we have all the sister sciences lending their aid, and that therefore the advance in astronomy should be made with constantly increasing strides.

The author of this work has put before us the labour of M. Flammarion in an English dress, and has added other matters—notably a chapter containing the researches of Mr. Haliburton on the Pleiades, to many the most interesting part of the book. We are carried back to the time when nations thought as the child did in the lines of Tom Hood, quoted by the author:—

> "I remember, I remember, the fir trees straight and high,
> And how I thought their slender tops were close against the sky;
> It was a childish fantasy, but now 'tis little joy,
> To know I'm further off from heaven than when I was a boy."

Mr. Blake commences by calling attention to the contemplation by our ancestors of the awe-inspiring phenomena of the heavens by night, the rising and setting of the sun, moon, and planets, the slow and silent motion of the constellations from east to west. To them the sky was a lofty canopy studded with stars, the earth a vast plain, the solid basis of the universe. Two distinct regions appeared to compose the whole system—the upper one, or the air, in which were the moving stars, and the firmament over all; and the lower one, the earth and the sea.

It is to be expected that in early times religious beliefs and rites were mixed up with and were derived from the motions and appearance of the heavenly bodies. The Druids appear to have seen or imagined that the moon was a body like the earth, having mountains, and, according to Plutarch, furrowed with several Mediterraneans, which the Grecian philosophers compared to the Red and Caspian seas. This celestial earth was supposed by the western theologians to be the abode of departed souls, the place of immortality. The festivals were therefore ranged accordingly, and the Druids were represented as holding a crescent in their hands.

The origin of the names of the constellations has always been a source of speculation, and the chapter on this subject is well worth study. For the names of several of them there appears to be some show of reason, but others have been named from mere caprice, or in honour of some person or event. In the case of the "Locks of Berenice," the story goes that Berenice was the spouse and sister of Ptolemy Euergetes, and that she made a vow to cut off her locks and devote them to Venus if her husband returned victorious, and, to console the king, the astrologer placed her locks among the stars. The Great Bear, the Ἄρκτος μεγάλη of the Greeks, the Okouari (bear) of the Iroquois may have been so called, as Aristotle observes, because the bear is the only animal that dared venture into the regions of the north. The Arabs called the bears the great and little coffins, and the Christian Arabs made the Great Bear the grave of Lazarus, and the three weepers Mary, Martha, and their maid.

The history of the signs of the zodiac is traced downwards in the several nations, and it is pointed out that the names may have originated in the rising of constellations at the times of certain important events, as Aquarius at the time of the inundation at Thebes, and the Bull at the time of ploughing, but this does not account for all. Further, we find how the precession of the equinoxes furnishes us with a means of fixing the date of the signs receiving their names; at that date the names of the signs of course corresponded to the zodiacal constellations, and if we find in any description that the equinox is said to be in the sign of the Bull we know that the method of naming dates back to some 3,000 years ago, for at that period the equinox happened in the constellation of the Bull. According to our present nomenclature the equinox happens in Aries, but really when the sun is in Pisces; our method therefore dates back to about 2,300 years ago when the equinox was in the constellation of

Aries, or more probably to the time of Hipparchus, when the equinox was exactly at the star β Arietis. It occurs to us that the worship of the Bull and Golden Calf was in vogue during the time that the equinox happened in the constellation of Taurus, that the Ram and Lamb were held in estimation at a later date when the equinox happened in the constellation of Aries.

The most prominent group of stars in the heavens—the Pleiades—has always been an object of attention, and we are glad to find an interesting chapter on this subject based on the careful work of Mr. Haliburton. The Pleiades, we learn, were observed for the purpose of dividing the year into two parts—one "the Pleiades above," and the other "the Pleiades below." During one half-year, while they were east of the sun, they would be visible at sunset and the reverse during the other half. The culmination of the Pleiades at midnight appears to have been with many nations the starting-point of the year, and here again the precession of the equinoxes has an interesting effect, since the tropical year is shorter than the sidereal. Thus the dates of the latter keep advancing on those of the former, and so long as dates were regulated by the stars all the countries would agree in the time of their festivals; but, as the author puts it, "as soon as a solar calendar was arranged, and it was found that at that time this position coincided with a certain day, say the Pleiades culminating at midnight on November 17, then some would keep on the date November 17 as the important day, even when the Pleiades no longer culminated at midnight then, and others would keep reckoning by the stars, and so have a different date."

The instance given of the 17th November seems to be somewhat strange, for, on referring to our star maps, it appears that the Pleiades culminate now at midnight on or about the 14th November, and years ago the midnight culmination took place of course earlier in the year. It is, however, possible that judgment of the date of midnight culmination was in error.

Mr. Blake then goes on to point out that a new year's festival determined by the Pleiades is the most universal of customs. The Australians hold their new year's corroborree in November at the midnight culmination, and in India the year was determined by the Pleiades, and on the 17th day of November is celebrated the Hindoo Durga, the festival of the dead, and new year's commemoration. So also the Egyptians regulated their solar calendar that the day might be unchanged, and the commemoration of the dead took place on the 17th of their month Athyr, the same date at which the Mosaic account of the deluge makes the same commence. This, we agree with the author, is no chance coincidence.

We cannot think, however, that the explanation of the origin of November 17 is clear, for although some 4,000 years ago the equinoctial point was close to the Pleiades, there appears no particular reason that the day on which the equinox happened when near that group would be called November 17, and if it was so called how comes it that the midnight culmination happens now within three days of the same date, while our calendar has continually been changing with reference to sidereal events? If we assume that the commemorations of India and other places are kept on the day of midnight culmination of this group, without reference to the calendar, then the events would happen now without much error on November 17, and will happen on December 17 some 2,200 years hence, and if we reckon back according to our calendar to a time—to some 4,000 years ago—the culmination and festivals would have happened on the autumnal (spring of the southern hemisphere) equinox—September 21. We do not see from the text how the Egyptian and Mosaic dates of November 17, although perhaps connected together, can have any connection with the festivals of other nations kept on that date in modern times. The calendar might have been arranged to suit the sidereal year up to a comparatively late date, but our calendar has been fitted to the tropical year much too long to allow, at its commencement, the midnight culmination of the Pleiades to have happened anywhere near November 17.

In other words, the festivals depending on the midnight culmination of the Pleiades will necessarily be kept on or about the same day, and that day happens to be February 14, or, say November 17; now unless the calendar be a sidereal one, which it is not, this festival must have, in bygone years, happened earlier than November 17. It would seem, therefore, that some other event than the culmination of the Pleiades happened, by which the Mosaic and Egyptian date of November 17 was fixed.

The further account of the Pleiades and the relation to the passage in the Pyramid of Gizeh, as investigated by Piazzi Smyth, is extremely interesting.

In the chapter on astronomical systems there is much worth reading, and the diagrams show the gradual advance of observation and order over imagination, and it seems curious to us at the present time that the ancients should have gone so far out of their way to describe the earth as a flat surface floating, with roots, on pillars, on the backs of elephants standing on a tortoise, as a portion of a cylinder, as cubical, or as having various other forms. The geography and cosmography are no less interesting, and a large number of diagrams of maps are given, many of which appear to have been made to suit the superstitious ideas of the fathers of the various churches rather than the results of observation.

The chapters on Eclipses and Comets, with the anecdotes of the consternation and awe produced by their appearance, give us a very correct idea of the all-supreme superstition of the middle and earlier ages; but even now among civilised nations there appears to be a large amount of superstition to be eradicated.

OUR BOOK SHELF

Acoustics, Light, and Heat. By William Lees, M.A., &c. Glasgow: Collins, Sons, and Co., 1877. (Collins's Advanced Science Series.)

THIS is a good specimen of a series of text-books, among which Dr. Guthrie's capital compendium of Magnetism and Electricity, and several other valuable works have appeared. It is stated, in a brief preface, to be founded on notes of the late Dr. W. S. Davis of Derby, who was to have undertaken its preparation, and to whom the first chapter, as well as the Appendix on the Doctrine of Energy, are due.

Text-books are far from easy to write in a satisfactory manner; by their very definition and nature they contain no novelty, except such as can be secured by clear treatment and lucid exposition of subjects already familiar.

They are, moreover, being issued in such numbers, under the present demand for popular education, that their very likeness to one another is fatiguing. They require also in their construction the rare faculty, whether intuitive or gained by long experience, of insight into a student's probable difficulties; for it seems desirable that they should rather aim at being employed as condensors and systematisers of knowledge already acquired generally from the study of larger and more diffuse treatises, than as independent works. It is in this respect that useful practical knowledge differs from "cram"; a distinction very real, though more difficult to define than to understand. The concentrated food offered by such compilations is less easy of digestion, and more readily expelled from the mental economy, than that which is more gradually administered and more completely assimilated.

The writer of the present manual has, for instance, only seventy pages to devote to Sound, one hundred and eighteen to Light, and ninety-one to Heat, exclusive of the Appendix. But it is remarkable how much he succeeds in compressing within these very restricted limits. The illustrative experiments are, as a rule, simple and well chosen, though occasionally trite, and even of doubtful accuracy; as is seen in the drawing of the periodic curve of a musical sound at p. 40, and that of dispersion of light on p. 135. On the other hand, the use of a long spiral steel spring to illustrate waves of compression and rarefaction, the description of the effects of Temperature on Sound-waves, and the chapters on Interference, Diffraction, and Polarisation of Light, especially in its Circular and Rotatory forms, are ingenious and easy to comprehend.

A few simple numerical examples are given of each important law, with their solutions, and the mode of working out; a method which probably tends more than any other to fix essential points on the memory of the student.

W. H. STONE

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.]

Postulates and Axioms

A STRONG committee, appointed, or rather re-appointed, for the purpose, reported last year to the British Association upon the Syllabus drawn up by the Association for the Improvement of Geometrical Teaching. I have only just seen a copy of the report, and I wish to point out that it incidentally touches in a misleading fashion upon a matter which, though primarily of only historical interest, is really of theoretical importance too, if not (in the strictest sense) for the special purpose of the committee; I mean upon the different ways of distributing the fundamental assumptions under the two heads of postulate and axiom.

Let us stop for a moment at the historical point of view. It is well known that the received text of Euclid, which we may consider represented by David Gregory's edition (Oxford, 1703), misplaces the assumption about right angles, the assumption at the base of the theory of parallels, and the assumption that two straight lines do not inclose a space. That is to say, whereas in the correct text these are the 4th, 5th, and 6th postulates, the received text makes them the 10th, 11th, and 12th common notions, or, as we usually say, axioms.

Now, when the report speaks of Euclid in this connection, it means something nearly identical with the received text. Not quite, however; for, though the language is not clear in all respects, it clearly says thus much, that Euclid divided the axioms into general and specially geometrical. But this is not the case in either text; for in both texts the first seven common notions are general, the 8th geometrical, and the 9th general again, nor is the 8th distinguished from the rest by its grammatical form. But whether you follow the received text or depart from both, it is unhistorical to affirm of Euclid what is not true of the correct text.

Let us now consider the theoretical significance of the two distributions. The case is thus stated by De Morgan, under *Eucleides*, in Smith's "Dictionary of Greek and Roman Biography," p. 66b:—"The intention of Euclid seems to have been to distinguish between that which his reader must grant, or seek another system, whatever may be his opinion as to the propriety of the assumption, and that which there is no question everyone will grant. The modern editor merely distinguishes the assumed *problem* (or construction) from the assumed *theorem*." This latter distinction is at least as old as Proculus; but to De Morgan it is Euclid's, at least as concerns right angles and parallels, that "seems most reasonable; for it is certain," he continues, "that the first two assumptions can have no claim to rank among common notions or to be placed in the same list with 'the whole is greater than its part.'" We need not pursue the modern editor's distinction further; but Euclid's acquires a more definite significance in relation to those generalised conceptions of space which, since De Morgan wrote these words, have almost passed into popular science This in its generality is a difficult subject, but for the present purpose it is enough to regard plane geometry as a particular case of the geometry of points and lines on a given surface.

In this view the postulates specify the attributes of the plane which make plane geometry what it is Thus the first three, whatever else they do, provide that the power of drawing diagrams shall not be restricted by boundaries, and the fourth, "all right angles are equal," affirms that a complete rotation is the same in quantity at all points; thereby the first three exclude surfaces having such a singular locus as a cuspidal line, and the fourth excludes surfaces having such a point as the vertex of a cone. Again the fifth excludes anticlastic surfaces, and the sixth synclastic ones and any which, like the common cylinder, returns into itself. Nothing remains but the plane and such developable surfaces as the parabolic cylinder to which *mutatis mutandis* everything in plane geometry will equally apply.

The axioms, on the contrary, specify no property of any class of surfaces. This is crucially instanced in the one axiom (the 8th, that things congruent are equal) which does concern figures traced on surfaces of only a limited class. For this axiom merely says that if things coincide they are equal, not that figures in different places may be brought to coincide.

The question may be asked whether this last assumption ought not to be premised somewhere, that is, whether the method of superposition ought not to have been vindicated by expressly assuming that any plane figure may be laid down on any plane so as to coincide with a portion of it. The omission is an extremely curious fact—in Euclid, I mean, for it is not at all remarkable in his successors. On the one hand, express statement is superfluous in the sense that the assumption is implied in the last two postulates: for the fifth affirms that the "measure of curvature" of the plane is not negative, and the sixth that it is not positive, between them it is naught, and therefore constant; but this is the condition of superposableness. On the other hand, express statement is indispensable in the sense that the student cannot do without it, because the theory of measure of curvature does not belong to elementary geometry.

The fact is that Euclid has drawn the line with what is really remarkable accuracy, but is only seen to be so in virtue of principles not discerned, I believe, by any one before Gauss. Whatever may be the explanation of this phenomenon, to ignore it in speaking of Euclid's postulates and Euclid's axioms is to depart from history where adherence to history would be instructive in theory too.

It is of course another question whether this distinction of Euclid's ought to be preserved in books intended to supersede Euclid.

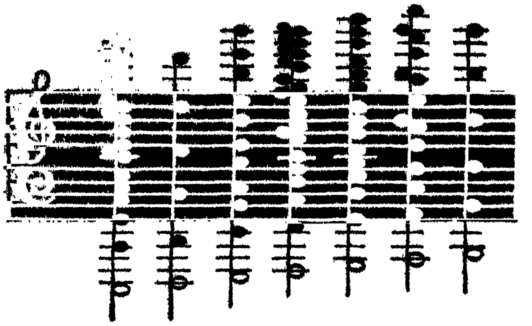
Hadley, Barnet

Just Intonation

THAT Mr. Chappell misunderstands me is due partly to his confounding vibration numbers with their ratios. Thus $\frac{9}{8}$ is the vibration number of the supertonic, where $\frac{1}{1}$ is that of the tonic; while 524288 is not the vibration number of any musical sound, though the ratio 524288 : 531441 = 2^{19} 3^{12} expresses an interval that may be picked out fourteen times in each octave of Mr. Colin Brown's keyboard. A still more complex interval $2^{22} : 3^{14}$ is found seven times in each octave.

I have followed Mr. Chappell's advice and purchased his sixpenny pamphlet, and having read it with the care it deserves, I can only say I dissent from a great part of it, especially where harmonics and the scale are treated of, and I am not surprised that its author cannot understand the numerical basis of Colin Brown's Just Intonation Harmonium.

The strict harmonic chords of the seven notes of the scale, including only sounds in the scale of C, and excluding all approximations, are these :—



Here it will be observed that all the tones of the scale are harmonics of F and of that note only (a circumstance first pointed out by Colin Brown). I do not admit that F and A are notes *interposed* in the scale of C. A. R. CLARKE

Ordnance Survey Office, Southampton, February 8

Protective Mimicry among Bats

I HAVE read with much interest the remarks of Dr. S. Archer in NATURE, vol. xv. p. 313, on the habits of *Rynchonycteris naso*, Wied. (= *Proboscidea saxatilis et rivalis*, Spix.), as they quite agree with notes on the same species made by me when travelling some years ago in British Guiana.

This is not, however, the first published notice of protective mimicry among bats. In my "Monograph of the Asiatic Chiroptera" (1876), I have referred to the peculiar markings of the wing and interfemoral membranes in *Kerivoula picta*, *Vespertilio formosus*, and *V. Welwitschii*, which are coloured on the same plan although these species are related in no other respects, and have stated that I believe these markings to be the result of "protective mimicry." Of one of the two first-named species, Mr. Swinhoe remarks :—"A species of *Kerivoula* allied to *K. picta* and *K. formosa*, was brought to me by a native. The body of this bat was of an orange brown; but the wings were painted with orange-yellow and black. It was caught, suspended head downwards, on a cluster of the round fruit of the Longan-tree (*Nephelium longanum*). Now this tree is an evergreen; and all the year through some portion of its foliage is undergoing decay, the particular leaves being, in such a stage, partially orange and black. This bat can, therefore, at all seasons, suspend from its branches, and elude its enemies by its resemblance to the leaf of the tree. It was in August when this specimen was brought to me. It had at that season found the fruit ripe and reddish-yellow, and had tried to escape observation in the semblance of its own tints to those of the fruit."[1]

A familiar instance of what appears to be "protective mimicry" occurs in the species of the genus *Pteropus* (Flying-foxes of European residents in India). These, the largest of all bats, measuring, on an average, nearly one foot in length with an expanse of wing of from four to five feet, are, from their large size, very conspicuous objects even when the wings are closed, and easily seen from the ground when hanging from lofty trees. With very few exceptions these bats have the fur of the back of the head and of the nape of the neck and shoulders of a more or less bright reddish or bright buff colour, contrasting strongly with the dark brown or black fur of the back. At first sight it might appear that this remarkable contrast of colours would render the animal more conspicuous to passing enemies, and consequently more subject to their attacks when hanging in a semi-torpid condition. But any one who has seen a colony of these bats suspended from the branches of a banyan tree, or from a silk cotton tree (*Eriodendron orientale*), must have been struck with their resemblance to large ripe fruits, and this is especially noticeable when they hang in clusters from the leaf-stalks of the cocoa-nut palm, where they may be easily mistaken for a bunch of ripe cocoa-nuts. Hanging close together, each with his head bent forwards on the chest, his body wrapped up in the ample folds of the large wings, and the back turned outwards, the brightly coloured head and neck is presented to view, and resembles the extremity of a ripe cocoa-nut, with which this anima also closely corresponds in size.[1]

The much smaller species of *Cynopterus* and *Macroglossus* which feed on the fruit of guavas, plantains, and mangoes, resemble these fruits closely in the yellow colour of their fur and i their size, so that it is very difficult to detect one of these bat when suspended among the leaves of any of these trees.

The resemblances, however, between these frugivorous bat and the fruits of the trees on which they roost, may be accidental, and, in the present state of our knowledge, we woul scarcely be justified in setting them down as the result of "protective mimicry," though there can be little doubt that, to whatever cause due, they aid in concealing these animals from th attacks of enemies.

I could adduce other instances of what appear to me to b cases of "protective mimicry" among bats, but my letter ha already much exceeded the limits intended by me when I commenced it, and I must reserve my remarks on the peculiar position of *Rynchonycteris naso* when resting on a perpendicula plane surface for another communication. G. E. DOBSON

Sense of Hearing in Birds and Insects

IN respect to "The Sense of Hearing in Birds," the habi of pattering with the feet while seeking food, which is commo to many worm-eating birds, seems to preclude the idea that suc birds at least depend to any great extent upon their powers o hearing. Gulls frequently tread or patter with their feet whil seeking food. The object being clearly to discover, from som slight movement, the whereabouts of their hidden prey. Plovers, doubtless with the same object, vibrate one foot rapidly wit tremulous motion on the ground. Now the plover is essentiall a worm-catching bird, more so even, probably, than the thrush. Light-footed, active yet stealthy in its movements, quick-sighted, and certainly quick of hearing, the plover, when feeding, runs little way, like the thrush, then stops, with head erect, lookin intently; listening it might well be thought *but for the tremulou motion of its foot*. The plover, at such time, trusts without doub to sight and not to its sense of hearing.

It is true that the thrush has not this trick of pattering wit the foot. It is true also that it has, while seeking food, ver much the look of listening attentively. The largeness of its ey and comparatively small development of its ear incline me, however, to believe with Mr. McLachlan (NATURE, vol. xv. p. 254), that the thrush also depends when feeding more on its power o sight than on its sense of hearing. C. J. A. MEYER

THE ATMOSPHERE OF THE ROCKY
e fathers TAINS[2]

ANYONE who observes with a large telescope soon becomes aware of the great obstacle atmospheric undulation offer to the pursuit of astronomy, particularly in the application o photography and the spectroscope. During two years when photographed the moon on every moonlight night at my observatory,[3] there were only three occasions on which the air wa still enough to give good results, and even then there was unsteadiness. Out of 1,500 lunar negatives, only one or tw were really fine pictures. A letter which the late Mr. Bon wrote to me states that in seventeen years he had never me with a perfectly faultless night at the Cambridge Observatory.

Such facts naturally cause astronomers to consider whether i is not possible to diminish atmospheric disturbances, and hav led to the celebrated expeditions of Prof. Piazzi Smyth to th Peak of Teneriffe, and Mr. Lassell to Malta. Theoretically i would seem that the only complete solution is to ascend hig mountain ranges or isolated peaks, and leave as much as possibl of the air below the telescope.

Having had occasion during the months of August and September, 1876, to go on a hunting trip with two distinguishe officers of the United States Army into the Rocky Mountain and Wahsatch range, I thought it desirable to carry a telescope, with a view of ascertaining whether there would be sufficient inducement to return with my 12-inch achromatic or 28-inch reflector, and make a prolonged stay.

[1] Proc. Zool. Soc. 1862, p. [illegible]

[1] In a note to Sir James Emmerson Tennent's "Ceylon," Mr. Thwaite remarks :—"These bats (*Pteropus medius*) take possession during the da of particular trees, upon which they hang like so much ripe fruit."

[2] "Astronomical Observations on the Atmosphere of the Rocky Mountains, made at Elevations of from 4,500 to 11,000 feet, in Utah, Wyomin Territory and Colorado." By Henry Draper, M.D., Professor of Analytica Chemistry and Physiology in the University of New York. Communicate by the author.

[3] Prof. Henry Draper's observatory is at Hastings-on-Hudson, near Ne York; latitude 40° 59′ 25″, longitude 73° 52′ 25″; elevation above the sea, [illegible] feet.

As it was not feasible to take an instrument of any great size, I contented myself with a small achromatic of unusual excellence. Though of only 1¼ inches aperture, it bears a power of 60 completely, and I think would carry 100. It was provided with a short brass tripod, holding an altitude and azimuth movement, giving both steadiness and smoothness of action. The eyepiece was capable of adjustment by a rack and pinion, and the object-glass was so arranged in its cell as to be free from injurious compression. This little lens stands the severe tests invented by Foucault, and in spite of its size is capable of doing good work.

In such observations on the atmosphere as those proposed during this trip, it is obvious that there are mainly two points to be considered: (1) freedom from tremor, and (2) transparency. A station combining both is most desirable, but a marked predominance of steadiness gives special advantages for celestial photography, while increase of transparency, even if accompanied by unsteadiness, is of value in eye observations. I had been led to suppose from conversations with Government officers and persons connected with the geological and geographical surveys of the territories, that the Wahsatch range, which is intermediate between the Sierra Nevada on the west and the true Rocky Mountains on the east, would offer the greatest advantages. This supposition turned out to be altogether incorrect, though it might have been argued that a high range flanked at a distance on either side by other higher ranges should have given the maximum chance for cloudless and still skies.

We first went to Salt Lake City, which, according to the Casella aneroid I carried, is at an elevation of 4,650 feet above the sea. It lies at the foot of the Wahsatch range. At eleven o'clock on the evening of arrival, August 25, I took some observations from the hotel after carefully centring the object-glass. Saturn looked about the same as on an ordinary night at my observatory. Capella, which was just clear of the house-tops across the street, twinkled as badly both to the naked eye and in the telescope as I have ever seen it at the sea-level. Lieut. Warren, of Camp Douglas [a military post near the city] said there had been a heavy rain the week previous, and the air was more moist than usual. The sun set among just such a bank of clouds as we are accustomed to see in New York. I was somewhat prepared for a tremulous condition in these high regions, because, the preceding night, having stopped for a few nights at Fort Steele, on the Union Pacific Railroad, I perceived that Antares twinkled very much, though we were nearly 7,000 feet above the sea.

However, in order to make a thorough trial it seemed best to ascend one of the high peaks of the Wahsatch, and accordingly the Red Butte was selected. The peak proved to be 7,350 feet high. Though it was quite clear when we started, clouds gathered in every direction as the sun went down, and at nightfall the sky was entirely overcast. Moreover, the wind blew so strongly that it was necessary to retire over the brow of the mountain, and eventually we returned to Camp Douglas. At this point, 5,250 feet above the sea, and about 600 feet higher than Salt Lake City, the telescope was set up to take advantage of some breaks in the clouds, through which the moon, Antares, ζ Ursæ Majoris, and Jupiter appeared. With a power of only twenty the twinkling was surprisingly great; I do not remember ever to have seen it worse with my large instruments.

These results led to an examination into the meteorology of Salt Lake City, so as to find out the rainfall and its distribution and the percentage of cloudy days.

It appears that the average annual rainfall for the past five years is $18\frac{48}{100}$ inches. There is no perfectly dry month, the nearest approach being during the summer. The cloudy dry days are 194 per annum, the disposition being similar to the rainfall.

A former pupil of mine, and graduate of the University, Dr. Benedict, informed me the Mormons believed the rainfall had much increased since their community had settled in Utah, and this seems to be borne out by the statement that whereas formerly three gallons of Salt Lake water produced on evaporation one gallon of salt, it now takes four gallons to produce the same quantity.

For these reasons it is doubtful whether there would be enough advantage in bringing a large telescope to this region to make it worth while to encounter the labour and expense.

On August 30, having taken an escort, we moved south from Fort Steele, latitude 41° 48′, longitude 107° 09′, along the North fork of the Platte River, into the main range of the Rocky Mountains. During the fifteen days' expedition there were only two nights on which we saw clouds enough to prevent astronomical working, and only one thunderstorm of any moment took place in our immediate vicinity; about one quarter of an inch of rain fell. The sky was rarely perfectly free from clouds, and many local thunderstorms occurred about the higher peaks, but they seldom extended to the plateaus below.

September 1 and 2 our camp was 8,900 feet above the sea in the vicinity of mountains rising 10,000 and 11,000 feet. These peaks seemed to be nearer than they really were, for the transparency of the air causes estimates of distance to be deceptive. From the top of one I subsequently saw the Seminole Mountain, which was 150 miles distant; it did not appear to be fifty miles away. The night of September 1 was quite clear, with very little cloud, and the atmosphere remarkably tranquil. Antares, when near setting, hardly twinkled at all, and Arcturus in the telescope, exhibited four diffraction rings unbroken by flickering. The central disc was as hard and sharply defined as the pin-hole in the lamp-screen I am accustomed to use in testing specula and lenses. I looked for the companion of Polaris, but partly on account of the nearly full moon, and partly from the thickness of the diffraction-rings, I could not be sure of it. The moon was perfectly steady; with a power of sixty there was no trace of twinkling at the terminator. I tried to see Titan, the largest satellite of Saturn, but did not succeed. At the time it was not certain whether this failure was due to the position of Titan with relation to Saturn, or whether it arose from the blinding effulgence of the moon. Capella was perfectly steady, though there was a slow change of colour from bluish to reddish, occupying about a second.

The succeeding night, at nine o'clock, though the sky was mostly covered with cumulus clouds in motion southward, I was astonished to find the terminator of the moon absolutely free from twinkling and Arcturus down among the tops of the dead aspen trees as steady as possible. The four diffraction rings round the central disc were not perfectly circular, but that was the fault of the lens. Every defect of centring or of surface and any vein in the glass comes out even more clearly than in the workshop examinations, because, while the air is as steady, the light is far more intense.

I am certain, if a large telescope could be brought here and maintained against the furious winds, great results might be attained if there is much of this weather. But this particular place is difficult of access, and possibly no better than other situations on the line of the railroad. The sky is not as black as I had expected; it is rather of a light blue, though the full moon makes much difference.

On several other nights, in both lower and higher places, I made observations, but never saw the combination of steadiness and transparency again. On the plateaus at the foot of the mountains and away from the groves of quaking aspen trees and pines, the sun sends down scorching rays all day long on the alkali plains, where only sage plants are sparsely scattered, and even on horseback one can see the heated waves rising from the ground. The air is far from being moist, for the lips are apt to crack and bleed, and the mucous membrane of the nose is parched. When the sun sets the ground rapidly radiates, and we frequently had by morning one quarter of an inch of ice in our vessels of water standing outside the tents. These plateaus are on an average about 7,250 feet above the sea. The mere fact of broken ground and wooded surroundings does not, however, suffice to produce, even at this season, a tranquil air; for when we rode over the Rocky Mountains, along the margin of perpetual snow, to the head-waters of Snake River, and camped at Trout Lake, nearly 10,000 feet high, though the air was exceedingly transparent, it was very unsteady. I rose at 4 A.M. to see Venus, and her splendour was so great that it led to a most delusive estimate of her apparent size. Occasionally, during clear frosty weather in midwinter, a night of similar characteristics is seen at my observatory. On such an occasion I obtained, at the principal focus of the 15½-inch reflector, a photograph of the moon near her third quarter in less than a second.

The officers of Fort Steele and the guides say it would be impossible to do any astronomical work in this region from the middle of October till the middle of May, that is, for seven months. The fierce winds, heavy falls of snow, and intense cold would be unbearable. Even in the beginning of September we needed large camp-fires in the morning and evening. Our camp at Trout Lake could only be reached for six weeks in summer on account of the depth of snow in the fallen timber.

On the whole, it may be remarked of this mountain region, that the astronomical condition, particularly for photographic researches, is unpromising. In only one place were steadiness and transparency combined, and only two nights out of fifteen at the best season of the year were exceptionally fine. The transparency was almost always much more marked than at the sea-level, but the tremulousness was as great, or even greater, than near New York. It is certain that during more than half the year no work of a delicate character could be done. At the end of August, in sheltered positions, and in good tents, we slept under half a dozen thicknesses of blanket, and only partially undressed. Such a degree of cold distracts the mind and numbs the body. Apparently, therefore, judging from present information, it would not be judicious to move a large telescope and physical observatory into these mountains with the hope of doing continuous work under the most favourable circumstances.

TESTIMONIAL TO MR. DARWIN

MR. DARWIN has received as a testimonial, on the occasion of his sixty-ninth birthday, an album, a magnificent folio, bound in velvet and silver, containing the photographs of 154 men of science in Germany. The list contains some of the best known and most highly honoured names in Europe. He has likewise received on the same occasion from Holland an album with the photographs of 217 distinguished professors and lovers of science in that country. These gifts are not only highly honourable to Mr. Darwin, but also to the senders as a proof of their generous sympathy with a foreigner; and they further show how widely the great principle of Evolution is now accepted by naturalists.

A German correspondent informs us that the German album bears on the handsome title-page the inscription "Dem Reformator der Naturgeschichte, Charles Darwin."

MICROSCOPICAL INVESTIGATION OF SANDS AND CLAYS[1]

THE anniversary address of the president, Mr. H. C. Sorby, F.R.S., at the Royal Microscopical Society on Wednesday, March 7, consisted mainly of an attempt to treat in a systematic manner the application of the microscope to the study of the mineral constituents of sands and clays. The various organisms found in such deposits have been much studied by Ehrenberg and other microscopists, and of late years much attention has been directed to the structure of igneous and other hard rocks, more or less allied to them, which can be cut into thin sections; but comparatively little attempt has been made to investigate the ultimate constitution of loose sands, muds, and clays.

The scope of this subject, as treated by the author, included the identification of the true mineral nature of the various particles, and the determination of the nature of the rock from which they were originally derived; the chief aim being to trace back the history of the material to the furthest possible extent.

After describing the manner in which the different kinds of deposits should be prepared, examined, and mounted as permanent objects, the author treated at some length on the conditions necessary for satisfactorily seeing the various particles with moderate or very high magnifying powers, and for observing their microscopic structure and optical characters. The particles of clay and the fluid-cavities in the grains of sand are often so minute as to task the power of the microscope to the fullest extent, and some indeed are so small that their perfect definition may perhaps be impossible by any means at our command. It was shown that the conditions under which many of the objects are visible are such that with highly convergent light and object-glasses of large aperture no dark outline is possible, and therefore they are quite invisible, but become quite distinct when the aperture is reduced to a moderate and appropriate amount. For this reason object-glasses of comparatively small aperture are far the best, since the focal point being further from the front lens, very high powers can be used in cases which are beyond the reach of lenses of large aperture.

The author then went into much detail to show the character of the grains of quartz, mica, and other minerals derived from the decomposition or breaking up of various crystalline rocks, and showed that on the whole there are many characteristic differences between the material derived from granitic and schistose rocks—this difference consisting mainly in the form, internal structure, and optical characters of the various constituent grains; the general conclusion being that a careful study of sands, muds, and clays enables us to form a very satisfactory opinion as to whether they were derived mainly from granitic or schistose rocks, or from a mixture of the two in some approximately definite proportion. It was also shown that the shape of the particles as originally derived from their parent rock is sufficiently definite and characteristic to enable us to form a very good opinion respecting the amount of subsequent mechanical or other change.

Applying those principles to the study of particular typical cases, it was shown that the coarser grained British sandstones have been mainly derived from granite rocks, of a character somewhat intermediate between those of the Scotch Highlands and Scandinavia. Some of these sandstones consist of grains which have undergone scarcely any wearing, and are as angular as those derived directly from decomposed granite, and are thus totally unlike the blown sand of the deserts, which are worn into perfectly rounded grains.

The finer grained sands are no less angular than the coarse, and have not been derived from the wearing down of larger fragments, but have resulted from the separation of the small from the large grains by the action of currents. Though some fine-grained sand-stones have been mainly derived from granitic rocks, yet, on the whole, the small particles of quartz have more commonly been derived from the breaking up of schistose rocks. Clays and shales consist to a great extent of particles identical in all their characters with those derived from the decomposition of felspars and other minerals which undergo a similar change. As a general rule we meet with many grains of sand even in clays chiefly consisting of extremely minute granules, which can easily be explained by the remarkable manner in which such material, when suspended in water, collects into small compound grains, which subside at a rate quite independent of what would be the velocity of subsidence of the separate particles if they were detached.

The conclusions derived from a study of the characters of the separate grains are confirmed by the occurrence of what may be truly considered to be grains of granite or mica schist. We also in some cases meet with grains sufficiently large to show the characteristic structure of the still more complex rocks of which they are composed. Thin sections of some of the oldest slates in Wales are thus as it were a perfect museum of specimens of the rocks existing at a still earlier period, broken up and worn down into the sands which formed these very ancient slates.

In order to establish these various conclusions it would be necessary to enter into a large amount of detail, but perhaps what has been said may suffice to indicate the general line of inquiry, and to show that by making full use of every microscopic means, it is possible to learn many important facts from such very unpromising materials as sands and clays.

---

[1] Abstract by the author.

REMARKABLE PLANTS[1]

II.—SOME CURIOUS ORCHIDS.

1. GENERAL *Structure of the Flower of Orchids.*—The exotic representatives of the natural order Orchideæ have long been favourite objects of cultivation in our hot-houses, from the beautiful and often bizarre form assumed by their curious flowers. Great as is the variety in the size, colour, and form of the flower in the different genera, it is, nevertheless, more than in most natural orders, constructed always on one plan in its main features. Before describing some of the more remarkable forms, it will be necessary to give a general description of this type, and to define the more important of the technical terms used by botanists in relation to it. Both in this account and in the description which follows of particular species, we are largely indebted to Mr. Darwin's most interesting work[2] on orchids, of which a new edition has just appeared; the illustrations are also reproduced, by the kindness of the publisher, from the same work.

In all orchids the number of sepals and petals (which together form the perianth) is three each, the former being almost always nearly or quite as brightly coloured as the latter. One of the petals—really the upper one, but, in consequence of the twisting of the ovary, apparently the lower one—is nearly always larger than the others, and is so situated as to form a convenient stage for insects to settle on. It is called the lower lip or *labellum* (Fig. 1, *l*), and often assumes the most singular and fantastic shapes. It secretes nectar or honey, which is often contained in a longer or shorter spur-shaped prolongation or nectary (*n*) at its back, but sometimes in the tissue itself, which is then commonly gnawed by insects. There is only one fertile stamen (rarely two), which is confluent with the stigma, and forms with it the *column*. The anther (*a*) consists of two cells, which are usually very distinct, and often so widely separated as to appear like two anthers. The pollen is not, in most orchids, in the form of a fine granular powder, but coherent into two club-shaped masses, the pollen-masses or *pollinia* (*p*), one contained in each anther-cell; these are prolonged below into a kind of stalk termed the *caudicle* (*c*). The ovary is inferior (beneath the calyx), often presenting the appearance of a stalk to the flower, and consists of three carpels closely united together into a single cavity. The single stigma (*s*) is sessile upon the ovary, and is confluent with the stamen (*gynandrous*). Its upper part is modified into an extraordinary organ called the *rostellum* (*r*), which, when mature, consists partly or entirely of viscid matter. In many species the pollinia are firmly attached to a portion of the exterior membrane of the stigma, which, when insects visit the flower, is removed, together with the pollinia. This removable portion of the rostellum is called the *viscid disc* (*d*), or by some authors the "gland" or "retinaculum"; when large, the portion to which the pollinia is attached is called the *pedicel* (often confounded with the caudicle). The part of the rostellum which is left after the removal of the disc and viscid matter is called the *fovea*, or sometimes the "pouch" or "bursicula." In the present paper we propose to give an account of a few orchids, interesting from the remarkable mode in which fertilisation by insects is effected.

2. *Coryanthes macrantha.*—The genus *Coryanthes* belongs to the tribe Vandeæ, which includes many of the most magnificent extra-British orchids. The extraordinary mode of fertilisation is certified by Dr. Crüger, director of the Botanic Gardens at Trinidad. The accompanying figure (Fig. 2) represents the flower of *C. speciosa*, an allied species, but will serve to show the relative position of the parts. It is very large, and hangs downwards. The lower portion of the labellum (L) is converted into a kind of bucket (B). Two short appendages (H), which arise from the narrowed base of the labellum, stand directly over this bucket, and secrete so much limpid and slightly sweet fluid that it drops into the bucket; the quantity secreted by a single flower is said to be about an ounce, but it does not appear to attract insects. When the bucket is full, this fluid overflows at a channel which forms a kind of spout (P), closely over-arched by the end of the column, which bears the stigma and pollinia in such a position that an insect, forcing its way out of the bucket through this passage, would first brush with its back against the stigma, and afterwards against the viscid discs of the pollinia, and thus remove them. In *C. macrantha* the labellum is, according to Dr. Crüger,[3] provided with crests, which are gnawed by bees, as is commonly the case with the labellum of the Vandeæ. In this case the bees have been determined by Mr. F. Smith, of the British Museum, to belong to the genus *Euglossa*. Dr. Crüger states that these bees may be seen in great numbers disputing with each other for a place on the edge of the "hypochil" or basal part of the labellum. Partly by this contest, partly, perhaps, intoxicated by their food, they fall into the bucket, which is half full of the fluid already mentioned. They then crawl along in the water towards the anterior side of the bucket, where they arrive at the spout. But, in order to extricate itself through this opening, the bee has to use considerable exertion, as the mouth of the

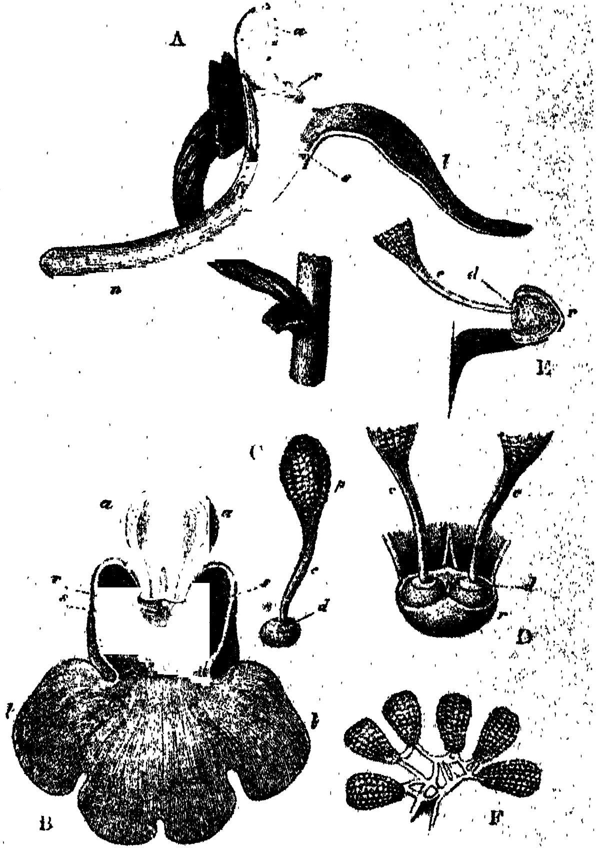

FIG. 1.—*Orchis mascula.* A, side view of flower, with greater part of perianth cut away; B, front view of flower; C, pollinium and viscid disc; D, caudicles with the viscid discs lying within the rostellum; E, section through rostellum; F, packets of pollen-grains; *a*, anther; *r*, rostellum; *s*, stigma; *l*, labellum; *n*, nectary; *p*, pollinium; *c*, caudicle of pollinium; *d*, viscid disc.

---

[2] "The Various Contrivances by which Orchids are Fertilised by Insects." By Charles Darwin, M.A., F.R.S., &c. Second Edition, revised, with Illustrations. (London: J. Murray, 1877.)

[3] *Journal of Linnean Society*, Botany, vol. viii., 1864, p. 130.

"epichil," or upper part of the labellum, fits closely to the column and is very stiff and elastic. The first bee which is immersed will have the pollinia glued to its back by their viscid disc. Having escaped through the passage with this appendage, the insect then returns nearly immediately to its feast, when it is generally precipitated a second time into the bucket, passes out through the same opening, and thus inserts the pollinia into the stigma as it forces its way out, thereby impregnating either the same or some other flowers. Dr. Crüger states that he has seen so many of the bees taking part in this operation that there is a continual procession of them through the passage. "There cannot be the least doubt," says Mr. Darwin, "that the fertilisation of the flower absolutely depends on insects crawling out through the passage formed by the extremity of the labellum and the over-arching column. If the large distal portion of the labellum or bucket had been dry the bees could easily have escaped by flying away. Therefore we must believe that the fluid is secreted by the appendages in such extraordinary quantity, and is collected in by the bucket, not as a palatable attraction for the bees, as these are known to gnaw the labellum, but for the sake of wetting their wings and thus compelling them to crawl out through the passage."

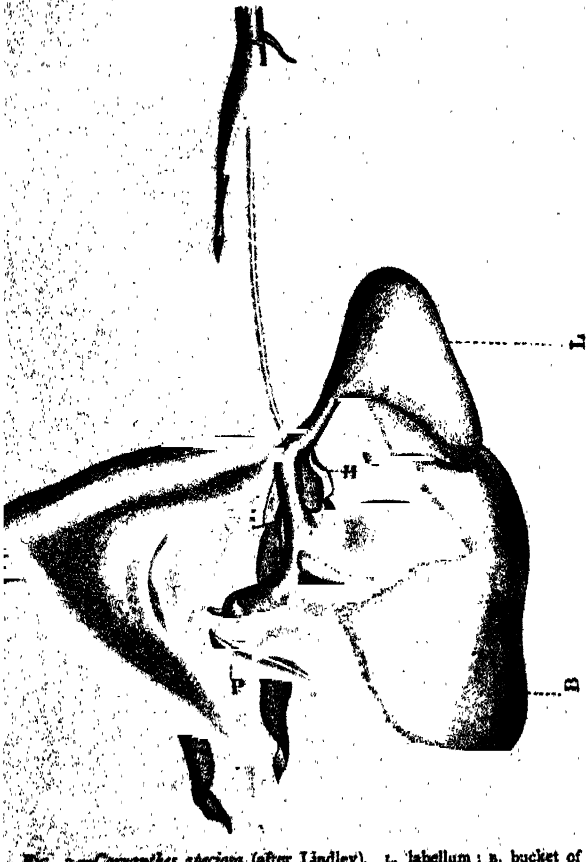

FIG. 2.—*Coryanthes speciosa* (after Lindley). L, labellum; B, bucket of labellum; H, fluid-secreting appendages; P, spout of bucket, over-arched by the end of the column bearing the anther and stigma.

3. *Catasetum saccatum.*—The genus *Catasetum* belongs also to the sub-order Vandeæ, and to a section of that order, the Catasetidæ, distinguished from all other orchids by several very remarkable peculiarities. In the first place it stands almost alone among all genera of orchids in having unisexual flowers; and so greatly do the male and female flowers—which are usually borne on different plants—differ from one another, that they were long regarded as belonging to different species, or even genera; while, to complicate the matter still further, some kinds have a third hermaphrodite form differing greatly from either of the others. Thus *Catasetum tridentatum* (male), *Monachanthus viridis* (female), and *Myanthus barbatus* (hermaphrodite), are now known to be three forms of the same species. The second peculiarity of the male flowers of *Catasetum* is that they are provided with an extraordinary mechanical contrivance by means of which the pollinia are forcibly ejected on to the back of the insect, and thus carried to a female flower of the same species. There is no nectar in the male flower to attract insects; the ejection of the pollinia results from the accidental touching, by the wing of a passing insect or of one seated on the labellum for the purpose of gnawing it, of two long horns or *antennæ*, which occur in no other genus, and are placed in such a position that when touched by the insect the pollinia are projected on to its body, to which they adhere by their blunt and excessively adhesive point. The insect then flies away to a female plant, and while standing in the same position as before on the flower, the pollen-bearing end of the pollinia is inserted into the stigmatic cavity, and a mass of pollen left on its viscid disc. Mr. Darwin has examined five species of *Catasetum*, and finds that this is the only possible way in which they can be fertilised.

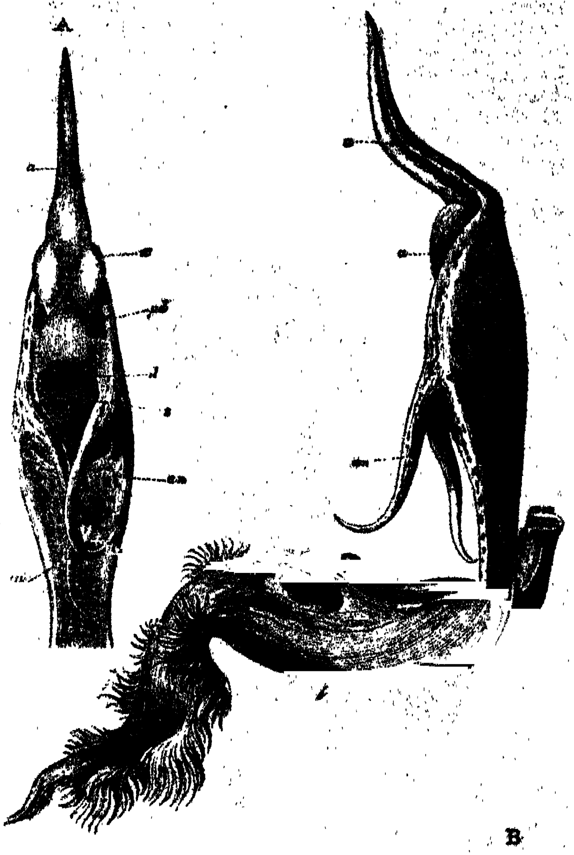

FIG. 3.—*Catasetum saccatum*. A, front view of column; B, side view of flower, with all the perianth except the labellum removed; *a*, anther; *an*, antennæ; *d*, viscid disc; *l*, labellum; *pd*, pedicel of pollinium; *s*, stigmatic chamber.

In the accompanying Fig. 3 (A being a front, B a side view of a flower, from which all the perianth except the labellum has been removed), *a* represents the anther containing the pollinia, and prolonged above into a long point, *an* the antennæ, which are rigid, curved, hollow horns tapering to a point; but the two differ from one another in this respect, that the apex of the left-hand one bends upwards, while the right-hand one hangs down, and is apparently almost always paralysed and functionless; *l* is the labellum; *d* the disc of the pollinium, which is remarkably large and viscid; *pd* the pedicel of the pollinium; *s* the stigmatic chamber, which is of course functionless in the male flower. The action of the parts is thus described by Mr. Darwin:—When the left-hand antenna is touched, the edges of the upper membrane of the disc, which are continuously united with the surrounding surface, instantly rupture, and the disc is set free. The highly elastic pedicel then instantly flirts the heavy disc out of the stigmatic chamber with such force that the whole pollinium is ejected, bringing away with it the two balls of pollen, and tearing the loosely-attached spike-like anther from the top of the column. The pollinium is always ejected with its viscid disc foremost, and with such force that it is thrown to a distance of two or three feet. On one occasion Mr. Darwin touched the antenna of an allied species, *C. callosum*, while holding the flower at about a yard's distance from the window, when the pollinium hit the glass, and stuck by its adhesive disc to the smooth vertical surface. A series of experiments showed that even violent concussion of any other part of the flower except the antenna produced no effect whatever in disturbing the pollinia.

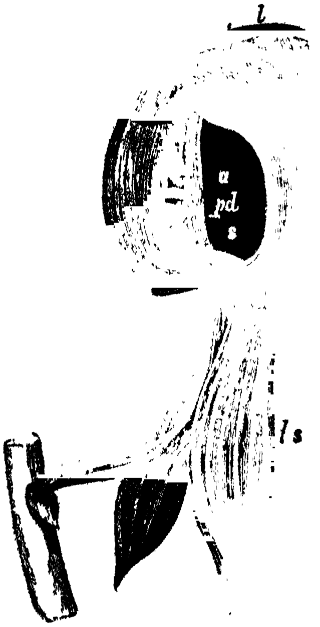

FIG. 4.—*Mormodes ignea*. Lateral view of flower with one of the sepals and one of the petals removed. *a*, anther; *pd*, pedicel of pollinium; *s*, stigma; *l*, labellum; *ls*, lateral sepal.

4. *Mormodes ignea*.—The genus *Mormodes* belongs also to the small family Catasetidæ; the pollinia are again violently ejected, as in *Catasetum*; but the mode in which this is effected is somewhat different, and very curious. The appearance presented by the flower is represented in Fig. 4. The base of the column is bent backwards, at right angles to the ovary, then resumes an upright position, and is finally again bent near the summit. It is also twisted so that the anther, rostellum, and the upper part of the stigma face one side of the flower, to the right or left, according to the position of the flower in the spike. In the drawing, *a* represents the anther, which is elongated and triangular, but does not extend to the apex of the column. A group of spiral vessels runs up the column as far as the summit of the anther; they are then reflexed, and run some way down the anther-case. The point of reflexion forms a short thin hinge, by which the top of the anther-case is articulated to the column beneath its bent surface; and this hinge appears to be the sensitive portion of the structure, conveying any stimulus from a touch to the disc of the pollinia, and causing the ejection of the latter. *pd* is the pedicel of the pollinium, covering the rostellum; *st*, the stigmatic surface, which extends down to the base of the column, and is hollowed out into a deep cavity at its upper end; *l* is the very remarkable labellum, narrowed at the base into a nearly cylindrical foot-stalk, and its sides so much reflexed as almost to meet at the back, forming a folded crest at the summit of the flower. Near the summit it has a slight cavity, into which the summit of the column fits, fixing it in its place. The whole labellum is compared by Mr. Darwin to a cocked hat supported by a foot-stalk, and placed on the head of the column. *ls* are the two lower sepals, which hang down like wings; the upper sepal and one of the lateral petals have been cut off. By a number of experiments Mr. Darwin found that the minute hinge in the anther-case already described is the only portion of the flower that is sensitive to touch. When an insect lights on the folded crest of the labellum, the only convenient landing-place, he will lean over the front of the column in order to gnaw or suck the bases of the petals, which are filled with a sweet fluid. In so doing, he will disturb the summit of the column which fits into the cavity of the labellum; this will press on the hinge in the anther-case; the stimulus will then be conveyed to the pollinium-disc, and the pollinium will be violently ejected. Owing to the peculiar structure of the parts, guided by the hinge, which now serves a second function, the direction in which the pollinium flies is necessarily vertically upwards. If no object is in the way, it is projected perpendicularly up in the air, an inch or two above and close in front of the terminal part of the labellum, and would then alight on the folded crest of the labellum immediately above the column. But if the insect which has caused the disturbance remains in the same position, the pollinium will necessarily alight on his head, and will thus be carried off to fertilise another flower. The pollinium has, however, still the anther-cap attached to it; this drops off, as the pedicel dries on exposure to the air and gradually straightens itself from the almost hoop-shaped form which it bore when ejected; and when this has been done, the pollen-masses attached to the head of the insect are precisely in a position to strike against the stigmatic surface of the next flower visited.

Other instances, almost as extraordinary, could be cited of the special contrivances met with in species belonging to this order, to insure cross-fertilisation rather than self-fertilisation of the flowers.

A. W. B.

THE MOVEMENT OF THE SOIL-CAP

AMID all their general tameness the Falkland Islands boast one natural phenomenon which is certainly exceptional, and at the same time very effective.

In the East Island most of the valleys are occupied by pale-grey glistening masses, from a few hundred yards to a mile or so in width, which look at a distance much like glaciers descending apparently from the adjacent ridges, and gradually increasing in volume, fed by tributary streams, until they reach the sea. Examined a little more closely, these are found to be vast accumulations of blocks of quartzite, irregular in form, but having a tendency to a rude diamond shape, from two to eight or ten or twenty feet long, and perhaps half as much in width, and of a thickness corresponding with that of the quartzite bands in the ridges above. The blocks are angular, like the fragments in a breccia, and they rest irregularly one upon the other, supported in all positions by the angles and edges of those beneath.

They are not weathered to any extent, though the edges and points are in most cases slightly rounded; and the surface, also perceptibly worn, but only by the action of the atmosphere, is smooth and polished; and a very thin, extremely hard, white lichen, which spreads over nearly the whole of them, gives them the effect of being covered with a thin layer of ice.

Far down below, under the stones, one can hear the stream of water gurgling which occupies the axis of the valley; and here and there, where a space between the blocks is unusually large and clear, a quivering reflection is sent back from a stray sunbeam.

At the mouth of the valley the section of the "stone river" exposed by the sea is like that of a stone drain on a huge scale, the stream running in a channel arched over by loose stone blocks, or finding its way through the spaces among them. There is scarcely any higher vegetation on the "stone river;" the surface of every block is slippery and clear, except where here and there a little peaty soil has lodged in a cranny, and you find a few trailing spikes of *Nassauvia serpens*, or a few heads of the graceful drooping chrysanthemum-like *Chabræa suaveolens*.

These "stone-rivers" are looked upon with great wonder by the shifting population of the Falklands, and they are shown to visitors with many strange speculations as to their mode of formation. Their origin seems, however, to be obvious and simple enough, and on that account their study is all the more instructive; for they form an extreme case of a phenomenon which is of wide occurrence, and whose consequences are, I believe, very much underrated.

There can be no doubt that the blocks of quartzite in the valleys are derived from the bands of quartzite in the ridges above, for they correspond with them in every respect; the difficulty is to account for their flowing down the valley, for the slope from the ridge to the valley is often not more than six to eight degrees, and the slope of the valley itself only two or three, in either case much too low to cause blocks of that form either to slide or to roll down.

The process appears to be this. The beds of quartzite are of very different hardness; some are soft, passing into a crumbling sandstone; while others are so hard as to yield but little to ordinary weathering. The softer bands are worn away in process of time, and the compact quartzites are left as long projecting ridges along the crests and flanks of the hill-ranges. When the process of the disintegration of the softer layers has gone on for some time the support of their adjacent beds is taken away from the denuded quartzites, and they give way in the direction of the joints, and the fragments fall over upon the gentle slope of the hillside. The vegetation soon covers the fallen fragments and usually near the sloping outcross of the hard quartz, a slight inequality only in the surface of the turf indicates that the loose blocks are embedded beneath it. Once embedded in the vegetable soil a number of causes tend to make the whole soil-cap, heavy blocks included, creep down even the least slope. I will only mention one or two of these. There is constant contraction and expansion of the spongy vegetable mass going on, as it is saturated with water or comparatively dry; and while with the expansion the blocks slip infinitesimally down, the subsequent contraction cannot pull them up against their weight; the rain-water trickling down the slope is removing every movable particle from before them; the vegetable matter on which they are immediately resting is undergoing a perpetual process of interstitial decay and removal. In this way the blocks are gradually borne down the slope in the soil-cap and piled in the valley below. The only other question is how the soil is afterwards removed and the blocks left bare. This, I have no doubt, is effected by the stream in the valley altering its course from time to time, and washing away the soil from beneath.

This is a process which, in some of the great "stone-rivers" in the Falkland Islands, must have taken an enormous length of time. I fear that the extreme glacialists will see in it a danger to the universal application of their beloved theory to all cases of scratching and grooving. I have known too much of the action of ice to have the slightest doubt of its power; but I say that ice had no hand whatever in the production of these grand "moraines" in the Falkland Islands.

In the West Highlands of Scotland, and in many other parts of the world, I have often noticed that when a hill of such a rock as clay-slate comes down with a gentle slope, the outcrop of the vertical or highly-inclined slates covered with a thick layer of vegetable soil or drift containing imbedded blocks and boulders derived from higher levels, the slates are frequently first slightly bent downwards, then abruptly curved and broken, and frequently the lines of the fragments of the fractured beds of slate can be traced for a yard or two in the soil-cap, gradually becoming parallel with its surface, and passing down in the direction of its line of descent. These movements are probably extremely slow. I well remember many years ago observing a case, somewhere in the west of Scotland, where a stream had exposed a fine section of the soil-cap with the lines of broken-down and crushed slate-beds carried far down the slope. The whole effect was so graphically one of vigorous and irresistible movement that I examined carefully some cottages and old trees in hope of finding some evidence of twisting or other irregular dislocation, but there appeared to be none such. The movement, if it were sufficiently rapid to make a sign during the life-time of a cottage or a tree, evidently pervaded the whole mass uniformly.

It seems to me almost self evident that wherever there is a slope, be it ever so gentle, the soil-cap must be in motion, be the motion ever so slow; and that it is dragging over the surface of the rock beneath the blocks and boulders which may be embedded in it, and frequently piling these in moraine-like masses, where the progress of the earth-glacier is partially arrested, as at the contracted mouth of a valley, when the water percolating through among them in time removes the intervening soil. As the avalanche is the catastrophe of ice-movement, so the land-slip is the catastrophe of the movement of the soil-cap.

As I have already said, I should be the last to undervalue the action of ice, or to doubt the abundant evidences of glacial action; but of this I feel convinced, that too little attention has been hitherto given to this parallel series of phenomena, which in many cases it will be found very difficult to discriminate; and that these phenomena must be carefully distinguished and eliminated before we can fully accept the grooving of rocks and the accumulation of moraines as complete evidence of a former existence of glacial conditions.

C. WYVILLE THOMSON

ON THE INFLUENCE OF GEOLOGICAL CHANGES ON THE EARTH'S AXIS OF ROTATION[1]

THE subject of the fixity or mobility of the earth's axis of rotation in that body, and the possibility of variations in the obliquity of the ecliptic has of late been attracting much attention. Sir W. Thomson referred shortly to it in his address at Glasgow last September, and Dr. Jules Carret has just published an ingenious book on the subject.[1]

---

[1] An account of a paper by G. H. Darwin, M.A., read before the Royal Society on November [illegible] 1876.

The paper, of which the following is an abstract, is an attempt to investigate the results of the supposition that the earth is slowly changing its shape from internal causes. The first part is devoted to the mathematical consideration of the precession and nutations of a spheroid slowly undergoing such a change. It is shown that the obliquity of the ecliptic must have remained sensibly constant throughout geological history, and that even gigantic polar icecaps cannot have altered the position of the Arctic circle by so much as three inches; and this would be the most favourable redistribution of matter for producing that effect.

But a slow distortion of the earth would displace the principal axis of figure of the earth, and the axis of rotation would always sensibly follow the axis of figure. Thus the result would be a change in the geographical position of the poles, without any alteration of the diameters of the arctic circles, or in the width of the tropics.

For reasons, which cannot be given here, it is maintained that the earth would not be rigid enough to resist the effects of considerable departures from the figure of equilibrium, such as would arise from a wandering of the pole of figure from its initial position; and that readjustments to an approximate form of equilibrium would probably take place, at considerable intervals of time, impulsively by means of earthquakes. Such periodical adjustments would not sensibly modify the geographical path of the principal axis as due to terrestrial deformation.

The rest of the paper is given to the consideration of the kinematical question of the change in the geographical position of the pole, due to any distortion of the earth. It is assumed, in the first place, that the deformation is such that there is no change in the strata of equal density; and accordingly all suppositions as to the nature of the internal changes accompanying geological upheaval and subsidence are set aside. The forms of continents and depressions are investigated, which would cause the maximum deflection of the pole for elevations and depressions of given amounts.

In order to make numerical application to the case of the earth, some estimate is required of the extent to which it may have become distorted during any one geological period. From the consideration of certain facts, the author believes that from $\frac{1}{10}$ to $\frac{1}{20}$ of the whole earth's surface may have, from time to time, undergone a consentaneous rise or fall; and that the vertical rise or fall may be about 10,000 feet, or rather equivalent to about 10,000 feet, when allowance is made for the influx of the sea into depressed areas.

The first application given in this paper is to continents and seas of the most favourable shapes and positions. It may be here stated that if $\frac{1}{200}$ of the earth's surface is elevated by 10,000 feet, the deflection of the pole is $11\frac{1}{4}'$; if $\frac{1}{20}$ of the whole surface, 1° $46\frac{1}{2}'$; if $\frac{1}{10}$, 3° 17′; and if $\frac{1}{2}$, 8° $4\frac{1}{2}'$.[2] In each case an equal area is supposed to fall simultaneously.

Other examples are also given for continents and seas which do not satisfy the maximum condition; in some the boundaries are abrupt cliffs, in others shelving.

The conclusion is arrived at that a single large geological change, such as those which obtain on the earth, is competent to produce an alteration in the position of the pole of *from one to three degrees of latitude*, on the hypothesis that there is no change in the law of internal density.

Various other hypotheses as to the nature of the internal changes accompanying the deformation of the earth are discussed.

1. It is shown that if upheaval and subsidence are due to a shrinking of the earth as a whole, but to the shrinking being quicker than the mean in some regions and slower in others, the results are the same as those previously attained.

2. The increase of surface-matter due to the deposit of marine strata also gives the same results.

3. The hypothesis that upheaval and subsidence are due to intumescence or contraction immediately under the regions in question is considered. Under certain special assumptions, too long to recapitulate, it is shown that the previous results must be largely reduced. It appears that if the swelling or contracting stratum is tolerably thin and at all near the surface, the deflection of the pole is reduced to quite an insignificant amount. Even if the intumescence extends right down to the centre of the earth in a cone bounded by the elevated region, the results would be only about $\frac{2}{3}$ of the former ones. Hence it appears that the earlier results can only be stated as the greatest possible for given superficial changes.

In conclusion it is pointed out that if the earth be quite rigid, no redistribution of matter in new continents could ever cause the deviation of the pole from its primitive position to exceed the limit of about 3°. But if the previously maintained view is correct, that the earth readjusts itself periodically to a new form of equilibrium, then there is a possibility of a cumulative effect; and the pole may have wandered some 10° or 15° from its primitive position, or have made a smaller excursion and returned to near its old place. No such cumulation is possible, however, with respect to the obliquity of the ecliptic.

It is suggested that possibly the glacial period may not have been really one of great cold, but that Europe and North America may have been then in a much higher latitude, and that on the pole retreating they were brought back again to the warmth. There seem to be, however, certain geological objections to this view.

THE NEW STAR IN CYGNUS[1]

On January 9 the sky was unusually clear and the spectrum of Dr. Schmidt's Nova came out with amazing sharpness and brilliancy. In addition to the five bright lines seen on the 2nd, two others were detected, viz.:—

		Mill mm	
No. 1a	W. L.	594	Very narrow line.
,, 7	,,	414±	Excessively faint, but still certainly and repeatedly seen.

Between wave-lengths 655 and 594 the spectrum was certainly banded, and, most probably, there were two additional faint maxima of brilliancy in that interval. The continuous spectrum attains a maximum in the region about W. L. 525, and extends, though possibly not without interruption, as far as the faint line No. 7. The star was estimated of seventh magnitude, and was of a red colour with a decided tinge of purple, reminding me forcibly of the varieties of red produced by the quartz-plate in Zöllner's photometer.

RALPH COPELAND

Lord Lindsay's Observatory, Dunecht, January 13

OUR ASTRONOMICAL COLUMN

THE NEW COMET.—The comet discovered by M. Borrelly, at Marseilles, on the morning of February 9, appears to have been found independently by Herr Pechule at the Observatory of Copenhagen on the following morning. During the past week it has been making a pretty near approach to the earth, and had the weather been more favourable in Europe, it would probably have been very generally observed.

The following elements of the orbit have been calculated by Mr. Hind from the first observation by M. Borrelly, one at

---

[1] "Le Déplacement Polaire." Savy, Paris, 1877.

[2] The area of Africa is about ·059, and of South America about ·033 of the earth's surface.

[1] *Astronomische Nachrichten*, No. 2,117.

Kiel on the 10th, and one made at the Imperial Observatory at Strasburg on the 15th, and communicated by Prof. Winnecke:—

Perihelion Passage, January 19·18017, Greenwich M.T.

	°	′	″	
Longitude of the perihelion ...	200	5	42	Apparent Equinox, Feb. 10.
" " ascending node	187	14	22	
Inclination to the ecliptic ...	27	5	13	
Logarithm of perihelion distance	9·907086			

Heliocentric motion—retrograde.

According to this orbit the comet was distant from the earth, at the time of discovery, 0·45, the earth's mean distance from the sun being taken as unity. Its apparent path in the heavens about the perigee, and up to March 6, will be sufficiently defined by the following ephemeris:—

For Greenwich Midnight.

	Right Ascension.	North Polar Distance.	Distance from the Earth.
	° ′	° ′	
February 13 ..	262 50	70 22	0·324
15	266 21	57 2	0·292
17... .	272 10	41 42	0·279
19. . ..	283 10	26 48	0·288
21. . .	307 40	15 35	0·318
23.....	359 21	11 52	0·363
25	27 41	15 9	0·418
27	42 51	19 43	0·479
March 6. . ..	58 51	31 1	0·719

From the above figures it will be seen that the diurnal motion, about the middle of the present month, amounted to 8° in arc of great circle; the comet was nearest to the earth soon after midnight on the 17th. At the time of perihelion passage it would be situated about 6° to the east of Antares, distant from the earth 1·15.

There is a certain similarity, but by no means a striking one, between the elements of this comet and those of the comet of 1590, observed by Tycho Brahé, the orbit of which was first calculated by Halley, and, in 1846, after a new reduction of Tycho's observations, by Mr. Hind (*Ast. Nach.*, No. 584). It may be worthy of remark that shortly after the passage of the ascending node, the comet of 1590 approaches very near to the orbit of the planet Venus, the least distance not exceeding 0·04. Still the differences between the elements of the comets of 1590 and 1877, especially in the perihelion distance, are material.

The "Berliner Astronomisches Jahrbuch."—Under the active superintendence of Prof. Tietjen, the *Berliner Jahrbuch* continues the heavy labour involved in the preparation of ephemerides of the extensive group of small planets, a work which for many years past has been made its specialty. In the volume for 1879 now before us, we have the places for 1877 of 151 out of the 172 actually known members of the group, No. 164, Eva, being the latest discovery included in the list. Also the elements of their orbits and the opposition magnitudes, a very useful addition towards the identification of these minute bodies amongst the fainter stars. The portion of the volume devoted to the small planets extends to 106 pages. The judicious transfer of the ephemeris of the moon, derived from Hansen's Tables from our *Nautical Almanac*, which appears between one and two years earlier, to the pages of the *Berliner Jahrbuch*, after adaptation to the meridian of Berlin, whereby a most serious expenditure of time and labour is saved, has already been noted in this column; it is a step which no doubt assists materially in completing the peculiar work of the *Jahrbuch*.

The following are names which have been recently proposed, for discoveries made within the last few years: No. 139 *Juewa*, 149 *Medusa*, 150 *Nuwa*, 155 *Scylla*, 160 *Una*, 161 *Athor*, 163 *Erigone*, 164 *Eva*. No. 162 is not yet named.

Only four of these planets (in addition to two of the old members) attain 8·5m. or upwards at their oppositions in 1877. Ariadne, in opposition on July 24, approaches the earth within about 0·84 of the earth's mean distance from the sun, and Iris, which at her opposition on November 18, is calculated to be 6·8m. or on the limit of acute unaided vision, will be distant from us 0·86—affording an opportunity which may be utilised for attempting direct measures of her diameter, though if we are not mistaken some pretty satisfactory measures were made at a favourable opposition a few years since, with a powerful refractor in this country. This planet when near the earth has a decidedly red light; at two oppositions within the last fifteen years it might be identified amongst the neighbouring stars by this circumstance alone.

CHEMICAL NOTES

Absorption of Light in the Blood.—In a number of cases of unintentional poisoning caused by carbon monoxide in Berlin during the past winter, oxygen has been used as an antidote. Dr. Baeblich, of Berlin, lately showed the desirability of the method by means of spectroscopic proof in a public lecture. As is well known, the spectrum of blood shows two well-defined bands between Fraunhofer's lines D and E. By the absorption of CO the position of these bands is very slightly changed in the direction of the red part of the spectrum. The difference is more strikingly shown by the addition of sulphide of ammonium. In the case of healthy blood the two bands of the spectrum disappear and are replaced by a single one situated midway between the positions of the former pair. Blood poisoned with CO shows no change in the bands by the same treatment. If oxygen is, however, added to it before the reduction with sulphide of ammonium, the characteristic spectrum of healthy blood is at once produced.

Physical Properties of Gallium.—M. Lecoq de Boisbaudran has introduced a new method for the extraction of this metal, and has investigated some of its physical properties. Its crystalline form is octahedral; the mean of six experiments gave as its melting point 30·15. Its specific gravity is 5·956; when fused it has a silver lustre, but on solidifying it shows a tinge of blue, losing its brilliancy. It is hardly acted on by nitric acid when diluted with an equal bulk of water.

Potassium Tri-iodide.—Mr. G. S. Johnson has recently published an investigation on this body, which is prepared when a strong solution of potassium iodide is saturated with iodine, and the resulting liquid allowed to evaporate slowly over oil of vitriol. The crystals are sometimes long and isolated, sometimes appearing as hexagonal plates exhibiting a stepped arrangement like those of potassium iodide. They have a steel-blue lustre, are very deliquescent, fusing at about 45° C., and have a specific gravity of 3·498. When the temperature is raised above 100°, iodine is freely evolved from the crystals, a white mass of potassium iodide alone remaining. On analysis the crystals yielded 90·2 to 90·4 per cent. of iodine and 9·2 per cent. of potassium; the theoretical quantities required, supposing the body to be KI_3, are iodine 90·692 per cent. and potassium 9·307 per cent. An excess of water decomposes potassium tri-iodide, with precipitation of the most of the iodine; the crystals, however, may be dissolved in small quantities of water or alcohol, and recrystallised over sulphuric acid.

Solution of Gases in Iron, Steel, and Manganese.—MM. Troost and Hautefeuille have published in the *Ann. Chim. Phys.*, [5] vii., a reprint of their researches on this subject, previously published in other journals. When cast iron is fused in contact with silica or silicates, carbonic oxide is produced by the action of the iron carbide on silica; the iron thus becomes richer in silicon, the carbon diminishing. Melted cast iron seems to occlude considerable quantities of hydrogen, this occlusion being increased by the presence of manganese and diminished by the presence of silicon. Carbonic oxide is not taken up to so great an extent as hydrogen by melted cast iron, its occlusion is almost entirely prevented by the presence of manganese. Gases are retained by pig iron after cooling, but can be extracted by heating the metal to 800°. Steel occludes less gas than cast iron, hydrogen predominating over carbonic oxide; on the other hand more carbonic oxide than hydrogen is occluded by soft iron. Finely divided iron free from gases decomposes water slowly at the ordinary temperature, rapidly at 100°, the decomposition being more rapid the finer the state of division of the iron.

NOTES

THE golden Baer medal was awarded this year, by the St. Petersburg Academy of Sciences, to Prof. Bunge, for his various works upon the flora of Russia. The Lomonosoff premium, value 1,000 roubles, was awarded to Prof. Beilstein, of Kazan, for researches on the properties of bodies of the benzoil series.

M. ANDRÉ, the astronomer who was sent by the French Institute to New Caledonia to observe the transit of Venus, has been appointed director of the new observatory established at Lyons by M. Waddington.

AT the half-yearly General Meeting of the Scottish Meteorological Society, held yesterday, the Duke of Richmond was elected President. The following papers were read:—1. On methods of estimating ozone and other constituents of the atmosphere, by Mr. E. M. Dixon, B.Sc., Office of Health, Glasgow. 2. On the peculiarities of the weather of December and January last, by Mr. Buchan, Secretary. 3. Observations of rainfall at sea on board ship, by Dr. Black, Surgeon-Major.

THE Report of the Treasury Meteorological Commission appointed in the autumn of 1875 has now been published. The chief recommendations are that ocean meteorology be transferred from the Meteorological Office to the Admiralty, that the annual Parliamentary Grant be increased from 10,000*l.* to 14,500*l.*, and that, in addition to the above, some pecuniary assistance, the amount not being specified, be given to the Scottish Meteorological Society, on whose claims to Government support the Commission was specially instructed to report.

WE recently announced (p. 116) that the city of Brunswick was making preparations to celebrate the 100th anniversary of the birth of Carl Friedrich Gauss, the "prince" of mathematicians, who was born in that city on April 30, 1777. It is proposed to erect a monument in Brunswick to Gauss, and from the circular which has been sent us we learn that the Monument Committee consists of the principal officials of the city, civil, professional, and commercial. No doubt many English men of science might wish to contribute to this monument; contributions should be addressed to the Gauss Monument Fund, Brunswick Bank.

WE can do no more this week than refer to the fact that the Oxford and Cambridge Universities Bill passed the second reading on Monday, as might have been expected, practically without opposition. The Bill does not differ essentially from those introduced last year in reference to the two Universities.

THE fourth Congress of Russian Archæologists will be opened on August 12, at Kazan. All communications should be addressed to Count Ouvaroff, at the Moscow Archæological Society.

WE are glad to hear that the founding of a Russian Anthropological Society at St. Petersburg may be considered as finally settled. Certainly many Russian scientific bodies have now special anthropological sections which, as for instance that of the Moscow Society of Friends of Natural Science, have done a good deal of valuable work, but it is also very desirable that the separate efforts of Russian anthropologists be more concentrated than they are at present.

THE Senatus Academicus of the University of St. Andrews have conferred the degree of LL.D. upon Dr. B. W. Richardson, F.R.S., and Dr. James Murie, F.L.S.

IN a small *brochure* recently published, Prof. Ragona, of the Royal Observatory of Modena, advocates the formation of an "Italian Meteorological Society." There are at present more than 100 meteorological stations throughout the peninsula, at various heights from the sea-level to 2,550 metres. Most are occupied also with magnetic observations; some are devoted almost exclusively to seismometry. The Minister of Agriculture, Industry, and Commerce publishes an *Italian Meteorological Bulletin*, and the Naval Minister sends out daily intimations of the state of the atmosphere throughout Europe, and of probabilities of weather. The proposed Society might hold an annual congress now in one city, now in another, and might, like the Austrian, receive a grant from Government.

DR. GABRIEL, of the University of Breslau, a well-known morphological investigator, has been sent by the Berlin Academy of Sciences to Naples to carry on for four months an extended series of observations on microscopic marine organisms. The necessary funds have been granted partly by the Academy and partly by the Prussian department of instruction.

THE Great Northern Railway Company have a bill now before Parliament for the construction of a line of railway from Shepreth to March, which will pass at a distance of not more than 1,700 feet from the Cambridge Observatory. From the experience of other observatories, and from the evidence of private letters, which Prof. Adams has received from several eminent astronomers, the Syndicate have strong reason to believe that the passage of trains, so near the Observatory, would very seriously affect the accuracy of the observations, or even cause their entire loss. The Syndicate therefore recommend, on good grounds, that the University should petition Parliament against the passing of the bill above referred to.

RUSSIA expended 345,000*l.* upon her seven universities during the past year.

OF the 13,356 new works issued in Germany during the past year, 848 were devoted to the natural sciences, 296 to geography and travel, and 190 to mathematics and astronomy.

IT is proposed to open before long a good aquarium at St. Petersburg. The institution is patronised by the Society of Acclimatisation, which will have, in connection with the aquarium, a garden for scientific experiments relative to the acclimatisation of plants.

THE immense number of wolves in Russia, to which reference was made some time ago, seems not to have been overrated. An official report of the *Zemstvo* of the Kerensk district (Penza Government), just published, estimates the ravages of wolves during the years 1874 and 1875 at 270 horses, 200 cows, 822 foals, 707 calves, 1,812 sheep, about 1,000 pigs, 3,616 geese and ducks, and 253 dogs.

WE recently announced the death of the eminent American palæontologist, Mr. F. B. Meek. He died within the walls of the Smithsonian Institution, where he had been permitted to occupy rooms for about eighteen years. He had been connected with the U.S. Geological and Geographical Survey of the Territories for the greater portion of the time since its first organisation in 1867. Mr. Meek was born in the city of Madison, Ind., December 10, 1817. From his earliest recollection he was interested in the Silurian fossils so abundant in the rocks of the neighbourhood of his home. He had then never heard of geology, but studied them with admiration and wonder as to their origin. Against his own wishes he entered into business, but during the financial crisis of 1847 he failed, and lost all his property. During the years 1848 and 1849 he was an assistant of Dr. D. D. Owen in the U.S. Geological Survey of Iowa, Wisconsin, and Minnesota, after which he returned to Owensboro, Ky. In 1852 he became the assistant of Prof. James Hall, the eminent palæontologist, of Albany, N.Y. He remained there until 1858, with the exception of three summers, two of which he spent in the Missouri State Geological Survey. In the summer of 1853 he was sent by Prof. Hall with Dr. Hayden as his associate, to explore the "Bad Lands" of Dakota, and brought back very valuable collections. This was the commencement of that long series of successful explorations of all portions of the west which have continued up to the present time. While at Albany he was constantly engaged in the most important palæontological works, the results of which were published in the proceedings of the American learned societies. In 1858 he went to Washington, where he resided until the time of his death, leaving the city only for a few months at a time, while engaged as palæontologist for the State of Illinois, Ohio, or in field explorations in the far west in connection with the U.S. Geological Survey under the direction of Prof. Hayden. His publications, apart from the State reports referred to, were very numerous, and bore the stamp of the most faithful and conscientious research. They are regarded all over the world as authority on the subjects of which they treat, and in very few cases have his conclusions ever been questioned. They may be found in the *Proceedings of the Academy of Natural Sciences*, Philadelphia, *American Journal of Science*, New Haven, *Albany Institute*, *Smithsonian Contributions*, and various and important reports in the publication of the U.S. Geological Survey for the Territories with which he was so long connected. He was so modest and retiring that he was scarcely known outside of a very limited circle of friends. He was a member of the National Academy of Sciences, and many other prominent scientific associations in America and in Europe. Prof. J. D. Dana, writing the day after his death, says: "American palæontology has lost, as regards the Invertebrate Department, half its working force at a blow. He has gone before his work was done. But what he had finished was enough for half-a-dozen ordinary men; a marvellous pile, if we view only the aggregate of volumes and memoirs, but far more marvellous when we look within at the amount of laboured descriptions and careful comparisons, and at the almost numberless illustrations, mostly from his own exact and beautiful drawings."

On Saturday, at the Society of Arts, Dr. Corfield, under the auspices of the Trades Guild of Learning, gives the next of the series of lectures on the Laws of Health. These lectures have been well attended and appreciated from the first. Prof. Huxley was chairman on the first occasion, Dean Stanley on the second, and at the lecture on February 10 Cardinal Manning presided. The Cardinal, after the lecture, heartily endorsed the statements of the lecturer; the lecture, he said, showed that the highest science came into the closest application in daily life. There are eight other lectures of the course.

The educational and scientific institutions inaugurated by the Khedive of Egypt in his schemes of reform are among the first to feel the effects of the present chaotic condition of Egyptian finances. Not long since the free public schools of Cairo were all closed, and now the vice-regal Geographical Society is upon the point of dissolution. The Khedive had gathered together several men of talent and experience to form this Society, with the intention of instituting an active and energetic scheme of exploration in Central Africa. Their names and the bulletins which have appeared, gave every promise of early and valuable additions being made to the cause of African research. The long-continued withholding of financial support has, however, so entirely crippled its operations, that the Society has for some time practically ceased to exist.

The last contribution of Karl von Baer, written ten days before his death, appears in the last number of the *Archiv für Anthropologie*, and discusses the subject of the source of the tin used by the ancients in their bronzes. The fact that the proportions of nine parts of copper to one of tin are noticeable in almost all antique bronze articles, would seem to indicate that its use spread from a single centre. Taking a hint from Strabo's statement that tin was found among the Drangians, he caused inquiries to be set on foot by Russian Government officials in Khorassan, who reported that there are extensive deposits of tin there, as well as of other metals, which are mixed in a primitive manner. These v. Baer regards as the sources of the numerous bronzes found in the ruins of Babylon and Assyria, but did not think it probable that they supplied the tin required by Scandinavia and the countries surrounding the Mediterranean before the discovery of the Cornish mines. The latter was probably brought by Phœnicians from Banca, although no mention of such journeys is extant.

In the February session of the Berlin Anthropological Society Prof. Virchow gave the results of a number of craniological measurements undertaken in Bulgaria. The general type is evidently not Slavonic but Finnish, and would seem to point to a distant emigration from among the Turco-finnish tribes of the Ural, to the region of the Danube. Two distinct subordinate types were noticed, one brachycephalic—pure Finnish; and the other macrocephalic, with retreating forehead, strikingly similar to that of the Australian negro. The Bulgarians gradually adopted the Slavonic language, and no trace of their original language, not even a manuscript, remains. Dr. Friedel exhibited at the same Session a large collection of stone hatchets lately found near Kopenick, in company with some peculiarly fashioned stone instruments, evidently used to prepare the hatchets, and possessing the same hardness as ordinary grindstones.

A telegram from Algiers announces that on the 16th inst. Lieut. Say and others left Ouarghe with twenty-four men and fifty camels, intending to explore the Sahara, and establish commercial connections with Algerian producers.

M. Krantz, the Director-general of the Universal Exhibition of 1878 proposes to hold an international piscicultural exhibition. All who desire to exhibit must intimate their intention to the Secretary before May 1, 1877. The administration does not undertake to procure sea water.

M. Quatrefages has just published, through Baillière, a work on anthropology. He attacks the evolution theory.

Mrs. Frances Elizabeth Hoggan, M.D. of Zurich, who has been for several years in practice in London, has just passed a successful examination in Dublin, and has received the Licence in Medicine and Midwifery of the King's and Queen's College of Physicians in Ireland, which of course secure for her official recognition in the United Kingdom. A paper by Doctor George and Mrs. Hoggan was recently read at the Royal Society on "Lymphatics of Muscles."

M. Waddington intends to propose to the French parliament the establishment in four large provincial towns of universities according to the English system. The faculties at present in existence in a number of towns will not be suppressed, but they will be necessarily to some extent cast into the shade. A sharp discussion is anticipated in Parliament, many large towns competing for selection as the seats of these new universities.

The third annual meeting of the Scientific Club was held at the Club House, Savile Row, on Thursday, the 15th inst., Major F. Duncan, R.A., D.C.L., &c., Chairman of the Committee, in the chair. The report for 1876, which showed the rapid progress made by the Club during the year, was unanimously adopted. The number of members, which is now over 600, is to be limited for the present to 700. Committee-men and auditors for 1877 were elected, and cordial votes of thanks to the Chairman, Committee, Auditors, and Secretary, concluded the meeting.

AT the annual meeting of the shareholders of the Brighton Aquarium, Mr. Arthur Wm. Waters stated his belief that if arrangements were made so that a naturalist could go to Brighton and have a table in a quiet room with the most necessary apparatus and chemicals for his study, animals kept living, and fresh ones brought him as required by the sailors under the instruction of the scientific staff, there are many who would gladly avail themselves of the opportunity. The difficulties of a naturalist at present who may go down to the sea-side for a short time to undertake elaborate physiological studies are very great, and he thinks that many, including science students from the universities, would be willing to pay for the advantages which might thus be afforded. Mr. Francis Francis, who has just been appointed naturalist director, said that it was intended to do this; and even to hear of the intention will be a source of satisfaction to those who desire the present aquaria to be made more useful. We hope that if the directors have any suitable place they will not delay to utilise it, and that it may turn out to be a source of permanent advantage, for scientific research will continue when rinking and other such amusements have been replaced by more novel attractions.

THE most important paper in the February number of Petermann's *Mittheilungen* is a detailed discussion of the projects for a railway to Central Africa from the Mediterranean Coast, by Dr. G. Rohlfs. Dr. Rohlfs discusses the various schemes which have been proposed, speaks very unfavourably of that which would carry a line from Algeria southwards, and advocates strongly a line from the coast of Tripoli, especially from Braiga at the head of the Gulf of Sidra, to Lake Chad. He analyses all the difficulties and advantages of this route, and thus introduces much information on the region between these two points, as well as on the whole Saharan region. He proposes, as the only feasible plan, that the undertaking should be an international one.

IN the same number Dr. Behm continues his monthly summary of geographical news. He refers to a work by A. Kirchenbauer, "Die Irrfahrt des Odysseus als eine Umschiffung Afrika's erklärt" (Berlin, Calvary), in which the author, by the application of astronomy and mathematical geography, endeavours to show that the Kernel of the Odyssey is a tradition belonging to the fifteenth century B.C., of a circumnavigation of Africa from the Red Sea to the Mediterranean. The Lotophagi were South Arabians, Polyphemus was a Galla, whose cave was at Cape Guardafui, Circe ruled in Rodriguez, the Cimmerians dwelt in some South Polar land, and the Straits of Gibraltar were Scylla and Charybdis. Thus Ulysses was both the first African and first Polar explorer of whom we have any record. Dr. Behm states that the author discusses the subject with the greatest seriousness and acuteness.

THE December *Bulletin* of the French Geographical Society contains papers by Mr. J. B. Paquier, "On Russian and English Explorations in Central Asia;" by M. A. V. Parisot, "On the Region between Ouarglâ and El Golêa;" by Abbé Durand, "On Portuguese India;" and by Abbé Desgodins, "On the Territory of Batang." A letter from Dr. Emil Bessels, of the *Polaris* Expedition, accompanies a map exhibiting approximately the lines of equal tides in the North Atlantic, North Pacific, and Arctic Oceans, for the purpose of showing from what direction the tidal wave is propagated towards Polaris Bay.

L'Exploration for February 7 contains an interesting paper by M. Henry Bionne on the Colonial *régime* of France.

CAPT. HOWGATE's scheme of Polar exploration by means of a colony placed at Discovery Bay, to which we referred in a recent number, has been referred by the United States Congress to the Committee on Naval Affairs. It has received the support of the principal United States scientific societies, and already there have been many suitable volunteers. We should not be surprised, therefore, to hear that the grant has been made, and if men can be found suitable and willing to form such a colony, the experiment seems worth trying.

A SENSATION has been created in the geographical circles of Paris by the opinion expressed by Dr. Pogge at the Geographical Society of Berlin, that the Lualaba was flowing in the Ogovai. The Ogovai delta is part of the French Gaboon settlement. MM. Brazza, Marche, and others are engaged in exploring the river, which they have heard from natives flows out of a large lacustrine basin. It is feared the explorers cannot reach the end of their journey without receiving fresh reinforcements from home.

THE Geographical Society of Geneva voted at its last meeting its adhesion to the resolutions of the conference, for the exploration of Central Africa. A special Swiss committee, to form part of the Association, is to be appointed before long at Geneva.

M. BONNAT, the French African explorer, who has been up the Volta (Ashanti) as far as Salaga, states that from that place much-frequented routes strike off to Timbuctoo in the west, and Lake Tchad in the east, and that from these places trade caravans are constantly passing to and from Mexico and Tripoli. He bought European goods at Salaga, which entered Africa by the Mediterranean. M. Bonnat is organising a large expedition for the thorough exploration of the region from which he has just returned.

WE are glad to notice that science was well represented at the preliminary meeting last Saturday to make arrangements for the celebration of the 400th anniversary of the introduction of printing into England by Caxton. Science owes much to this art, and in recent years has to some extent repaid her debt by the vast improvements which have been introduced, based on the principles she has discovered.

FATHER SECCHI has compiled a very useful list of 444 coloured stars, which is published in the *Memorie della Società degli Spettroscopisti Italiani*. Many of them appear to be taken from Schiellerup's catalogues, from Lalande and Sir J. Herschel; to these have been added Mr. Birmingham's newly-discovered coloured stars. A note is added to each star, showing the colour and type of spectrum. The number of the star in Chambers's catalogue is given, when mentioned there, and the R.A. and Declination is given for the year 1870. We note that by far the greater number of stars are red, and the spectra of the third and fourth types prevail. This catalogue will prove useful, first, in detecting the variability of the stars, and secondly, the change of spectrum when variable. The following are representative stars of the types to which they belong:—1. Sirius, α Lyræ, white stars; 2. Capella, Pollux, yellow stars; 3. α Orionis, β Pegasi, α Herculis, red-yellow stars; 4. Small blood-red stars.

WE notice in the fifteenth volume of the *Globe*, published by the Geographical Society of Geneva, a very interesting report by M. H. D. Saussure on the present state of cartography in Switzerland. The author not only gives a detailed report on the numerous Swiss cartographical works which were so much praised at the Paris Geographical Exhibition, but also sketches the history of cartography in his country, and skilfully discusses the relative values of different modes of representing on a map the various characters of land, and of dressing maps for various special purposes.

SOME fifty years ago Ampère stated his belief in the existence of molecular electric currents permanently flowing in bodies, and he applied this hypothesis to the explanation of the reciprocal action between movable conductors through which galvanic currents are passing and permanent magnets. According to Ampère a permanent magnet contains, in proportion to its strength, a larger or smaller number of molecular currents of the same direction, each of which behaves like a small molecular magnet. In pursuance of this theory, Herr Zoellner has lately made a series of investigations and has recorded the results of his experiments in a paper read before the Royal Saxon Society of Sciences at Leipzig during the past year. With regard to the constitution of material molecules Herr Zoellner expresses his opinion "that each material molecule of a body consists of a conglomeration of (Ampère's) molecular currents of any direction, with a certain quantity of freely movable electric particles, which, under the influence of electrostatic or electrodynamic induction forces, execute such motions or groupings as are determined by Weber's law of electric reciprocal action." It is but fair to state that Weber's views on this subject were identical, and he stated them as early as in 1851 in his explanation of diamagnetism. Zoellner makes a whole series of deductions from this theory, all of which agree with observed phenomena and laws found in various domains of physical science.

THE Rev. T. R. R. Stebbing sends us an interesting letter on the true origin and correct pronunciation of the name *Antedon*, which we regret we have not space to print in full. As the result of careful inquiry, Mr. Stebbing concludes that the name is undoubtedly feminine, that the middle syllable should be pronounced long, and that the aspirate which de Fréminville dropped ought to be restored to the spelling. "If, then, we were to adopt the compromise suggested in Mr. Herbert Carpenter's important letter (vol. xv. p. 197), we should have to write, instead of either *Comatula rosacea* or *Antedon rosaceus*, the trinomial, *Comatula* (*anthedon*) *rosacea*. To sanction such an innovation as Mr. Carpenter proposes, no doubt some general agreement would be required, and the same general agreement might be usefully employed in sanctioning a statute of limitations against the revival of obsolete names, and to insure the publication of new scientific names in one or other of a very limited number of chronicles. Some international science congress of the future may perhaps achieve the requisite legislation."

THE *Journal* of the Society of Arts for February 16 contains a useful paper by Dr. R. J. Mann, on "Recent Explorations of the Lake Systems of Central Africa."

WE notice an important German work, by the Bernese Professor, Dr. Emmert, on the diseases of the eye, occasioned by various professions, and especially by the vicious arrangements in schools. An inquiry made by the learned Professor in the cantons of Berne, Solothurn, and Neuchâtel proves that an increasing myopy is the fate of all scholars, and that at the age of twenty years there are very few of them who are not afflicted with this disease. Various hints by the author as to improved arrangements to be adopted in schools deserve the attention of school boards.

A RECENT subscriber will find an account of Siemens' Bathometer in NATURE, March 30, 1876 (vol. xiii. p. 431).

THE additions to the Zoological Society's Gardens during the past week include two Pennant's Parrakeets (*Platycercus pennanti*) from New South Wales, presented by Mr. E. Sargent; an Anaconda (*Eunectes murinus*), a Crested Curassow (*Crax alector*), and two Green-billed Curassows (*C. viridirostris*) from South America; two Feline Douroucoulis (*Nyctipithecus felinus*) from South Brazil; two Cariamis (*Cariama cristata*), from South America, purchased.

SOCIETIES AND ACADEMIES

LONDON

Royal Astronomical Society, February 9.—Annual general meeting.—William Huggins, D.C.L., president, in the chair. The following gentlemen—A. Mason Worthington, B.A., John Sidney White, and George Francis Hardy, were elected fellows of the Society. The annual report of the society showed that the number of Fellows had been increased during the past year, and that the society's library had been enriched by several important presents of books and manuscripts. Ten minor planets have been discovered in the course of last year, six of them in America, and four in France. In solar physics Prof. Tacchini has made an interesting investigation as to the relative height of solar prominences at different times of the sun-spot period. Prof. Young has determined the rate of the solar rotation by means of the displacement of the dark lines in the spectrum of the sun's limb. He has also proved that the 1474 line is double, and that the two components are of unequal strength; the coronal line corresponds to the stronger of the two, whilst the other is one of the faint lines in the spectrum of iron. Mr. Huggins' photographs of the spectra of stars were also referred to, and a short account was given of the observations of the new star in Cygnus, which was discovered by Dr. Schmidt, at Athens, on November 24, 1876. Its spectrum gives several bright lines, amongst which are three of the hydrogen lines, C being the brightest of all, the sodium line D, or the chromosphere line near D, the magnesium lines *b*, and the coronal line 1474. The reduction of the observations of the transit of Venus has been proceeding continuously at the Greenwich Observatory, under the direction of Capt. Tupman. All the observations with transit instruments at the various stations for local time and longitudes of Honolulu and Rodriguez by the observations of the moon in zenith distance have been completely reduced. An idea of the magnitude of the undertaking may be formed when it is stated that these two last calculations required the use of three millions of figures. The Report having been adopted, the Society proceeded to the election of Officers for the ensuing year, and the following gentlemen were elected: As President, William Huggins, F.R.S. As Vice-Presidents: J. C. Adams, F.R.S., Lowndean Professor of Astronomy, Cambridge; Sir G. B. Airy, K.C.B., F.R.S., Astronomer Royal; Arthur Cayley, F.R.S., Sadlerian Professor of Geometry, Cambridge; Edwin Dunkin, F.R.S. As Treasurer, Samuel Charles Whitbread, F.R.S. As Secretaries: J. W. Lee Glaisher, F.R.S.; A. Cowper Ranyard, M.A. As Foreign Secretary, Lord Lindsay, M.P. As Council: John Brett, Esq.; W. H. M. Christie, M.A. Warren De La Rue, F.R.S.; J. R. Hind, F.R.S., Superintendent of the *Nautical Almanac*; E. B. Knobel; George Knott; William Lassell, F.R.S.; E. Neison; Capt. Wm. Noble; Rev. S. J. Perry, F.R.S.; Earl of Rosse, F.R.S.; Capt. G. L. Tupman, R.M.A.

Geological Society, January 24.—Prof. P. Martin Duncan, M.B., F.R.S., president, in the chair.—George Barrow, William Heerlein Lindley, and Joseph Samuel Martin, were elected Fellows of the Society.—The following communications were read:—Note on the question of the glacial or volcanic origin of the Talchir boulder-bed of India and the Karoo boulder-bed of South Africa, by H. F. Blanford, F.G.S. The author, referring to a doubt expressed by the President in a paper on Australian tertiary corals as to the glacial origin of the Talchir boulder-bed, indicated that the hypothesis of its formation by the action of local glaciers under present climatal conditions would require the elevation of the whole region to the extent of 14,000 or 15,000 feet, and the assumption that the denudation of this great mountain mass was so moderate that large tracts of the ancient surface are still preserved at levels now only a few hundred feet above the sea. This the author regarded as very improbable. He assumed that the President, rejecting the evidence adduced by various writers in favour of the glacial origin of the Talchir and Karoo boulder-beds, was inclined to fall back upon the notion of their being of volcanic origin, and quoted a letter from Mr. King, who had described the Talchir rocks of Kámáram as trappean, in which that gentleman stated that the rocks so interpreted by him prove to be dark green and brownish mudstone. He cited further evidence of like nature, and concluded that the ascription of a volcanic origin to these boulder-beds was probably in all cases due to similar misinterpretations.—On British cretaceous patelloid gasteroporada, by John Starkie Gardner, F.G.S. In this paper the author commenced by a general statement as to the classification of the forms to be described in it, which he referred to the families Patellidæ, Fissurellidæ, Calyptræidæ, and Capulidæ. He noticed thirty species, which are mostly of rare occurrence, and nineteen of these were described as new. Four genera were indicated as new to the Cretaceous series, and one as new to the Cretaceous in England. The new species were *Acmæa formosa* and *plana*, *Helcion Meyeri*, *Anisomyon vectis*, *Scurria calyptræiformis* and *depressa*, *Emarginula puncturella*, *divisiensis*, *ancistra*, *Meyeri*, and *unicostata*, *Puncturella antiqua*, *Calyptræa concentrica*, *Crepidula chamæformis*, *Crucibulum giganteum*, *Pileopsis neocomiensis*, *dubius* and *Seeleyi*, and *Hipponyx Dixoni*. Most of the Patellidæ were from the Neocomian, and the majority of the Fissurellidæ from the Upper Greensand; the species of the other two families were scattered through the series. The author referred to the indications of depth of deposit and other conditions furnished by these Mollusca, and also to the resemblance presented by many of them to certain bivalves common in the same rocks, which he regarded as a sort of mimicry.—Observations on remains of the mammoth and other mammals from Northern Spain, by A. Leith Adams, F.R.S.—The remains noticed in this paper were obtained by MM. O'Reilly and Sullivan in a cavern discovered at about twelve metres from the surface, in the valley of Udias, near Santander, by a boring made through limestone in search of calamine. They were found close to a mound of soil which had fallen down a funnel at one end of the cavity, and more or less buried in a bed of calamine which covered the floor. The cavern was evidently an enlarged joint or rock-fissure, into which the entire carcases, or else the living animals, had been precipitated from time to time The author had identified among these remains numerous portions, including teeth of *Elephas primigenius*, which is important as furnishing the first instance of the occurrence of that animal in Spain. He also recorded *Bos primigenius* and *Cervus elaphus* (?), and stated that MM. O'Reilly and Sullivan mention a long curved tooth which he thought might be a canine of Hippopotamus.

Chemical Society, February 15—Dr. Gilbert, F.R.S., vice-president, in the chair.—Dr. Dupre, F.R.S., read a paper on the estimation of urea by means of hypobromite, in which he described a new form of apparatus and certain modifications in details to facilitate the working of Russell and West's process. The other communications were on a new carbometer for the estimation of carbonic anhydride, by Mr. S. T. Pruen and Dr. G. Jones, being a modification of Scheibler's "calcimeter."—On the influence exerted by ammonium sulphide in preventing the action of various solutions on copper, by Mr. F. W. Shaw and Dr. P. Carnelly.—An experimental inquiry as to the changes which occur in the composition of waters from wells near the sea, by Mr. W. H. Watson.—On the solvent action of various saline solutions upon lead, by Mr. M. M. P. Muir.—Derivatives of Di-sobulyl, by Mr. W. Carleton-Williams, and notes on madder-colouring matters, by Dr. E. Schunck and Dr. H. Roemer.

STOCKHOLM

Academy of Sciences, October 11, 1876.—Baron Fock gave an account of a report by O. Nylander, assistant at the Academy of Agriculture, of a journey he had undertaken with the Letterstedt grant for the purpose of studying the industries associated with agriculture.—Prof. Torell also gave an account of a report by Edward Erdman, the geologist, of a tour he had made, with Government assistance, in Central Europe in 1875.—Prof. Smith gave a short account of the expedition to North-western Russia and the region round the White Sea, undertaken by Lieut. H. Sandeberg last summer.—Prof. Stål stated that the Vylder collections had been bought for the natural history department of the Riks Museum, through the liberal contributions of private persons, and gave a short account of their contents.—General-director Berlin communicated the result of the latest analyses by Valler of the mineral water at Porla, and Prof. Nordenskjöld gave a full and interesting narrative of his last expedition from Tromsö to Jenissei.—The following communications were received:—On the course of the alteration which a surface undergoes when it is bent, by Prof. Daug.—On compounds of cyanide of mercury with chlorides of the earthy metals, by J. E. Ahlén.

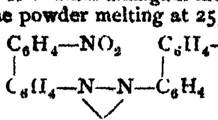
November 8, 1876.—Herr Edlund communicated the results of his examination of the galvanic currents which are caused by the motion of fluid bodies.—Prof. Nordenskjöld exhibited pieces of a mammoth or fossil rhinoceros hide, found last summer near the confluence of the Mesenkin with the Jenissei, and several meteorites which fell at Ställdalen, in Westmanland, on the 28th of last June, and gave an account of the nature of the meteorites in question.—Herr Gyldén exhibited a calculating machine constructed by Engineer Pettersson for the purpose of adding, subtracting, multiplying, and dividing, and gave an account of a communication by Prof. T. N. Thiele, of Copenhagen, entitled, "Some geometrical propositions concerning a problem in theoretical astronomy."—The following papers were communicated: A new species of the family Portunidæ from the Scandinavian coast, by Docent Carl Bovallius; Communication from Upsala Chemical Laboratory, 20, on *g* (gamma) dichloronaphthaline and bromo-chloronaphthaline, by Prof. P. T. Cleve; Remarks on Dr. Bioren de Haans Tables d'intégrales définies (Amsterdam, 1858), by Lektor Lindman, member of the Academy; and Researches on the cooling of bodies, by Prof. G. R. Dahlander.

BERLIN

German Chemical Society, January 29.—A. W. Hofmann, vice-president, in the chair.—W. Beetz claims priority for observing the disengagement of hydrogen at both poles of a battery (as lately described by Elsasser).—W. Bornemann published observations on the solubility of chloride of iodine, and R. Ulbricht some on the determination of water and of sugar in wine. The latter chemist gives warning of a fraud by which glass weights are sold instead of ones made from rock crystal.—R. Dyckerhoff has transformed monochloro-acetophenone, $C_6H_5—CO—CH_2Cl$, by the action of PCl_5 into two chlorides:

$$C_6H_5 . CCl_2 . CHCl \text{ and } C_6H_5 . CCl . CHCl;$$

—V. Meyer, T. Barbieri, and F. Forster by joint and elaborate researches refute the pretended observation of Linnemann and Zotta that *normal butylamine* and nitrous acid yield *isobutylic* alcohol. The reaction only yields normal primary butylic alcohol, normal butylene, and normal secondary butylic alcohol, but no isobutylic alcohol.—H. Wald has transformed paradinitrodiphenyl by the action of sodium-amalgam into paradinitro-azoxydiphenyl, a crystalline powder melting at 255°, and soluble

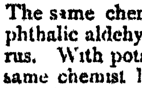


$$\begin{array}{ccccc} C_6H_4—NO_2 & & & & C_6H_4—NO_2 \\ | & & & & | \\ C_6H_4 & —N— & & —N— & C_6H_4 \\ & & \diagdown\!\!\diagup & & \\ & & O & & \end{array}$$

in aniline, but not in alcohol, ether, or chloroform, and yielding benzidine by further reduction with tin and hydrochloric acid. Isodinitrodiphenyl and sodium amalgam yield dinitro-azodiphenyl, $(C_6H_4NO_2—C_6H_4N)_2$, a yellow powder melting at 187°.—C. Kimich published researches on methazonic acid, the sodium-salt of which is engendered by the action of heat on nitromethan-sodium:—

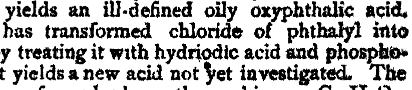
$$2CH_2NaNO_2 = NaOH + C_2H_3NaN_2O_3.$$

This salt with nitrate of diazobenzol, yields red crystals of a mixed azo-compound, $C_6H_5N_2 . C_2H_3N_2O_3$ (azonitromethalphenyl), in which two atoms of hydrogen can be replaced by metals. Nitrate of diazotoluol gives a corresponding compound.—G. Burkhardt has transformed amidoterephthalic into oxyterephthalic acid (with nitrous acid), a powder giving a crystallised barium salt and methylic ether. Hydrochloric acid transforms it into oxybenzoic (not salicylic) acid.—A. Baeyer has studied amidophthalic acid and its well-crystallised ethylic ether, which, with nitrous acid, yields an ill-defined oily oxyphthalic acid. The same chemist has transformed chloride of phthalyl into phthalic aldehyde by treating it with hydriodic acid and phosphorus. With potash it yields a new acid not yet investigated. The same chemist has transformed phenanthrenechinone, $C_{14}H_8O_2$, by boiling it with soda into diphenylenglycolic acid, $C_{14}H_{10}O_3$:—



$$\begin{array}{l} C_6H_4—CO \\ |\qquad\quad | \\ C_6H_4—CO \end{array}$$

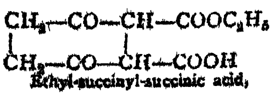
Phenanthrenechinon.



$$\begin{array}{l} C_6H_4—COH \\ | \\ C_6H_4—COOH \end{array} \quad \text{or} \quad \begin{array}{l} C_6H_4\diagdown\;\;\diagup CO_2H \\ |\qquad\quad C \\ C_6H_4\diagup\;\;\diagdown OH \end{array}$$

Diphenylen-glycolic acid.

He rejects the former formula of the latter body, because it does *not* yield by oxidation diphenic acid.—G. Schultz, by passing oil of turpentine through red-hot tubes, has obtained benzol, toluol, xylol, naphtalene, phenanthrene, anthracene, and methylanthracene.—F. Hermann has studied the action of sodium on succinic ether. The product (probably impure succino-succinic ether) yields, treated with potash and with acetic acid, an acid of the composition



$$\begin{array}{l} CH_2—CO—CH—COOC_2H_5 \\ |\qquad\qquad\quad | \\ CH_2—CO—CH—COOH \end{array}$$

Ethyl-succinyl-succinic acid,

while with sulphuric acid it forms a black amorphous mass, which by distillation yields hydrochinone. The product of potash with bromine gives bromanile $C_6Br_4O_2$. Air and potash transform the ether into $C_6H_4O_2(CO_2H)_2$ chinon dicarbonic acid, yellow hair-like crystals.—E. Schunck and H. Roemer, in order to discover traces of alizarine in purpurine, expose the solution to the air until the latter is oxidised, when alizarine, remaining behind unaltered, can be recognised by its absorption-bands in the spectroscope. The same chemists have found that certain impure purpurines yield a precipitate with alum, which is decomposed by hydrochloric acid with greater difficulty than the purpurine compound. The compound thus obtained forms gold-brown needles fusing at 231° decomposed by heat into carbonic anhydride and purpuroxanthin, and corresponding to the formula of purpuroxanthincarbonic acid $C_{11}H_8O_4COOH$.—A. Kern published researches on the action of iodide of methyle on aniline, from which he concludes that only dimethyl-aniline and no monomethyl aniline is formed in this reaction.—R. Meyer has tried in vain to convert cuminol into cymol; and thinks that former assertions to the contrary depend upon the presence of preformed cymol in cuminol.—M. Muencke (of the firm of Warmbrunn and Quilitz, in Berlin) showed a model of a double aspirator, also a Bunsen burner with a tube to prolong it, and a modification of Fletcher's hot air blast.—G. Gabriel described phenylic and ethylic ethers of tribasic thioformic acid, $CH(SR)_3$, obtained by the action of chloroform on the sodium compounds of the corresponding mercaptans.—A. Klobukowsky showed a tube filled with oxide of iron for E. Kopp's method of determining chlorine, bromine, and iodine in organic compounds, and praised the simplicity of this method.—A. Czech and H. Schwebel have found that isocyanide of phenyl and formic acid are formed by the action of dichloracetic acid on aniline.—A. W. Hofmann showed a new yellowish-red colouring substance called chrysoidine, and established the following remarkable analogies:—

$C_{12}H_{11}N_3$ Martius yellow = Amidoazobenzol,
$C_{12}H_{12}N_4$ Chrysoidine = Diamidoazobenzol,
$C_{12}H_{13}N_5$ Phenylene brown = Triamidoazobenzol.

The first body is obtained by the action of nitrous acid on aniline; the third by the action of nitrous acid on phenylene diamine; the new colour (chrysoidine) by the action of phenylen diamine on newly-prepared diazobenzole in alcoholic solution.

Vienna

Imperial Academy of Sciences, November 9, 1876.—On parthenogenesis of angiospermous plants, by M. Kerner.—On the shell-glands of Copepoda, by M. Claus.—On a modification of Dumas' method of determination of vapour densities, by M. Habermann.—Researches on the origin of the lowest organisms, by M. Krasan.—On the action of secondary electric currents on nerves, by M. Heischl.

Paris

Academy of Sciences, February 12.—M. Peligot in the chair.—The following papers were read:—Discovery of three small planets, 170, 171, and 172, and of a comet, at Toulouse and Marseilles, by MM. Tisserand and Stephan, communicated by M. Leverrier.—Researches on calorific spectra (continued), by M. Desains. With refracting apparatus of rock salt, the heat accompanying the luminous rays in the solar spectrum is about a third of the total heat; in the spectrum of incandescent platinum it is only a small fraction. Similar results are had with flint apparatus, and M. Desains was unable to make the difference disappear by sending the rays from the metal through layers of water, though this shortened the dark spectrum. But spectra from the electric lamp may be rendered much more like those obtained from the sun's rays. The heat in their luminous part seems to be about one-sixth of the total heat, and if the rays be sent through a layer of water of 3 to 4 cm., the calorific intensity of the dark part is considerably reduced, while the luminous heat is hardly affected; this latter being then about a third of the total heat as in the solar spectrum.—Preliminaries of a study of living and fossil European oaks, compared together, by M. De Saporta. The races most largely distributed in Europe, particularly *Quercus pedunculata*, *sessiliflora*, and *pubescens*, are comparatively recent, though their type is old. In the south of France, at least, these have been preceded by other oaks, that have been partly eliminated, partly confined further southwards.—On a new catalogue of coloured stars, and on the spectrum of Schmidt's star, by P. Secchi. This work is based on Schjellerup's catalogue, published in 1866.—Observations on the *comptes rendus* of the *séance* of February 5, 1877, by Gen. Morin. He expressed regret at the omission from *Comptes Rendus* o information given by MM. Wurtz, Pasteur, and Boussingault on certain falsifications of alimentary substances, and urged the importance of the subject, and of chemistry detecting such frauds. M. Pasteur stated that of fourteen cases of preserved peas bought at random in some of the principal quarters of Paris, ten contained copper, sometimes even about $\frac{1}{1000}$ of the total weight of the preserves, excluding the liquid; which always contains some copper when the peas contain it, but less.—M. Lory was elected correspondent for the section o mineralogy, in place of the late M. Naumann.—On the application of photography to observation of the transit of Venus, by M. Angot. This relates to determination of the instant of contacts.—Practical formulæ of velocities and pressures in arms, by M. Sarrau.—On a class of orthogonal systems, comprising isothermal systems as a particular case, by M. Darboux.—On nitrification by organised ferments, by MM. Schlœsing and Müntz. He obtained nitrification by passing ammoniacal waters through a porous substance charged with organic matters, but there was no trace of nitrate from a filter made of pure sand. The active matter, after being subjected to action of chloroform, lost its nitrifying properties exactly as if these special ferments had been killed.—Note on certain alterations of glass, by M. de Luynes. Often, in moist air, fine parallel striæ form on the surface, and scales come off, which are found to be of different composition from the glass. Alkalies are almost wholly absent in them, and they consist chiefly of earthy silicate; the proportion of silica rising to 78 per cent., while in normal glass it is only 68. The glass retains its transparence.—On phosphorescent organic bodies, by M. Radziszewski. Hydrobenzamide, amarine, lophine, and the raw product of the action of alcoholic ammonia on benzile show phosphorescence in the dark when brought into contact with an alcoholic solution of caustic potash.—On the fermentation of urine; reply to M. Pasteur, by Prof. Bastian.—On the toxical properties of salts of copper, by M. Bergeron.—Method for recognising iodine in cod-liver oil and experiments on absorption of iodide of potassium by fatty animal matters, by M. Barral. He saponifies the fatty matter with potash, burns the soap, and dissolves in alcohol the iodide of potassium formed. A goat received fifty centigrammes of iodide of potassium daily for eight days with its food. Butter prepared from its milk contained a good deal of iodine. The kid of a goat thus treated being killed, iodine was found in its fat and adipose tissue.—Researches on the history of respiration in fishes, by M. Jobert. He finds a peculiar respiratory system in the Callichthys.—On the transparence of the water of Lake Leman, by M. Forel. He explains the less transparence in summer than in winter, by a stratification of layers of different densities, due to heat on the surface; in winter there is uniform density, and powdery particles either sink to the bottom or rise to the surface.

THURSDAY, MARCH 1, 1877

GOVERNMENT GRANTS IN AID OF SCIENCE

THE Civil Service Estimates for this year contain three different sums proposed to be granted by the government in aid of scientific research. As the circumstances connected with these grants do not appear to be generally well understood, it may be convenient to those engaged in the study of science to have a short explanation given to them on the subject.

The oldest and best known of these grants is that of 1,000*l.* which has been given to the Royal Society for the last twenty years, for the encouragement of scientific research. The distribution of this grant is regulated by a Committee of the Council and other Fellows of the Royal Society, usually denominated the "Government Grant Committee." The manner in which it is expended is given in the published *Proceedings* of the Royal Society every year. Last year, we observe, grants of 100*l.* were sanctioned to Mr. J. A. Broun, for "investigating the effects due to the sun's rotation and magnetism;" to Mr. J. N. Lockyer, to enable him "to continue his spectroscopic researches;" to Dr. Carpenter, in aid of his work on *Comatula* (or *Antedon*, as he prefers to call it); and to Sir W. Thomson and Prof. J. Thomson for the construction of an analysing machine suitable for performing certain calculations connected with the observation of tides. Other smaller sums were assigned to Dr. Stenhouse, Mr. G. J. Romanes, Mr. W. Crookes, and Prof. W. E. Adams, in aid of various researches in which these philosophers are respectively engaged.

Last year, as we stated on a former occasion, in consequence of the report of the Royal Commission on Science, the propriety of increasing the amount of this grant was considered by the Government. It was ultimately arranged that instead of making any alteration in the mode of distributing the grant of 1,000*l.*, which seemed to have answered its purpose very satisfactorily, a second grant of 4,000*l.* should be made, to be admininistered in a different manner. Instead of being given by the Treasury direct to the Royal Society, the new grant, in order to carry out another recommendation of the Duke of Devonshire's Commission, to the effect that the scientific work and votes should be placed under one Minister, was placed in the Privy Council Estimates, and will be distributed directly by the Lord President, according to a scheme prepared by the "Government Grant" Committee of the Royal Society, together with the presidents of fifteen other learned societies, who, for this object, are *ex officio* members of this Committee.

There are now, therefore, two different grants in aid of scientific research administered by the Royal Society: that of 1,000*l.* received direct from the Treasury appropriated mainly to the providing of instruments and other assistance necessary to scientific inquiries; that of 4,000*l.* applied to the aid of scientific investigators not only by providing instruments and assistance, but by making personal allowances or grants of money to the investigators for their services. As regards the last-named fund, on the proposed distribution of which the Government Fund Committee is now occupied, we understand that the applications made for it for the present financial year (1876-77) have amounted to upwards of 14,000*l.* To three sub-committees (Physical, Chemical, and Biological) who have been for some time past engaged in investigating these applications, is assigned the pleasing task of reducing them to more moderate dimensions, and bringing them again before the whole Committee, which meets to-day, in order that they may be submitted to the Lord President of the Council for his final approval.

When it is possible to refer to the proceedings of the Committee without any breach of confidence, we shall state at length how the great question of the endowment of research has been aided, or the reverse, by the action of the Fund Committee. It is well known that there are many Fellows of the Royal Society whose positions as workers in science need not be too clearly defined, who view with mistrust the liberality of the Government. But we have the greatest confidence in the powerful Committee which has been formed, and believe that although it is possible mistakes may be made and endowments proposed which may perhaps have a different effect from that intended, that the proceedings of the Committee viewed as a whole will meet with the warmest approval of men of science, and that it will be acknowledged on all hands that an important step has been taken in the direction of increasing research in our country.

A third grant for scientific purposes, which has been made for some years by the Government, is not so generally well known amongst men of science, and as a change is to be made in its administration this year, it may be as well to give a few explanations on the subject. Commencing with the year 1871-72, as it appears from the Parliamentary return now before us, a sum of 2,000*l.* has been voted annually to the department of the Privy Council Office for "auxiliary scientific investigations." By reference to the same return, it will appear that in 1871-72 and the three succeeding financial years this sum, under the recommendation of Mr. John Simon, late Medical Officer of the Privy Council and Local Government Board, was divided pretty nearly equally between Dr. Sanderson and Dr. Thudichum, portions of the grant in each case being devoted to laboratory expenses and the payment of skilled assistants. The results of this expenditure have been various reports on such subjects as "Infective Inflammation," the "Chemical Changes in the Case of Typhus," and the "Pathology of "Sheep-pox," and other scientific investigations connected with questions of public health, which have been published as appendices to Mr. Simon's reports as Medical Officer of the Privy Council and Local Government Board. Mr. Simon having resigned his office last year, and there being no longer any medical officer attached to the Privy Council Office, the vote of 2,000*l.* has, we observe, in the Civil Service Estimates for the present year, been transferred to the Local Government Board, and will, we suppose, be administered in future by Mr. Sclater Booth, the President of the Board, under the advice of Dr. Seaton, who has succeeded Mr. Simon in his functions as principal medical officer of that department. Whether this transfer of the fund will involve any alteration in its disposal remains to be proved.

THE LIFE OF SIR WILLIAM FAIRBAIRN

The Life of Sir William Fairbairn, Bart., F.R.S., LL.D., D.C.L., &c. Partly Written by Himself. Edited and Completed by William Pole, F.R.S., Member of Council of the Institution of Civil Engineers. (London: Longmans, 1877.)

THE art of Engineering is one by which above all others the influence of science upon the civilisation of the world has been proclaimed with the loudest voice. Astronomy may deal with far more tremendous mechanical problems and may have done more for establishing the exactness of scientific research. Chemistry may have done much for the amelioration of suffering, and have given to the world vast commercial enterprises. Geology and Metallurgy have told men where to find and how to use the wealth beneath their feet; and to Physics we owe the Electric Telegraph and a thousand things besides. But Engineering, combining all of them with much that is its own, goes out to the world and makes itself heard and known by every class. Millions who never heard of the *Nautical Almanac* see the feats of navigation and the power of ocean ships. The locomotive, diving under mountains or flying over valleys leaving civilisation in its track, preaches the power of steam to people who may never hear of the dynamical nature of heat. And the splendid machinery by which the commonest things of life are made testifies to the greatness and humanising influence of that art which, above every other, directs the great powers in Nature to the use and convenience of man.

To Engineering, civil and mechanical, this country, more perhaps than any other, owes its wealth and not a little of its fame; and the British public has always delighted to honour the veterans of the profession to which its country owes so much, more especially those who by great originality of mind, broad unprejudiced common sense, sound reasoning, and indomitable perseverance, triumphing over all opposition and difficulty, and abandoning the beaten paths of their fellow-men (whenever those paths led wide of their mark), have cut out for themselves new roads and made themselves pioneers in their profession, adding to it fresh lustre, and lifting themselves thereby from a humble position of life to a great and honoured place in the estimation of their fellow-men. Of such men as Brindley, Watt, Telford, Stephenson, Rennie, Maudslay, Nasmyth, Whitworth, and Fairbairn, this country may justly be proud, for with their names are mixed up, in no small degree, its prosperity and its fame.

The story of such eventful lives cannot but be full of interest and instruction; interesting as tales of the vicissitudes of fortune, the difficulties, trials, hardships, and triumphs inseparable from the life of a "self-made" man, and instructive in the highest degree, as putting upon record the history and development of those branches of human progress which played so important a part in the drama of their lives.

The career of Sir William Fairbairn, which extended over eighty-five years, was an exceptionally eventful one, and the biography before us possesses an especial interest from the fact of its being partly written by himself, and written, too, in so pleasant and animated a style as to carry the reader with him into all the scenes of his life, and to show that he was as accomplished a writer as he was a mechanician. Indeed, he was a most prolific author, having given to the world some eighty publications, several being of the highest scientific character, and published in the *Philosophical Transactions*, as well as several large and important works upon engineering subjects.

William Fairbairn, like his friend, George Stephenson, raised himself from the humblest rank of life, being the son of a small farmer or "portioner" of Kelso, where he was born in the year 1789. When little over four years old he attended the parish school, where he learnt to read from some of the best poets and prose-writers, and in his own words, "if to these be added a course of Arithmetic as far as Practice and the Rule-of-Three, they will constitute the whole of my stock of knowledge up to my tenth year." He gives a lively description of the hard training which prevailed in Scotland at that period, and of the severity with which discipline was enforced in the Scottish schools. At the age of fifteen Fairbairn was apprenticed to a Mr. Robinson, a millwright at the Percy Main Colliery, near North Shields, and here he had a rough time of it. Surrounded by temptations of every kind, and with the lowest possible of companions to associate with, he sketched out for himself a weekly curriculum of study, in which literature, mathematics, and recreation were pretty evenly distributed. This he kept up with wonderful constancy, and in a short time was able to turn the tables upon those who ridiculed him, by proving the superiority which learning gave him.

It was also at this time that he made the acquaintance of George Stephenson, who had then charge of an engine at Willington Ballast Hill, only a mile or two from Percy Main Colliery. The two young men, who were nearly of the same age, and were both earnest in their love for mechanics, here formed a friendship which lasted through life. It is on record that in the summer evenings Fairbairn was accustomed to go over and see his friend, and would frequently attend to the Ballast Hill engine for a few hours, in order to enable Stephenson to take a two or three hours' turn at heaving ballast out of the collier vessels, by which he earned a small addition to his regular wages: and he often, in after life, alluded with pride and satisfaction to his early intimacy and close friendship with the great founder of the railway system.

At the age of twenty-one, Fairbairn, wishing to see more of the world, and being at this time of a roving disposition, went in search of other employment, which he obtained first at Newcastle, then at Bedlington. From here he went to London in the winter of 1811 with *2l. 7s. 6d.* in his pocket, and immediately set out to look for work, which he failed to get, through the tyranny of the Millwright's Trades-union Society. For some time after this William Fairbairn was more or less a "rolling stone," travelling about the country picking up odd repairing jobs, and seldom remaining in one place for long.

We find him in Bath, Bristol, South Wales, Dublin, Liverpool, and Manchester, which he entered in the winter of 1813, when he was in his twenty-fourth year, and obtained employment with Mr. Adam Parkinson, with whom he remained two years; he was at this time earning thirty shillings per week, and this enabled him to fulfil in 1816 his engagement of marriage, which had existed for five years. From this time he determined no longer to remain the servant of another, but by a bold effort to take an independent position.

The result of this determination was that he entered into a partnership with an old shopmate of the name of Lillie, and in a miserable shed which they hired for twelve shillings a week they set up a lathe which had to be turned by hand, and thus began a business which but a few years afterwards had a world-wide reputation.

The first order that came to the new firm was a somewhat important one—the taking down and renewal of the whole of the shafting in an extensive cotton-mill belonging to Messrs. Adam and George Murray. In carrying out this work, originality of mind and sound reasoning powers which Fairbairn brought to bear upon everything he undertook, came to his aid; he saw that the old system of mill-gearing was wrong in principle, that quick shafts and small drums would do the work with a great saving of power and space, and thus he revolutionised the whole system of mill-work, and the firm of Fairbairn and Lillie became the leading millwrights of the district. Orders poured in upon them from all sides, and they removed from the shed to a larger building, to which was afterwards added a cellar.

> "I was," Mr. Fairbairn says, "designer, draughtsman, and book-keeper, and in order to meet all the requirements of the concern and keep Mr. Lillie's department in the shop constantly going, I had to rise with the sun in the summer and some hours before it in winter, in order to make the entries and post the books before breakfast. In the remainder of the day I had either to draw out the work or to ride fifteen or sixteen miles on a hired hack to consult with proprietors, take dimensions, and arrange the principle upon which the work was to be constructed."

Four or five years passed in this manner, and though the firm was always short of money it was daily increasing in prosperity; orders came in far beyond what they could execute, they kept adding to their stock of tools, and ultimately purchased a second-hand steam-engine by Boulton and Watt, bought a piece of ground, and erected a larger and more convenient workshop.

In the year 1824 Mr. Fairbairn designed and carried out the great Catrine Bank water-wheels in Ayrshire, in which he introduced so many improvements upon the old system of water power, that his firm for many years stood almost alone for such work, and received orders from all parts of the Continent until the principle which he had introduced became generally known. Thus the business increased, and in the year 1830 their stock-book showed a balance of nearly 40,000*l.*, and left them sufficient funds to increase their works, so as to be capable of employing 300 men. During this year William Fairbairn was elected a member of the Institution of Civil Engineers under the presidency of Thomas Telford.

The following two years were occupied in his celebrated experiments for the investigation of the properties of iron boats and the application of steam power to canal navigation, and it was in connection with this investigation that he made his first essay in engineering literature, "Remarks on Canal Navigation," which was published by Longmans in 1831.

These experiments led to the construction by his firm and from his designs, of the *Lord Dundas*, a small paddle-wheel vessel, built entirely of iron, and driven by a steam-engine of 0-horse-power. This was the first iron steam-vessel, and the results of its trials were looked for with considerable excitement. Mr. Fairbairn gives a most interesting account of this little vessel and of her sea trip from Liverpool to Glasgow, a voyage not unattended with danger through the error of the compass due to the magnetic influence of the iron, of which the vessel was constructed; and no greater instance of the clearness of perception of this young engineer can be given than the fact that he not only detected at once the cause of the aberration of the vessel's course, but also corrected the compass error, compensating the ship's attraction by pieces of iron placed in the vicinity of the needle.

In the year 1832 a dissolution of partnership took place, and the Manchester works came into the sole possession of Mr. Fairbairn. Soon after this the subject of iron shipbuilding began to attract public attention, and he had many orders for vessels between 100 and 250 tons burden, which had to be built in Manchester, taken to pieces, and rebuilt at a seaport. To avoid this obvious inconvenience, and believing there was large business to be done in this branch of Engineering, Mr. Fairbairn bought a plot of land on the Thames, at Millwall, where, besides his Manchester business, he carried on for thirteen years large ship-building operations, having during that time built upwards of a hundred vessels, including several for the Royal Navy; but, with the exception of the first two years, the concern was a losing one, and it was ultimately wound up and sold at great loss. After passing through several hands it came into the possession of Mr. Scott Russell, and it was on this spot that the *Great Eastern* was built.

It was at these works that Fairbairn's celebrated experimental researches, in connection with Mr. Eaton Hodgkinson, upon the strength of cast-iron were carried on, and it was here that he conducted the experiments previous to the designing of the Britannia and Conway tubular bridges, and which led to his invention of the rectangular self-supporting tube, having cellular top and bottom sides. This is the essential principle of construction in those triumphant feats of engineering skill, and in connection with which his share of the merit is too often passed over.

This invention, for which a patent was taken out in his name with the concurrence of Mr. Stephenson, led to his being invited by the Chevalier Bunsen, at that time the Prussian Minister, to visit Berlin in order to confer with the authorities upon the erection at Cologne of a tubular bridge for the purpose of carrying the railway across the Rhine. This bridge, as far as he was concerned, was never built, but it led to a warm friendship between himself and Alexander von Humboldt, as well as with Bunsen, and the chapter relating to this connection will be of the greatest interest to the readers of this journal, containing, as it does, letters of Humboldt and Bunsen, and some very interesting letters of Sir William Fairbairn. Describing, in a letter to Dr. Robinson, of Armagh Observatory, his dining at the table of the King of Prussia where he made the acquaintance of Humboldt, he gives his impression of the great philosopher as follows:—

"I must, however, inform you that I was seated with feelings of pride and gratification beside a greater man than the King, and enjoyed the benefit of a conversation similar to that I had the pleasure to listen to on the occasion of a recent visit to a highly valued friend of kindred mind and pursuits. I cannot express to you how much I valued the society of this amiable and distinguished man. At eighty years of age he possesses the mental energies of a man of forty, and retains what appears to me to be the desideratum of advancing years, a mind susceptible of impressions, with a power of discernment and retention which can only be looked for in the maturity of life. Such, however, is the mind of Humboldt, perfectly alive to every improvement and every development in the advancement of his favourite studies."

It is pleasant to compare this letter with one written by Humboldt to Bunsen, as showing that this cordial feeling was mutual between them; in it Baron Humboldt says:—

"I cannot be grateful enough to you for having made us acquainted with a man possessing so much knowledge, so highly esteemed by all, so amiable, and so modest;" and he adds: "The king was enchanted by the demeanour of the great man, and Mr. Fairbairn did not like less the frank and hearty demeanour of the King."

An interesting chapter of this interesting book is that devoted to the researches for the experimental determination of the influence of pressure in the process of solidification as bearing upon the solution of the question of the solidity or fluidity of the centre of the earth, and the thickness of the earth's crust. This inquiry was instigated by the late Mr. Hopkins, of Cambridge, and was carried on at Mr. Fairbairn's Works at Manchester, in conjunction with Mr. Joule and Prof. (now Sir William) Thomson. As the experiments involved the submitting of various substances to enormous pressures—sometimes as great as 6,000 pounds upon the square inch—the mechanical fertility of Mr. Fairbairn's mind was of very great value to the investigation. The results of these experiments pointed to the conclusion that the least thickness that can be assigned to the solid envelope of the earth must be considerably greater than geologists have imagined it to be. This investigation was carried on three-and-twenty years ago, and it is interesting to notice that its result corroborates in a remarkable degree the conclusion which Sir William Thomson enunciated at the recent meeting of the British Association at Glasgow.

As a scientific man Sir William Fairbairn held a high position, he had an essentially analytical mind, seeing, by an intuitive reasoning characteristic of him, into the principles of things, separating essential from accidental results, and thereby directing his experiments to the best advantage. In 1850 he became a Fellow of the Royal Society, and two years after a Corresponding Member of the Institute of France. In 1861 he was the president of the Manchester Literary and Philosophical Society, which office he had held for five years. In 1860 he received one of the Royal medals of the Royal Society for his papers in the *Philosophical Transactions*, and the following year he held the office of President of the British Association, which met at Manchester. In consideration of this and of his services to engineering science he was offered the dignity of knighthood, which he refused. Eight years after, and when in the eightieth year of his age, he accepted a baronetcy which was offered him by Mr. Gladstone's Government. He survived this honour five years.

A more useful and eventful life than that of Sir William Fairbairn rarely falls to the lot of a biographer to record. The work before us shows, however, that it has fallen into good hands. Dr. Pole is himself an engineer and a man of science; he was associated with Sir William Fairbairn in many of his works, and he possessed exceptional qualifications for telling the story of such a life. The interest—whether personal, historical, or scientific—is maintained throughout the book, and as an autobiography of great literary merit we would recommend it to our readers.

C. W. C.

GROTH'S "CRYSTALLOGRAPHY"

Physikalische Krystallographie und Einleitung in die krystallographische Kenntniss der wichtigeren Substanzen. Von P. Groth. Mit 557 Holzschnitten im Text, einer Buntdruck, und 2 lithographirten Tafeln. (Leipzig: Wilhelm Engelmann, 1876.)

PROF. GROTH has written a good book on a subject for which, if it attracts but few students in England, German universities will supply readers. It is a good book, as being written by a man whose work puts him in an authoritative position for writing it, while to anyone who is master of the small mathematical experience needed it is eminently readable, is to the point, and not too voluminous. It is moreover copiously and well illustrated. Of course, even as an Arabic chronicler of the events of his time, invariably commences his history with the origin of things, and the early traditions of mankind, so a German professor who writes on crystallographic optics, of necessity devotes a good many pages to a sketch of the fundamental laws of optics and the general principles of the undulatory theory. Our author, however, while doing so, never loses sight of his purpose, and a few pages so occupied are probably intended to fill a void in the training of some of those for whom the book is intended.

Indeed for the student who wishes to obtain only so much knowledge of the principles of physical optics as is requisite for following the methods of the crystallographer, it would be difficult to find a more compendious and useful statement and illustration of those principles than in Prof. Groth's book; the exposition of them being so completely cleared of difficult mathematical language that the student might be led on to the possession of a fair insight into the optical characters of a crystal without any idea of the profound and splendid series of mathematical achievements by which the theory of light has been elaborated.

Prof. Groth has dealt in a similar if less complete way with the thermic properties of crystals. One might perhaps have expected a fuller treatment of the subjects of cohesion and cleavage, of the relations of crystals to magnetism, and of the results and the best methods of experimenting on pyroelectric crystals, in a treatise on the physical aspects of crystallography.

What is perhaps the best part of Prof. Groth's work is the description of the instruments used by the crystallographer, such as the "polarisation-instrument" as he calls that necessary companion which has been hitherto known, under its very usual form, as a Nörremberg, or as a polariscope, or as a polarising microscope. This instrument has been reconstructed by our author in an

PROF. W. H. FLOWER, F.R.S., will commence his course of Hunterian Lectures at the Royal College of Surgeons in Lincoln's Inn Fields, on Friday, March 9. The lectures, nine in number, will be delivered on Mondays, Wednesdays, and Fridays, at four o'clock, the subject being "The Comparative Anatomy of Man." From the prospectus, we learn that after treating of the variations in the human external, dental, and osteological characters, Prof. Flower will discuss the methods of estimating the capacity of the skull, craniometry, and the peculiarities of the brain. It is worthy of remark that anyone anxious to attend these lectures, if not connected with the College, will be allowed to do so upon application for a card of admission.

THE Association of German naturalists meets at Munich on September 18, and not in February, as stated in a recent number.

WE are glad to be able to state that a final settlement has been arranged between Mr. Floyd and the trustees of the late Mr. Lick's legacy on the one hand, and Mr. Lick, the son of the testator and the other relatives on the other. After a deduction of about 200,000 dollars the whole of the estates will be reserved for the ends proposed by Mr. Lick, the father. The sum so secured for scientific purposes amounts to a little less than three million of dollars.

THE French Society of Aerial Navigation has published a circular stating that owing to internal difficulties the meetings are suspended up to May 1. Another society was established by French aeronauts—who escaped from Paris by balloon during the siege—last April and is called the School of French Aeronauts. They confine themselves to practical ends, devoting themselves exclusively to the use of balloons for scientific purposes.

A NEW aeronautical periodical, *l'Aerostat*, has been published in Paris by M. Achille Rouland, secretary of the School of French Aeronauts. It is to appear three times a month, and to contain a summary of all aeronautic news.

The Denstonian is the name of a journal published as the organ of St. Chad's College, Denstone, Uttoxeter. It devotes some space to natural history.

"GEOLOGICAL Time" was the subject of the presidential address of Mr. T. Mellard Reade to the Liverpool Geological Society, and which has been published in a separate form.

NEWMAN'S *Entomologist* now appears as *The Entomologist*, and several new features have been added which will increase its scientific value.

A SPECIAL committee, intrusted with the elaboration of a scheme for the representation of Russian gardening at the Paris Exhibition of 1878, has been appointed by the Russian Society of Gardening.

BY order of the Lord President of the Council, a letter, written by Mr. Andrew Murray, on Injurious Insects has been sent to the Secretaries of the Agricultural Societies of England, Scotland, and Ireland. Mr. Murray proposes a method of stamping out these insects which is worthy of being tried.

DR. PETERMANN has just published an index to his *Mittheilungen* for the period between 1865–1874. This will be of great value to geographers, and its value is much enhanced by two most ingeniously-constructed index-maps which show the various parts of the earth that have been mapped in the *Mittheilungen* during that period, and in a simple way indicate where the map will be found. Besides a general index-map there are maps of the various Continents and of the Arctic and Antarctic regions. By differently coloured lines the scale of the special map referred to is shown, as also its character, whether outline, topographical, physical, or geological.

A MEMORIAL to Lomonosoff, erected in the square of the University of Moscow, was unveiled on the anniversary-day of the University, January 24. The memorial, which was erected at the very moderate cost of 225*l.*, collected among professors and students of the Moscow University (founded by Lomonosoff in 1755), is very modest. It consists of a small bust placed on a high very plain pyramidal pedestal bearing the inscription: "To Lomonosoff—the Moscow University: year 1877." In an address by M. Solovieff, Professor of History, he briefly sketched the impulse given to science in Russia by Lomonosoff, and insisted especially on the importance of his works in the development of the history of his nation. No reference was made to the task performed by Russia's first physicist. We are glad to take this opportunity to say that it is a great pity that the Russian learned societies have not yet published a collection of the works of Lomonosoff, all the more as many of his writings, dispersed in rare old periodicals, are now totally unknown or forgotten. This neglect induces us to think that Russian men of science have not yet fully appreciated the depth and width of the physical conceptions of this remarkable physicist of the past century, who not only devoted his time to the study of the most important questions of astronomy, physics, and physical geography (as, for instance, the transit of Venus, the existence of ascending warm currents in the atmosphere), but also in a now forgotten, but able paper on the Arctic Seas, expressed himself very explicitly as to heat being but a mode of motion. We think, therefore, that a complete edition of Lomonosoff's works would be not only an addition to the glory of the science of the eighteenth century, but also a most interesting acquisition for all those who are interested in the history of science.

A PARTY of the Swiss Alpine Club have availed themselves of the prevailing mild weather to extend their yearly winter excursion in the mountains as far as the Col de Balme. They crossed the mountain-pass on January 21, and, after many pleasant adventures, reached the hotels of the Col, which were so deeply buried in snow that the way to the rooms had to be made through the windows of the first floor. Other parties, of French and Swiss excursionists, visited about the same time the renowned archæological ground lying in the Jura between Montbelliard and Porrentruy. The special aim of the excursions was to organise a scheme for a thorough exploration and a detailed survey of these localities to be undertaken next summer. If we take into account the immense number of caves, rocky *abris* (shelters), tumuli, grave-walls, open dwelling-places, and megalithic stones scattered over this part of the Jura, and the strange anomalies observed in the geographical distribution of these remains of prehistoric man (only caverns and rocky *abris* being known in the Swiss part of the Jura, whilst the French part abounds with all kinds of remains enumerated above), we cannot but hope that an exploration of these localities will result in valuable contributions to prehistoric archæology.

A NEW form of marine sounder has been described to the French Academy by M. Tardieu. It consists of a spherical envelope of caoutchouc, a few centimetres in thickness, communicating with an iron reservoir by means of a tube of small diameter fitted with a valve. The caoutchouc envelope being filled with mercury, any increase of the exterior pressure makes a certain quantity of mercury pass into the iron reservoir, whence, however, it cannot return. When the apparatus has been lowered in deep water, the weight of the mercury found in the reservoir enables one to determine the pressure to which it has been subjected, and therefore the depth.

M. FELIX PLATEAU read, at a recent meeting of the Belgian Academy, a paper giving an account of the journeys of a large number of Belgian naturalists during the last two centuries. This paper is now published separately (Hayez, Brussels), and contains much important information.

THE Russian Government having refused to enact a law by which all the *koorgans*, or ancient and prehistoric grave-mounds, so numerous in Russia, would be proclaimed the property of the state, a private society is now in way of formation for the same purpose. The society proposes to enter into negotiations with proprietors of land for receiving from them grants of property on the *koorgans*, and to undertake afterwards a series of systematical explorations of these mounds.

THE *Denver News* states that after a severe snowstorm on the night of December 22, 1876, the sun, next morning, rose clear, but the air was filled with particles of frost, the refraction from which caused the appearance of "mock suns" or "sun dogs." First, extending from the sun right and left was a circle entirely around the heavens. Along it were the "sun dogs" in their usual places, with extra ones in the north-west, south-east, and south-west, being directly opposite the sun and at right angles to that line. A very bright circle, like a continuous rainbow, surrounded the sun, at an angle twenty or thirty degrees from it, and crossing the horizontal circle at the most brilliant of the false suns. Another and similar circle, and of about the same diameter, occupied the zenith. Thus there was a complete circle around the horizon, and twenty to thirty-five degrees above it two complete rainbow circles of exceeding brightness and seven "mock suns" or "sun dogs." The spectacle lasted, with changing effects, for two hours or more.

AUSTRIAN census statistics show that cretinism is prevalent to a great extent in the more mountainous portions of the empire. The proportion in 10,000 inhabitants is 40 in the Salzburg district, 18·3 in Upper Austria, 17 in Styria, 10 in Silesia, 7·6 in Tyrol, &c. As yet no institution has been provided by the state for the reception of the unfortunate victims.

A SERIES of measurements of the calorific intensity of solar radiations and of their absorption by the terrestrial atmosphere, has been lately made by M. Crova. His mode of observation is described in the December number of the *Journal de Physique*. He has ascertained that the law of transmission of radiations may be represented by an expression of the form $y = \frac{C}{(1+ax)^{b}}$, in which y represents the calorific intensity of radiations which have traversed an atmospheric thickness equal to x, C is the solar constant which, in the author's experiments, is represented by values generally superior to two units of heat received per minute on a square centimetre; a and b are two numerical constants determined by the position of tangents to the curve drawn at different points. The coefficient of transmissibility of the radiations through an atmospheric thickness equal to unity varied, in the circumstances in which M. Crova measured it, between about 0·940 and 0·800, according as the atmospheric thickness already traversed was more or less considerable.

MINERALOGISTS have often been troubled to distinguish with certainty between apatite and nephelin. A. Streng communicates in the last *Mineralogischen Mittheilungen*, a simple but secure method for overcoming this difficulty. If a drop of a concentrated solution of ammonium molybdate in nitric acid be placed on a thin section of an apatite crystal under a microscope, the observer notices quickly the formation of a circle of small yellow crystals of $10M_{o}O_3 + PO_4(NH_4)_3$, either in the form of regular octahedrons or of regular rhombic dodecahedrons. A second test is the following. If a drop of sulphuric acid be added to a section which is already partially dissolved in nitric acid, the formation of crystals of gypsum is easily noticed. Nephelin yields negative results in both cases; a positive test for its presence consists in the addition of a drop of hydrochloric acid to a thin section under the microscope. After the lapse of a few minutes the formation of numerous small colourless cubes of sodium chloride is quite perceptible. They result from the decomposition of the silicate of sodium by hydrochloric acid, and the insolubility in the latter of the salt thereby formed.

THE *Bulletin* of the Belgian Academy of Science (vol. 42, Nos. 9 and 10) contains the second part of an interesting memoir by M. J. Plateau, "On Accidental or Subjective Colours." The author had advanced, in 1834, a theory for the explanation of the subjective colours, and especially insisted on the circumstance that, after having looked some time upon a coloured body, we mostly do not see the true complementary colour, but some other: the orange, for instance, instead of a pure yellow, after the blue; or a violet, instead of the blue, after the yellow. He explained it by supposing, firstly, that the retina, after having received the impression of some colour, comes immediately into such a condition as if it were influenced by the opposite colour, but that this subjective impression soon disappears, and reappears again, alternating with reappearing impressions of the primitive colour of the coloured body; and secondly, that similar phenomena take place also in space, *i.e.*, that the image of the coloured body on the retina is surrounded, firstly, by a narrow strip of the same colour as the body (which phenomenon we call irradiation), and then by a strip of opposite colour, around which, under some circumstances, may reappear a third strip, of the colour of the body looked upon. This theory having been much opposed since its appearance, especially in Germany and England, the author now discusses the various objections advanced against it; those relative to the first part of the theory were the subject of the first part of the memoir (*Bulletin*, vol. 39, 1875), and those relative to its second part are dealt with in this second memoir. The author begins his discussion with the objections against his theory of irradiation, dealing at great length with the opinions and objections of Helmholtz, and treating very skilfully the many difficulties of the whole question, among which the various myopy of the observers seems to be an important one. Further, the author criticises the theories of irradiation advanced until now (the imperfect accommodation of the eye, its spherical and chromatic aberration, and the diffraction at the borders of the pupil), and concludes that the fact that two neighbouring irradiations may mutually neutralise each other, would alone be sufficient to condemn all these theories. The memoir is to be continued.

A COMPARISON has recently been made by Dr. Buff between the indications of the thermomultiplier and the radiometer. The two instruments were placed side by side in the cone of light admitted through an aperture of a board from a gas lamp, which could easily be regulated and kept constant for some minutes. There was a glass disc in front of the thermopile. In the galvanometer the deflections of the needle were proportional to the deflecting force up to 21°. On tabulating deflections and numbers of rotations, it appears that their product is very nearly a constant number, warranting the inference that *the velocity of rotation of the little wheel is inversely proportional to the heat action of the penetrating rays.* This confirms the view that the turning of the radiometer is due to an action of heat rays which penetrate the glass. "If the radiometer," says Dr. Buff, "is incapable of measuring a mechanical force of light, it none the less wears its present name with full right. It is a special form of thermometer, only exclusively for heat rays of high refrangibility, whose heating force is proportional to the velocity of rotation of the wheel."

THE additions to the Zoological Society's Gardens during the past week include a Mauge's Dasyure (*Dasyurus maugei*) from Australia, presented by Mr. Robert S. Craig; a Slender-billed Cockatoo (*Licmetis tenuirostris*) from Australia, presented by Mr. Bartle G. Goldsmid; a Chilian Sea Eagle (*Geranoaetus aguia*) from South America, presented by Mr. C. Clifton; a Levaillant's Amazon (*Chrysotis levaillanti*) from Mexico, pre-regions into the higher latitudes, and the polar air brings the less rotatory velocity of the polar regions into the lower latitudes. The latter constitute the trade-winds, which move more slowly than the earth's rotation, and consequently appear as an atmospheric current from the east; the former constitute the "counter-trades," which move more rapidly than the earth's rotation, and appear as an atmospheric current from the west.

The centrifugal force of the "counter-trades," as they circle round the poles, is the cause of the polar depression of the barometer.

The law of reaction makes it impossible for the earth's rotation to be either accelerated or retarded by the winds, and consequently the entire "torsional force" exerted by the winds on the earth must, at any given time, be equal in the easterly and westerly directions.

I have now described in outline what theory shows that the circulation of the atmosphere would be in the absence of watery vapour and in the presence of the sun's heat and the earth's rotation; and observation shows that such is the actual circulation on the large scale, and not taking account of local disturbances.

Joseph John Murphy

Old Forge, Dunmurry, Co. Antrim, February 23

Halo round Shadow

It is not uncommon for an observer, when looking at his own shadow on rough ground or turbid water, to see its head surrounded by a halo, of which the brightest part is in contact with the shadow.

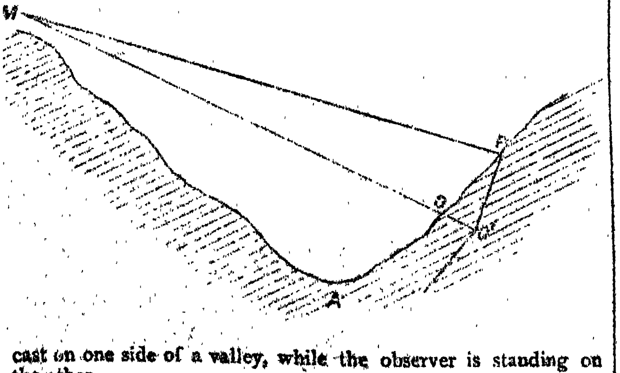
This phenomenon has often elicited notice, but as far as I am aware has not before now been explained, nor do those who have mentioned it seem to have observed that its appearance depended on the nature of the surface receiving the shadow.

The conditions necessary for the production of these halos are—

1. That the screen, as whatever the shadow is cast on may be called, should not be a continuous surface, but a number of small surfaces with intervals between them, each of these small surfaces of course casting its own shadow on whatever happens to be behind it.
2. That the shadow should be at a considerable distance from the observer.
3. That the light should not fall very obliquely on the screen.

The first of these conditions only is essential, but the fulfilment of the last two makes the phenomenon more marked.

Rough grass forms a good screen, especially if, as in the diagram, conditions 2 and 3 are fulfilled by the shadow being cast on one side of a valley, while the observer is standing on the other.



In the case of the shadow on turbid water, it must be remembered that it is not the surface of the water which forms the screen, but the particles suspended in it.

The general explanation of these halos is this—

From the observer's point of view the screen in the immediate neighbourhood of the shadow of the head is seen in nearly the same direction as it would be from the source of light. In this direction, therefore, each of the small surfaces of which the screen is made up will hide its own shadow, but this will be true of no other direction; and the effect on the whole will be that the screen will appear brighter close to the shadow of the observer's head than elsewhere.

To examine this rather more in detail, let M A O be a section of the ground passing through the observer at M and his shadow at O. Let

$$O'P = r \quad O'MP = i$$
$$O'PM = \text{a right angle.}$$

Let w and w' be the projections on $O'P$ of the average breadth of the sections of the small surfaces made by the plane M A O, and the average distance between them respectively, and let h be the average distance of each of the small surfaces from its own shadow.

Then the amount of light received from any space $r\,d\theta\,(w + w')$ may, *cæteris paribus*, be taken without any great error as a measure of the brightness of the zone whose mean radius is r, and whose breadth is $w + w'$ ($d\theta$ being a small rotation of r about $O'M$), and this will be proportional to $w + w' - h$ sin. i. The decrease in brightness is proportional to h and sin. i, and will reach a maximum when h sin. $i = w$, if $w < w'$, or $= w'$ if $w' < w$.

Outside the circle defined by this value of i the brightness will be sensibly constant, because the quantities of which w, w' and h are the average values have all manner of actual values, even in a very small space.

These expressions are only approximate, but they serve, as well as the longer exact formulæ, to show the general laws of the phenomenon.

Arnulph Malloch

Meteor

This evening, at close upon twenty minutes past six, as I was walking in my garden towards the almost full moon (which was very bright), I observed a brilliant meteor pass from right to left over, and very near, the moon's disc. It was visible for a distance of about twice her diameter. From the amount of daylight, and the extreme brightness of the moon, I judge this meteor to be worth recording.

C. M. Ingleby

Valentines, Ilford, February 26

Tape-worm of Rabbits

So far as I am aware the only evidence in favour of the view that *Bothriocephali* present no hydatid stage is that which has been furnished by the researches of Knoch. To me it has always seemed that this evidence is insufficient fully to overcome the analogical probability that tape-worms of this genus resemble tape-worms of other genera in passing through a hydatid stage—and this notwithstanding the occurrence of a ciliated embryo. However, in my previous letter I ought no doubt to have alluded to the researches of Knoch, and should certainly have done so had my object in writing been other than it was, *i.e.*, merely to ascertain whether anyone had as yet taken the trouble to trace the life-history of the rabbit's tape-worm.

February 20

George J. Romanes

A PROBLEM IN THE NATURAL HISTORY OF THE SALMON.

Mr. Frank Buckland, in giving evidence before the Parliamentary Committee, which during last session of Parliament inquired into the condition of our oyster fisheries, stated that "a salmon (? *Salmo salar*) does not breed every year, but every three years!" On being asked by a member of the Committee if he had any proof of his averment, Mr. Buckland stated that, "he had a great idea of it," but was deficient in proof. Before examining this alleged fact in the life of the salmon, advanced by Mr. Buckland, it is proper that we should state briefly what induced him to make known his idea.

While illustrating the theory of oyster-spatting, and telling the Commissioners that all the individual oysters on a *scalp* would not be found exuding their young at the same time, however favourable for spatting the period might be, Mr. Buckland also enunciated his opinion as to the periods at which salmon spawn. That gentleman holds that only one of every six oysters on a *scalp* will be found in a procreant state during the same season; and, by way of clenching his illustration, he said, "you never get salmon always breeding the same year, they take time to recover themselves, and so forth." This latter statement is rather obscure; but the interpretation undoubtedly is, that the same salmon does not breed every season. It would be instructive if Mr. Buckland were to state his ideas on this feature of the natural history of *Salmo salar* at greater length, giving at the same time a *précis* of the data on which he has formed his opinion; because the views hitherto entertained of the spawning of salmon have been mostly contrary to those promulgated by Mr. Buckland, the prevailing idea being that salmon spawn annually. Some persons, indeed, promulgated a theory of the salmon being able to spawn twice in the same year, doubtless founded on the fact of individuals having been known to go to, and return from, the sea within a few months. There is not, however, any exact proof of these facts. There are, also, one or two gentlemen of opinion that the fish in question only spawns every two years; but the opinion hitherto has been very general that salmon deposit their ova annually.

It is remarkable how ignorant we still are of the most important phases of salmon life, notwithstanding the active investigation of the last twenty years; and it is still more remarkable that some of the best informed salmon anglers, intelligent students of the natural history of the *Salar* group of fishes, should hold diametrically opposite opinions, both on this and other important points of salmon life. One gentleman, whose works on angling have a wide reputation, and whose knowledge of fish-life is extensive, tells us he has no doubt the same salmon spawns every year, which, he further says, "is the generally accepted opinion on our border rivers by anglers and fishermen of the professional caste." The same gentleman informs us that the late Mr. Robert Buist, superintendent of the River Tay Salmon Fisheries, was induced by experience to arrive at a similar conclusion. Mr. Buist, who took great interest in the Stormontfield salmon nursery, was usually present every season at the capture of the gravid fish, from which the required supply of ova to fill the breeding boxes was obtained. On one of these occasions a fine grilse was captured, in good condition for being artificially spawned; and, after being deprived of her ova, the fish was carefully marked, and restored to the river from whence she had been taken. "On the following year, at the same spot, the *same fish*, but now grown into a salmon, was retaken, full of ova, and again stripped, in order to aid in stocking the breeding boxes at Stormontfield!" This incident Mr. Buist held to be decisive of two points in the natural history of the salmon; first, that a grilse becomes a salmon, and is not a distinct member of the *Salar* family, a point in salmon life which was at one time hotly discussed; and, second, that the same salmon spawn every year. Another gentleman, Mr. Brown, who at one time gave his personal aid in the salmon breeding experiments carried on at Stormontfield, relates, in his notice of the proceedings, that "one year we had a very fine male fish of 24 lbs., which we marked with a wire, and *two years* afterwards we spawned him from the same ford a few pounds heavier." This same fish *may* have visited the spawning ground also in the preceding year without being recaptured for spawning purposes.

Our angling authority says further, in his communication: "I have had many opportunities of examining spent and half-spent females—those in which what is vulgarly termed the *waim* was exhausted, a few particles of ova remaining, and those taken by me or others in a spawning state; and I invariably found new formations of ova, in the shape of two lobes, corresponding to what are found in the spring run or clean salmon, and often measuring two inches in length, according to the size of the female *kelt*, or half-spawned *baggit*. This formation cannot be taken otherwise than as an index of what was to happen after the migration seawards had been accomplished, and the term of the salmon's stay in the salt water had expired—a term which may extend to six or eight months, but has been ascertained in well-ordered rivers not to exceed that period."

None of the great naturalists, or fishers, who write on the natural history of fish—Jardine, Yarrell, or Couch—have thrown any light upon this phase of the life of the salmon. We search their works in vain to obtain information on this interesting point. The late Mr. Russel, in his book, "The Salmon," speaking at one place of the mysterious clean run fish of the early springtime, thinks "they must have passed the autumn or earlier winter in the sea; then they must have passed the winter without breeding, and thus we have the discouraging fact or hypothesis that the salmon is a fish which does not breed every year."

We have the authority of a gentleman residing in the north of Scotland, who is well versed in the economy of our salmon rivers, for stating that the salmon only spawns every two years. He says: "I have marked hundreds of *kelts* in the months of February, March, and April, returning downwards to the sea; I have marked them with different marks every season, so that there could be no mistake, and I have never seen one single instance of one being marked in spring return to spawn the autumn of the same year; but I have seen hundreds with the individual mark return next spring good, clean, fine full fish. I believe that all salmon spawn only once in two years till they get too old, when they become barren; but still they frequent the fresh water, I suppose from habit, although there is no sign of roe or milt, and I have seen and taken them off the *redds* along with fish which were in the act of depositing their spawn."

It would be tedious to run through the facts of the numerous controversies which have arisen as to the rate at which salmon grow. The experiment of marking large numbers of these fish has been often resorted to, and at different places. Mr. Young of Invershin, in his day a well-known authority on the natural history of the salmon, tells us that *spawned* grilses of four pounds weight were repeatedly marked; and after their journey to the sea it was found that these grilses had become beautiful salmon, varying from nine to fourteen pounds weight, "the majority" returning in about eight weeks. It is much to be regretted that Mr. Young was not more explicit in his statements, because it would have been most interesting to know when these fish returned, after an absence of only two months, if they were again ready to spawn. It is these records of quick journeys that have doubtless given rise to the theory of the Rev. Dugald Williamson, which is that salmon in the course of the year perform two migrations. At any rate, we are entitled to ask this question: What does a salmon, which is only away from its birthplace for eight weeks, do with itself during the other ten months of the year? The rate of growth indicated by Mr. Young is most astonishing, and had it not been corroborated by other observers, would have been considered doubtful. A fish marked many years ago by the Duke of Athole was found to have increased eleven pounds and a quarter in the short space of five weeks and two days! The rate of growth of the salmon is so assured, that smolts have been found to return from the sea as grilse in the same season during which they left for the salt water; but, curiously enough, none of the observers took note of what we now consider the only unsolved problem in connection with the growth of the salmon, namely, whether the *same* fish spawns annually, once in two years, or once in three years. Probably Mr. Buckland will make some additional statement on the subject. A Tay salmon fishery proprietor, whom we have consulted as to this problem in the life of the fish, will not, with all his experience, which has been very varied, and has extended over many years, venture to give an opinion, and "thinks that the question is almost beyond the reach of positive proof." It is therefore incumbent on her Majesty's Inspector of Salmon Fisheries to prove his case.

THE SOUTH-AFRICAN MUSEUM

SINCE we last gave a notice of this institution we have learned, with much pleasure, that the Cape Government has made liberal provision for its more efficient administration and maintenance. There is none of the more important British Colonies which has of late made more rapid progress than the Cape in material prosperity, and it is most gratifying to find that the Molteno administration (the first ministry organised under the Parliamentary System of Government initiated in 1872) has not been oblivious of the claims of science during its four years' tenure of office. In the estimates for the financial year 1876–77, as passed by the Colonial Legislature, we find provision made for Botanical Gardens to the extent of 2,900*l*; for Public Libraries, 2,600*l*.; for Museums, 1,300*l*; while such items as "Geological Researches, 1,500*l*;" "In aid of publishing Dr. Bleek's Bushman Researches, 200*l*;" and "Meteorological Commission, 250*l*," sufficiently prove that the duty of endowing research is practically recognised by the Cape authorities. The present able Governor, Sir Henry Barkley, F.R.S., is as well and widely known for his attachment to scientific pursuits as for his distinction in Colonial administration, and we think we cannot err in tracing to his judicious influence much of the enlightened action of his responsible advisers in their recommendations to the Parliament.

The South-African Museum is located in Cape Town, and is the public museum of the Colony It was instituted in 1855 under the auspices of Sir George Grey, a governor distinguished for his energy and success in initiating measures for awakening and developing the intellectual life of the Colony. Many years before there had existed a South-African Museum in Cape Town, consisting of the combined collections formed by the Expedition for Exploring the Interior, under the superintendence of the celebrated zoologist, Sir Andrew Smith, and by M Verreaux, but this museum was devoid of means for permanent maintenance, and after languishing for a while came to an untimely end for want of public support. Many of its finest specimens, however—and notably those of the magnificent larger mammals characteristic of the region which constituted its chief ornament—were fortunately secured for the British Museum, and still form an imposing feature of the national collection. The new, or present institution, was started by public subscription aided by an annual grant from the Government of 300*l*. Two trustees were appointed by the Governor, and a third elected annually by the subscribers; but in 1857 the collections already brought together were of sufficient importance to induce the passing of an "Act to Incorporate the South-African Museum," under which all the three trustees were to be appointed by the Governor, and to be vested with full powers for the entire management and control of the institution. Under this Act the Museum has continued to be and is still administered.

In happy contrast to the untoward fate of too many kindred institutions, the South-African Museum has from the first been most fortunate in the possession of trustees who were men of culture and of scientific attainments, and for fifteen years it enjoyed the further advantage of the services of Mr. E. L. Layard, C.M.G. (now H.M. Consul in New Caledonia), as its Curator.

The usual difficulties attended the acquisition of suitable premises for the Museum, but these were eventually obviated by the erection at the cost of the public of a building expressly designed for the purpose; and on April 5, 1860, the Museum was opened to the public in its new quarters.

As mentioned in our notice already referred to, the Cape Museum appears, notwithstanding the advantages stated, to have suffered from the chronic complaint of very insufficient funds. The system of support partly from the Colonial Treasury, and partly from private subscriptions, seems to have failed, the subscribers lost by death or departure from the Colony not being as a rule replaced by others; and of late years the institution depended almost wholly on the government subsidy of 300*l*. With such limited means at their disposal, it was obviously out of the question for the Trustees to award an adequate remuneration to the Curator, and they had no alternative but to make shift with engaging the services of a gentleman willing to devote a part of his time to the Museum. This unsatisfactory state of things has now been remedied by the government on the recommendation of the Trustees, constituting the Curatorship a Civil Service appointment, with a suitable salary. We congratulate Mr. Trimen—who has been for four years endeavouring to satisfy simultaneously the rival claims on his attention of an ordinary public office, and of a museum of natural history—upon his appointment to the Curatorship on its improved basis, and we consider that great credit attaches to the Cape Government for effecting so desirable a reform. We must not omit to mention, moreover, that, under further legislative provision, a new gallery has just been erected in the Museum, and other much needed repairs and improvements in course of execution are approaching completion.

ATLANTIC SOUNDINGS

THE recently-announced discovery by Commander Gorringe, of the United States sloop *Gettysburg*, of a bank of soundings bearing N. 85° W., and distant 130 miles from Cape St. Vincent, during the last voyage of the vessel across the Atlantic, taken in combination with previous soundings obtained in the same region of the North Atlantic, suggests the probable existence of a submarine ridge or plateau connecting the island of Madeira with the coast of Portugal, and the possible subaerial connection in prehistoric times of that island with the south-western extremity of Europe. The soundings obtained in January, 1873, by H.M.S. *Challenger*, and in July, 1874, by the German frigate *Gazelle*, furnish additional data, with the help of which the accompanying contour-chart has been constructed.

These soundings reveal the existence of a channel of an average depth of from 2,000 to 2,500 fathoms, extending in a north-easterly direction from its entrance between Madeira and the Canary Islands towards Cape St. Vincent. It is bounded on the west and north by the submarine ridge which unites Madeira with the Josephine bank and the recently-discovered Gettysburg bank, on the east by the coasts of Portugal and Morocco, and on the south by the submarine plateau which connects the Canary Islands with the African continent.

As shown in the chart, this channel is virtually an extension or branch of the still deeper channel which runs up between Madeira and the Azores. The island of Madeira, with the adjacent islands of the Dezertas and Porto Santo, occupies the southern extremity of the dividing ridge, and marks the junction of the two channels. Confined by a comparatively steep bank on the west and a more gentle slope towards the African shore, this eastern branch seems to attain its greatest depth off Cape St. Vincent, after which it contracts into a narrower channel, less than 2,000 fathoms deep, and continuing northwards as far as the latitude of Cape Roca, it once more joins the vast abysses of the Atlantic. The Strait of Gibraltar is undoubtedly a recently-formed connecting-link between this basin and that of the Mediterranean.

Commander Gorringe, when about 150 miles from the Strait of Gibraltar, found that the soundings decreased from 2 700 fathoms to 1,600 fathoms in the distance of a few miles. The subsequent soundings, five miles apart, gave 900, 500, 400, and 100 fathoms, and eventually a depth of 32 fathoms was obtained, in which the vessel anchored. The bottom was found to consist of live pink

coral, and the position of the bank in lat. 36° 29′ N., long. 11° 33′ W. In other words, Commander Gorringe, on his journey westward from the Strait, after passing over the northern extremity of the deep channel, sounded up the steep slope of the submarine plateau which connects Portugal with Madeira, and within a short distance of a sounding of 1,525 fathoms obtained by H.M.S. *Challenger* on January 30, 1873, in lat. 36° 23′ N., long. 11° 18′ W.

The sketch-map does not pretend to be more than an approximation founded upon the still limited number of soundings obtained up to this date, but the bottom-temperatures observed in this part of the North Atlantic tend to corroborate the views which I have ventured to express. They show that the submarine flow of cold water of antarctic origin, which has been traced as far north as the Bay of Biscay, also fills up the lower depths of the channel which stretches up towards Cape St. Vincent. On the other hand, the channel between the coast of Portugal and the Gettysburg Bank is occupied by the warm water of the Gulf Stream return-current, which, spreading itself out over the banks to westward, explains the presence of the live coral found by Commander Gorringe.

JOHN JAMES WILD

HUMMOCKY MORAINE DRIFT

DURING his survey of the West Pacific slopes, Clarence King found and has since described, hummocks of moraine drift on the "dying-out glaciers," which are somewhat similar to the "hog-wallows;" and J. le Conte has described dying-out glaciers and moraine drifts of California. Abstracts of these descriptions will be found in the *American Journal of Science and Arts*, and the full description of the West Pacific slopes in Clarence King's report. In West Galway, Ireland, there are in places large tracts of drift sometimes like Clarence King's description, in others like the "hog-wallow;" that in the Memoirs of the Irish branch of the Geological Survey have been described as "rocky moraine drift." The accompanying sketch is of some of these drift hummocks on the north slope of Croagh-na-Cloosh, south of Oughterard.

Perched Erratic Blocks on Croagh-na-Cloosh.

G. H. KINAHAN

CONTRACTION OF THE LEAF OF "DIONÆA MUSCIPULA"[1]

IN the first section of this paper the authors give an account of the mechanical effects which ensue on exciting the sensitive hairs of the Dionæa leaf. The following is a *résumé* of the principal conclusions at which the authors have arrived:—

If the sensitive hair of a vigorous leaf be touched with very great care by a camel-hair pencil, no visible effect on the leaf will be produced, and a similar gentle contact can be repeated several times before the leaf begins to answer to the excitation by any movement. Sooner or later, however, the marginal hairs bend inwards and the lobes slightly approach each other. The first effectual excitation is followed by an almost imperceptible movement; after this each successive approach of the lobes in nearly every case exceeds that of its predecessor. The interval which elapses between excitation and effect diminishes as the extent of the effect increases, both facts having the same meaning, namely that in the plant, as in certain cases well known to the animal physiologist, inadequate excitations, when repeated, exercise their influence by what has been termed "summation," and thus the last contraction, that by which the leaf closes, is the result of the summation of the excitation which immediately preceded it with all the previous excitations. After the leaf has closed it still contracts at each excitation, and attempts to clench itself with greater and greater force. The interval between an excitation and the resulting movement varies from two to ten seconds.

The authors next proceed to a consideration of the electrical condition of the leaf in an unexcited state, which has recently been made the subject of a minute investigation[1] by Prof. Munk, of Berlin, who has found—1. That if we conceive the external surface of the leaf divided into strips by parallel lines crossing the midrib nearly at right angles, and coinciding with the veining, any point of the external surface of each strip is negative to any point nearer the midrib. 2. That in comparing different points of the midrib with each other, there is one whose position is two-thirds of the distance from the near to the far end of the midrib, which is positive to the rest. 3. He has further stated that the potential of any point on the internal surface of the lobe is exactly equal to that of the corresponding and opposite point on the external surface. Of these three proportions the first two are confirmed, in the main, by the authors of the present paper; as regards normal leaves, however, they take exception to his conclusions on the two under-mentioned points—(*a*) That although there is a spot of greatest positivity on the midrib, more or less corresponding in position to that mentioned by Prof. Munk, yet its position is by no means so definite as Prof. Munk states, but varies in different leaves. (*b*) That the different points in his isoelectrical negative line are never found to be absolutely identical. From the third proposition the authors generally express their dissent. They, however, content themselves for the present with stating two general conclusions—1. That the part of the midrib which lies nearest the two central sensitive hairs is positive to every other part of the external surface of the leaf, but has usually the same potential as the petiole and other inactive parts of the plant. 2. That the external surface, so long as the leaf is in vigour, is always positive to the internal surface.

The method used in this research differs from that generally employed in previous investigations, relating to animal or plant electricity, in two important particulars:—1. In the adoption of Lippmann's electrometer[2] (which has already been used by Prof. Marey in investigations on animal electricity) as the instrument for observing the electrical changes. 2. In the substitution of a constant for a variable potential as a standard of comparison with the potential under investigation.

In comparing the potentials of two points the following arrangement was usually adopted:—The pot containing the plant[3] had been previously kept plunged in water. Three non-polarisable electrodes were used, by one of them (the "fixed electrode") the damp surface of the pot is connected with the gas-pipes of the building, the other two ("movable electrodes") are in contact with the two points under observation. By means of a switch, either of these two movable electrodes can be brought into connection with one end of the electrometer, the other end being connected with earth.

When the whole of the outer surface of a leaf is covered with a mass of kaolin, moistened with salt-solution, and brought into connection with one end of the electrometer, the other end being connected by means of the fixed electrode with the petiole or pot, the effect of exciting a sensitive hair is to produce an

---

[1] Abstract of paper on the Mechanical Effects and on the Electrical Disturbance consequent on Excitation of the leaf of *Dionæa muscipula*, by J. Burdon-Sanderson, M.D., F.R.S., Professor of Physiology in University College, and F. J. M. Page, B.Sc., F.C.S. Read before the Royal Society, December 14, 1876.

[1] Reichert's and du Bois-Reymond's Archiv, 1876.

[2] See the original paper, or Lippman, *Pogg. Ann.*, 1873, **149**, 546.

[3] Most of the observations were made at Kew in the month of August, 1876, the plants being obtained from the Royal Gardens, through the kindness of the Director.

"excursion" indicating a change of potential *in a negative direction* at the movable contact amounting to 3·5 to 5·0 *d* $\left(d = \frac{1 \text{ De La Rue element}}{100}\right)$.

If a similar plug is applied to the internal surface, so as to cover the whole of it, the result is the same, but the extent of the excursion is somewhat less. Hence it may be generally stated that during the electrical disturbance *the surface of the leaf becomes more negative*[1] *as compared with any other surface of which the potential is constant*, and that on the external surface the change is greater than on the internal. This electrical disturbance is limited to the leaf and ceases at the point dividing the petiole from the isthmus or bridge, by which it is united with the leaf; on the petiole side of this point no sign of electrical disturbance is shown by the electrometer.

For various reasons the authors determined to direct their attention to the middle third of the leaf. The following were selected as representative points of contact:—(1) a point (*il*) on the internal surface of the leaf equidistant from the three sensitive hairs; (2) a point on the external surface (*el*) exactly opposite to *il*; (3) and (4) points on the internal (*im*) and external (*em*) surfaces of the midrib, where the line joining the points *il* on either lobe cuts the midrib; (5) the petiole (*p*); and (6) the bridge or isthmus (*b*) already mentioned. The letter P denotes the potential at any point, and V the variation of the potential during the electrical disturbance.

In four leaves the potentials and variations of the external surfaces of the midrib and lobe were severally in hundredths of a De La Rue cell:—

em P as compared with *p*P ...	0	0	0	0
el P „ *p*P ...	1 6	0	0	1 6
em V	−5·0	−6·5	−4·2	−4·5
el V	−2·0	−6·5	−4·0	−4·0

The external variation is usually greater than the internal of a corresponding point, and the variation at *em* is usually greater than that at any other point; thus in six leaves—

el V =	−3·6	−4·0	−4·2	−4·0	−4·0	−4·5
il V =	−1·5	−1·7	−1·6	−1·8	−2·2	−2·2

and

im V = −3·0 −3·5
em V = −5·5

When a leaf is excited at intervals of a minute or oftener by single shocks from a du Bois-Reymond's induction coil,[2] which are of just sufficient intensity to produce a response, it invariably happens that after a time the electrical variation ceases. The variation can be reproduced either by (1) shifting the needle-points to a fresh spot, (2) by increasing the strength of the induction-current, or (3) by allowing the leaf to rest for a longer interval. With relation to electrical stimuli, it is shown that the excitability of the leaf resembles that of the terminal organs of the higher animals, in this respect, viz., that *relatively feeble stimuli*, if applied at very short intervals and repeatedly, are competent to elicit a response.

If a leaf be excited at short intervals by faradisation, the excitations (makes *and* breaks) being continued each time until an excursion is produced, the combined effects of summation and gradually increasing exhaustion can be readily observed. At first the leaf responds after eight to ten excitations, but gradually the number of excitations required to awaken the tissues to action increases, the effect being postponed for longer and longer periods, until it finally fails to occur. When a leaf is excited at regular intervals by single shocks of such intensity as to be just beyond the limit of adequacy, the effects sometimes become rhythmical.

The time which intervenes between an excitation and the beginning of the electrical disturbance varies in different leaves, and is very much affected by variations of temperature. This time the authors have called the *period of electrical delay*.

As a mean of many experiments it was found that when the fixed electrode was on the petiole and the movable electrode on *em*, the *delay* was 0·295 second. If the movable electrode was at *el* or *il*, the delay varied according to the proximity of the sensitive hair touched to the point of application of the movable electrode. Thus if the movable electrode was at *el* and a sensitive hair on the same lobe was touched, the delay was 0·237 sec.; but, if a hair on the opposite lobe was touched the delay was 0·403 sec., the disturbance having to make its way from the sensitive hair on the opposite lobe through and across the midrib and up to the electrode. It is obvious that by measuring the distance between the hair touched and the electrode we can ascertain, more or less exactly, the rate of the transmission of what may be called the "wave of negative variation" through the leaf. From many experiments, the stimulation being sometimes mechanical and sometimes electrical, it was found that the wave traversed a distance of about 8 mm. in 0·18 sec., or at a rate of about 4·4 centims. per second. When the *period of delay* at *el* was compared with that at *il*, it was found that it was shorter at *el* than *il*; *e.g.*, in some experiments (the excitation being weak faradisation and the excursions being taken from *el* and *il* alternately), the following numbers were obtained:—

Inside	0·71	0·61	0·68	0·75	0·95 sec.
Outside	0·48	0·50	0·52	0·65	0·49 „

Finally, if either *el*, *il*, *em*, or *im* be compared with the bridge *b*, it will be found that the *period of delay* at *b* will be much greater than that at any of the other points;

thus *el*	0·26	0·24	0·12	0·18 sec.
bridge (*b*)	0·87	0·65	0·85	0·83 „

In normally active leaves, in which the disturbance is first seen about a sixth of a second after mechanical stimulation, the excursion attains its maximum in about one second, and the whole disturbance is over in about two seconds after the excitation, so that the electrical disturbance is entirely over before the mechanical effect begins, and consequently occurs in a period which in muscle is called the period of latent stimulation.

All these periods are, however, very much modified by temperature, being shortened if the temperature is raised (within certain limits), and lengthened if the temperature falls.

The following is one of several tables given in the paper, illustrating the effect of temperature on the periods of delay, maximum and total duration of the electrical disturbance:—

		In leaf at ordinary temperature.	In warm chamber at 45° C.	Cooled by proximity of a block of ice.
Time in seconds after excitation.	To beginning of excursion	0·23	0·41	0·44
	To maximum „ ...	1·40	0·79	1·68
	To end „ ...	2·2	1·37	2·94

---

[1] It is interesting to note that the surface of a frog muscle, during the electrical disturbance which precedes contraction, becomes *positive*.

[2] Two steel needles encased in glass, and bound together, were used as exciting electrodes, the points of the needles being thrust through the epidermis of the leaf.

THE SPONTANEOUS GENERATION QUESTION[1]

AT the meeting of the French Academy of Sciences on January 29, M. Pasteur read the following reply to Dr. Bastian:—

Dr. Bastian, in reply to the communication which I made on January 8, along with M. Joubert, addressed to the Academy last Monday a long note, in which he still contrives, I think, to elude the main point of the debate. In our communication of January [illegible] there was one word of prime significance, *pure potash*; but, what is surprising, in the reply of three pages of Dr. Bastian there is not even allusion made to that condition of purity, which was everything.

I shall make a new attempt to recall the English *savant* to the criterion, from which he cannot escape, do what he will.

The discussion was raised by his statement, that a solution of boiled potash caused bacteria to appear in sterile urine at 50°, after it had been added to the latter in quantity sufficient for exact neutralisation. Dr. Bastian concluded that he had thus discovered the physico-chemical conditions of the spontaneous generation of certain bacteria.

This is my reply to the learned London professor of pathological anatomy:—

I defy Dr. Bastian to obtain, in presence of competent judges, the result to which I have referred, with sterile urine, on the sole condition that the solution of potash which he employs be pure, *i.e.* made with pure water and pure potash, both free from organic matter. If Dr. Bastian wishes to use a solution of impure potash, I freely authorise him to take any in the English or any other Pharmacopœia, being diluted or concentrated, on the sole condition that that solution shall be raised beforehand to 110° for twenty minutes, or to 130° for five minutes.

---

[1] Continued from p. [illegible].

This is clear enough, it seems to me, and Dr. Bastian will understand me this time.

The following reply to the above was read at the Academy on February 12:[1]—

At the *séance* of January 29, M. Pasteur, in reply to a communication which I had made at the previous *séance*, challenges me to cause sterile urine to ferment by the addition of a suitable quantity of *liquor potassæ*, "on the sole condition that this solution shall be raised beforehand to 110° for twenty minutes, or to 130° for five minutes."

In order that M. Pasteur may not attribute to me the least desire "to elude the main point of the debate," and also with the view of testifying the respect which I consider due to the opinions of so distinguished an investigator, I hastened at once to accept his challenge. During the last week I have repeated my experiments several times, and with a degree of precaution going much beyond the severity of the conditions prescribed by M. Pasteur.

I repeated them at first with liquor potassæ which had been previously raised to *110° C. for sixty minutes*, and afterwards with liquor potassæ which had been raised, in the same manner, to *110° C. for twenty hours*. The results have been altogether similar to those produced upon sterile urine by liquor potassæ, which has been raised only to 100°, when added in suitable quantity; that is to say, *in twenty-four to forty-eight hours the urine was in full fermentation and swarmed with bacteria*. The specimens of urine employed had a specific gravity ranging from 1,020–1,022, and they required about 3 per cent. of liquor potassæ for neutralisation.

If M. Pasteur has found himself unable to renounce his interpretation of my experiments on account of "la preuve manifeste," which I have cited in my last communication (p. 189 of the *Compt. Rend.*), I hope he will frankly accept the disproof of his views furnished by the experiments which I have now the honour of communicating to the Academy, and which have been made in acceptance of his own challenge. These experiments I hope in a short time to repeat before competent judges.

Verbal Reply of M. Pasteur.

I thank Dr. Bastian for having accepted the proposition which I made to him at the *séance* of the 29th of January. In consequence, I have the honour to beg the Academy to appoint a commission to report upon the fact which is under discussion between Dr. Bastian and myself.

I hope that Dr. Bastian will seek to induce the Royal Society of London, of which he is a member, to nominate a commission for the same purpose.

At the *séance* of February 19, it was announced that MM. Dumas, Milne-Edwards, and Boussingault have been appointed to constitute a commission charged to express an opinion on the fact which is under discussion between Dr. Bastian and M. Pasteur.

OUR ASTRONOMICAL COLUMN

The New Comet.—Elements of the new comet calculated by Dr. Hartwig of Strasburg from observations to February 15 are almost identical with those given in this column last week. Observations have been made at Berlin, Copenhagen, Leipsic, Lund, Paris, and Strasburg. On the 16th the comet appeared to the unaided vision a little brighter than the well-known cluster in Hercules, and in the telescope presented itself as a round nebulosity, ten minutes in diameter, with a small central nucleus: this apparent measure corresponds to a real diameter of 77,000 miles.

The following ephemeris for every second midnight, Greenwich time, may facilitate observations. The intensity of light is assumed, as usual, to be represented by the reciprocal of the product of the squares of the distances from the earth and sun: it will be remarked that on the last date, the degree of brightness is only one-sixth of that on the first date of the ephemeris:—

	Right Ascension. h. m.	North Polar Distance. ° ′	Distance from the Earth.	Intensity of Light.
March 3	3 39·5	27 12	0·613	2·06
5	3 51·1	29 56	0·683	1·59
7	3 59·5	32 11	0·754	1·25
9	4 5·8	34 4	0·826	1·00
11	4 11·0	35 38	0·898	0·81
13	4 15·2	36 59	0·970	0·67
15	4 18·9	38 8	1·042	0·56
17	4 22·2	39 9	1·114	0·47
19	4 25·1	40 1	1·185	0·39
21	4 27·8	40 47	1·256	0·34

The Variable-star T Coronæ Borealis.—In No. 2,118 of the *Astronomische Nachrichten*, Prof. Schmidt, of Athens, publishes numerous comparisons of the brightness of this star, the so-called *Nova* of 1866, with a neighbouring star which he satisfied himself is not variable, and finds that during the period 1866-1876 there have been fluctuations of brightness exhibiting a certain regularity, from which he deduces the most probable period 93·7 days. Prof. Schönfeld, at Bonn, has also noted these changes, and has determined the times of maxima at which the star varied from 7·8 m. to 9·0 m. T Coronæ therefore exhibits a similar phenomenon to that already remarked about η Argus, "Nova Ophiuchi, 1848," and the star which is almost precisely in the position of Tycho Brahe's famous object of 1572.

The Radcliffe Observations, 1874.—With the marked regularity which distinguishes the publication of the Oxford observations, the Radcliffe observer has just circulated the thirty-fourth volume of the series, containing the observations made in 1874. The usual contents of the handsome octavo so punctually presented to us by the Rev. R. Main are too well known to require any detailed account here. The heliometer has been chiefly employed, as before, in the measurement of a selected list of double-stars, a number of which were also observed for position with the meridian circle. Observations of shooting-stars in the year 1876 are included in this volume, with the view of placing them early in the hands of those who are interested in the study of meteoric astronomy.

We believe we are correct in stating that the next volume will contain observations of the solar spots, commenced at the Radcliffe Observatory in 1875, and which will therefore be a new feature in the publication.

Dun Echt Observatory Publications, Vol. I.—The difficulty of procuring Struve's great work, the "Mensuræ Micrometricæ," has suggested to Lord Lindsay the formation of a summary of the measures of double-stars contained in it in a convenient and portable form, which has been presented to the astronomical world, as the first volume of publications of the Dun Echt Observatory. The positions of the stars are brought up to 1875; in the text Struve's first epoch is given, the subsequent ones being added in foot-notes, or in the case of binaries and other stars frequently observed, in an appendix. The highest and lowest powers used in the measures, the magnitudes and colours of the components, and the page of the original work, where the measures are to be found, are included in the summary.

There can be no doubt that Lord Lindsay's volume will be welcomed by a large number of amateurs, who are interested in double-star astronomy, but to whom Struve's great work is difficult of access, to say nothing of its awkward size for frequent use, when obtained. The transcript and reduction of places from 1826 to 1875, appears to have been made with great care, as we are able to testify from a number of cases examined—*including* instances where the variation of precession has required to be taken into account. That equal care has been exercised in the correction of the press, is also apparent, and as an admirable specimen of astronomical typography, Lord Lindsay's summary of the "Mensuræ Micrometricæ" is probably unsurpassed.

---

[1] "On the Fermentation of Urine; reply to M. Pasteur." By H. Charlton Bastian.

From the absence of a publisher's name on the title-page, it is to be inferred that it has been Lord Lindsay's intention to circulate his volume privately amongst astronomers; and we know that this has been done to a most liberal extent: still there must be many persons, unknown to the author, who would gladly provide themselves with so unexpected and useful an addition to astronomical literature, and we would suggest whether it might not be desirable to place this volume, which appears to be intended as the precursor of a series, on sale to the astronomical public.

NOTES

The Italian Scientific Association, or Society of the Forty, has conferred on Sir William Thomson the prize instituted by Carlo Matteucci, for the Italian or foreigner, who, by his writings or discoveries, has contributed most to the advancement of science.

At the annual meeting of the Geological Society, the Wollaston Gold Medal was presented to Mr. Robert Mallet, F.R.S., and the proceeds of the Wollaston Donation Fund, to Mr. R. Etheridge, jun., F.G.S.; the Murchison Medal to Rev. W. B. Clarke, F.R.S., Sydney, and the proceeds of the Murchison Geological Fund to the Rev. J. F. Blake, F.G.S.; the Lyell Medal and part of the Lyell Fund, to Dr. James Hector, F.R.S., New Zealand, and the balance of the Lyell Fund to Mr. W. Pengelly, F.R.S.; the Bigsby Medal to Prof. O. C. Marsh, F.G.S., Yale College, U.S.

The total expenditure on the new building at South Kensington for the reception of the Natural History Collections now in the British Museum is stated in the new Civil Service Estimates to have been 206,472*l.* up to September 30 last. A further sum of 36,650*l.* is required to carry on the works up to the end of the present financial year. This amount has been already voted. The proposed vote for the present financial year 1877-78 is 70,000*l.*, leaving the amount of 81,878*l.* necessary to complete the building, the total estimate having been 395,000*l.* We may remark that it is not only in this country that a new Museum of Natural History is in progress. Both at Paris and at Berlin the present buildings for the National Museum are found to be too small, and large sums are to be appropriated to their reconstruction.

The new Civil Service Estimates also contain an account of the proposed expenditure on the working out of the collections brought home by H.M.S. *Challenger*, which amounts altogether to 4,000*l.* Of this 1,560*l.* is to be devoted to "salaries," 800*l.* to "piece-work," 1,200*l.* to "plates," 240*l.* to "travelling expenses," and 200*l.* to "stores." The salary of the director is to be 500*l.* per annum, that of his chief assistant 400*l.*

In the Civil Service Estimates for the present year under the head of "British Museum," it will be found that 800*l.* are asked for for acquisitions in the Department of Mineralogy, 800*l.* for Fossils, 1,200*l.* for Zoological, and 400*l.* for Botanical specimens. At the same time it may be noted that the sum of 10,000*l.* is to be devoted to the purchase of printed books, although copies of all books published in the United Kingdom are furnished gratis to the Museum.

Prof. Alfred Newton, F.R.S., has been elected to a Fellowship at Magdalene College, Cambridge.

The death is announced, at the age of seventy-six years, of Admiral Wilkes, of the U.S. Navy. Probably our readers will better recognise him under the name of Commodore Wilkes, the commander of the well-known U.S. exploring expedition of 1838-42, the results of which were of great scientific importance. Wilkes was the author of a work on the Theory of Winds. He was the same Wilkes who, by his conduct in the Mason and Slidell incident of the American civil war, nearly caused war between this country and the United States.

Poggendorff's *Annalen* will be continued under the editorship of Prof. G. Wiedemann, in Leipsic, who is already the editor of the supplement (*Beiblatter*), and Prof. Helmholtz will join him in his new task. The old staff of contributors have declared their willingness to continue the publication of their researches in the *Annalen*.

At the Royal Geographical Society on Monday, papers were read "On his recent journey to Lake Nyassa," by Mr. E. D. Young, R.N., and an "Examination of a route for wheeled vehicles between the east coast of Africa and Ugogo," by the Rev. Roger Price.

Mr. L. Heiligbrodt, of Bastrop, Texas, has been engaged since 1867 in making collections of the reptiles and insects of that district.

Prof. Kundt has been chosen Rector of Strassburg University for this year.

Prof. Schwendener, of Basel, has been called to the chair of the late Prof. Hofmeister, of Tubingen.

We learn from Helsingfors that M. Henez has returned from his travels in Russian Lapland. He has been studying the little-known language of the Lapps on the Murmansk peninsula. Besides a collection of interesting ethnological data, he has brought with him a complete translation of the Gospel of St. Matthew, which, we believe, will be published by the English Bible Society in Russian type.

We notice an interesting Russian monograph by M. Malieff—"Anthropological Sketch of the Bashkirs,"—which has appeared in Kazan. The author, who was sent to the Orenburg Government by the Kazan University, to collect skulls of Bashkirs, and spent some time among this people, gives a number of anthropological measurements of men, statistics as to births, and various interesting information on the present state of the Bashkirs, their rapid increase, their customs, religion, &c., and discusses their future prospects.

The *Golos* announces that the Moscow Society for Promoting the Development of Russian Marine Trade will continue next year the exploration to the Gulf of the Obi, and also build some vessels for exporting, in 1878, various merchandises from the Obi into Europe, especially of ship-building wood to England. M. Dahl, a teacher at the Gainag Marine School in Livonia, with some of his pupils, will be intrusted with this task.

Some difficulties have been met with in the advance of Potanin's expedition in Western Mongolia. When passing by the convent of Shara Sumson the members of the expedition were assailed by the monks, and student Posdnéeff and the interpreter received severe injuries. Nevertheless, Potanin continues to advance into the interior of the country.

The occurrence of gold disseminated in small quantities through the older geological formations of Australia has been known for many years. But Mr. C. S. Wilkinson, of the Geological Survey of New South Wales, has observed what seems to be a new fact, that gold in sufficient quantity to be worth mining, occurs in a conglomerate belonging to the Coal-measures, and that the alluvial gold of the Old Tallawang diggings has been derived from the waste of these conglomerates. He justly points out that, apart from the scientific interest belonging to so venerable an auriferous alluvium, considerable commercial importance attaches to its discovery, seeing that the conglomerates may now become a new source of supply for the precious metal. At Clough's Gully the actual conglomerate is now being worked, and yields from 1 dwt. to 15 dwts. of gold per ton, and nuggets sometimes weighing 5 ounces.

improved form, which gives a field nearly if not quite as large as that of the instrument of Nörremberg and somewhat better definition near the edges; and, by the use of a scale engraved on a glass plate, approximate measurements of the angle of the optic axes of a crystal can be obtained when the apparent angle is not too great for the optic axes, or rather the "eyes" of the axes to be seen in the field of the instrument.

The application of the principle of von Kobell's stauroscope, enhanced in its sensitiveness by the use of the ingenious doubled calcite plate of Brezina, is also valuable for ensuring precision in determining the directions of the principal sections of a crystal, and is for example far more commodious than Descloizeaux's method of dividing a plate of an oblique crystal, cut parallel to the plane of symmetry, into two, and turning them after the manner of an artificial twin.

The crystallographic portion of Prof. Groth's work is good, especially so from the point of view of the student in the German universities, where the honoured name of Naumann still holds crystallographers by the spell of a notation which has the advantage of looking very simple, while in reality it is complex and incomplete, and for purposes of calculation, and indeed for other than a very superficial crystallographic representation of crystal forms —not of crystal faces— has next to no value.

Of course, Prof. Groth is too sound and excellent a crystallographer not to feel and to acknowledge as he does in his preface, the great superiority of the method of Prof. Miller for all the purposes which give crystallography its character as a science; and accordingly he introduces his readers to the system of Miller, co-ordinating the two methods of notation in his descriptions of crystalline forms.

Indeed, when he touches on the fundamental principles of crystallography in his section on the doctrine of zones, he discards at once the notation of his illustrious countryman, and handles the subject entirely in the language and method of Miller; a language and method which in fact are the result of an elegant development of the original principle of Weiss, and were first independently employed by the famous German mathematician, Grassmann. In point of fact every crystallographer now uses the Millerian formulæ, and actually while using the notation of Naumann, prefers to translate it into the simpler symbols of Miller in order to deduce the determinants rather than employ the earlier modes of calculation.

Again, what crystallographer who has had to convert the notation of Naumann for the rhombohedral into that for the hexagonal system, but knows the complexity of the process, and must recognise the superficial character of that notation? Moreover, for a distinctive representation of hemi-symmetrical or tetarto-symmetrical forms in language or writing that carries a scientific meaning, the notation of Naumann is powerless.

But Prof. Groth is writing for a German public, and he has to write a book that will be read. It is to be hoped that his work will be widely read, so widely as that his intelligent countrymen may be prepared, when it reaches a second or at furthest a third edition, to accept the change to the Anglo-German notation and methods which Weiss, Neumann, Grassmann, Whewell, and Miller (five of the greatest names among European crystallographers), have elaborated.

There remains, however, a word to be said upon the examples selected by Prof. Groth to illustrate this part of his treatise. They are as interesting to the crystallographer as they are excellent from the point of view of illustrations; for the publication of several of them in this form serves to bring together valuable illustrations of the different kinds of merosymmetry, of which some are new, while others have to be sought for only in the memoirs in which they appeared.

It may have been the result of a practical estimate of the smallness of the number of Englishmen who would have been interested in seeing them, that prevented Herr Fuess, the optical-instrument-maker of Berlin, from sending to the Loan Exhibition a set of the instruments in the improvement of which he has been so largely guided by Prof. Groth. It was, however, a short-sighted view, for the students of this subject are increasing; the physical laboratories of Oxford and Cambridge, and some London teachers of physics, are, for instance, turning out students quite competent to handle and to appreciate such implements of research; and for all such students the instruments of Soleil and the other French makers represented in the Loan Collection naturally have the greater attraction due to proximity and to their having been for several months where they could be seen and handled by English teachers and their students.

OUR BOOK SHELF

La Digestion Végétale, Note sur le Rôle des Ferments dans la Nutrition des Plantes. Par E. Morren. (Gand, 1876.)

THIS paper is brought forward by Prof. Morren as a supplement to his observations on carnivorous plants. Its main point is the statement that digestion is not a function exclusively of those plants termed "carnivorous," but is a process common to all living beings, vegetable as well as animal. Animal digestion is, he states, according to the most approved view, a process of fermentation consisting essentially in a transformation of colloids into crystalloids, this change being a necessary preliminary to absorption. In the same manner all plants digest; and the process is precisely analogous to that of animals, and is again essential before assimilation is possible. The ordinary vegetable ferment for the conversion of starch into glucose is diastase, which has been detected in barley; it occurs also in the tubers of the potato, near the "eyes." For the fermentation or digestion of nitrogenous substances, albuminoids, a different ferment is required, and this we have in pepsine, which has been detected by several observers in the viscid secretion of *Nepenthes*, *Drosera*, and other insectivorous plants. According to Masters, it occurs also in the nectaries of *Helleborus*; and a similar substance has long been known in the latex of *Carica Papaya*. Vegetable digestion is therefore as widely diffused and as various a phenomenon as animal digestion, and consists in the transformation of the raw insoluble food material into soluble crystalloids capable of assimilation. It takes place chiefly in the "reservoirs of reserve-material"—seeds, underground stems, roots, the bark, the pith. The nutrition of plants is made up of three successive processes:—elaboration, digestion, assimilation. The first consists in the production, out of its elements, of a carbo-hydrate, and can take place only under the influence of light. Digestion consists essentially in hydration—as in the conversion of starch into glucose—and is associated with an evolution of carbonic acid. It is accompanied by a molecular change which renders the resulting product soluble and diffusible. Assimilation is simply the absorption by the living tissue of the substances thus prepared, one of the chief processes which accompanies it being the reversion, by loss of water, of the glucose to the condition of cellulose, a substance isomeric but not isomorphic with starch. Intussusception, therefore, is a process which can only succeed digestion. No essential difference can, in fact, be maintained between the manner in which animals and plants digest their food. A. W. B.

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.]

Hygroscopic Seeds

I HAVE lately received an interesting letter from Fritz Müller, in St. Catherina, Brazil, on the subject of hygroscopic seeds. He tells me that in the highlands of the Uruguay he has succeeded in discovering more than a dozen grasses, as well as a species of geranium, whose awns are capable of hygroscopic torsion. He has been so kind as to send me specimens of the grass-seeds, and many of them appear to be as beautifully adapted as those of Stipa, Avena, &c., for penetrating the ground in the manner which I have elsewhere described.[1] The most curious among the specimens received are the seeds belonging to the genus Aristida. In one of these the awn is longitudinally divided into three fine tails, six or eight inches in length, each of which twists on its own axis when the seed is dried. These tails project in three directions, and more or less at right angles to the axis of the seed, and Fritz Muller states that they serve to hold it in an upright position with its lower end resting on the ground. The seed is pointed and barbed in the usual manner, and when it is made to rotate by the twisting of the awns, it evidently forms a most effectual boring-instrument, for Fritz Muller found many seeds which had penetrated the hard soil in which the parent plant was growing. Another species of Aristida is interesting to me, because it illustrates the explanation which I gave of the torsion of the awn of Stipa, namely, that each individual cell of which the awn is composed is capable of torsion, and their combined action results in the twisting of the whole awn. Now in this species of Aristida, each of the three tails into which the awn is divided is capable of torsion on its own axis, and as the seed dries they twist up into a perfect three-stranded rope, just as the component cells combine to produce the rope-like twist of the Stipa awn. And as the tails wind together and form the strands, the seed is made to rotate and thus bury itself in the ground.

Down, Beckenham, February 19 FRANCIS DARWIN

Mind and Matter

BUT for illness I would have made an earlier reply to Mr. Duncan's courteously-expressed objections (NATURE, vol. xv., p. 295) to my analysis (NATURE, vol. xv., p. 217) of his very ingenious "solution" (NATURE, vol. xv., p. 78). A general "mistake," and an "essential omission," are the charges against me. The mistake is in "regarding what was intended to solve a problem as intended to prove an alleged fact." "The alleged fact," he adds, "that consciousness depends on nervous organisation, I assumed to be a fact, and undertook to indicate *how* the dependence might be conceived, or regarded, to exist." He says that I clearly understood this "at starting." Where now is it that I "fell into the error?" His first step towards "clearing away difficulties in the way of our *conceiving* the relation of consciousness to matter," is to allege this fact: "It is no more difficult to conceive of matter being subjective than of spirit being subjective." This is a dogmatic statement about our powers of conceiving; no hint of help as to *how* we may conceive. We ordinarily conceive of "spirit"—the "ego," the "subject"—as susceptible to consciousness, or "subjective," because we (the ego) feel we are conscious; but is it "as easy" to conceive of a stone as susceptible to consciousness, *i.e.* subjective? To say *it is*, I called a *petitio principii*, because it assumes that conceivability which has to be established. I used the word "probability" as involving conceivability; for can we intelligibly assume a probability without a conception of what that probability is? But Mr. Duncan contends that his position is "conceivable as a hypothesis, true or false." Unquestionably we may conceive some one stating any hypothesis—a stone feels, fire freezes—but to conceive one doing this is not to have a concept of any part of the operation as hypothesised, however we may attach a meaning to the terms as such. Again, if any hypothesis, true or false, is already conceivable, this fact cannot favour Mr. Duncan.

So far I have not been led "to mistake allegations of the conceivability of a notion for assumptions or intended proofs that the notion is true." To the next position, "How energy is related to matter, is no less mysterious than how subjectivity may be a property of matter," my objection was twofold: first, to the illogical form; second, to the argument itself. Mr. Duncan replies, "The parity of mystery was not intended to establish parity of probability as to facts, but merely parity of conceivability." Now what *is conceivable* in the known case? The *fact* of energy being related to matter. Next, what here is mysterious or *inconceivable?*—the *manner how* these are related. Finally, what is the parallel to establish? Mr. Duncan answers, "Not the parity of probability as to facts, but merely parity of conceivability." But the conceivability of *how* energy is related to matter equals zero, therefore, by parity of reasoning, the conceivability of how subjectivity is related to matter equals zero. I commented, therefore, on all that this argument supplied—a bare shadow of *probability*. My next objection to the position, "Energy may be divided, why not subjectivity?" is strictly categorical, and no flaw has been found in it, nor, intrinsically, in any of my objections, which have now been shown to apply to "conceivability." Of the omission, Mr. Duncan says:—"The essential part of my solution which indicated roughly the *modus* of the connection between matter and consciousness, and which dealt with the great difficulty of the question, How to account for the two aspects of matter, the conscious and the unconscious? has not been touched by Mr. Tupper." Because all this was based on the untenable ground that "subjectivity may be divided," I closed my analysis here; but will conclude with a few remarks on the ingenious and original parallels drawn by Mr. Duncan.

"As energy potential is rest, so subjectivity potential is unconsciousness. As kinetic energy is motion, so active subjectivity is consciousness." Now energy, both to the materialist and his opponent, is a hypothesis, not a phenomenon; and it is not legitimate to support one hypothesis by another.

Again, if subjectivity is defined "susceptibility to consciousness," some sub-definition of "susceptibility" is needed; for if non-innervated matter, as Mr. Duncan admits, is never conscious, then matter *in this form being non-susceptible to consciousness*, is by the definition non-subjective: a conclusion opposed to Mr. Duncan's "all matter is subjective or susceptible to consciousness," his qualification, that non-innervated matter is only "potentially subjective" not availing unless this term mean non-subjective, and leave us with the above contradiction. The expression "all forms of matter may, by innervation, be made susceptible," &c., would indeed carry the conclusion "all matter may be made subjective," but then subjectivity would be an accident, not a property of matter as defined by Mr. Duncan. Lastly, to the phenomenalist who would investigate, and not create, nature, matter, or a fancied common substance for the support of all phenomena, is perhaps the most unwarranted of all assumptions.

J. L. TUPPER

Atmospheric Currents

[illegible] CLEMENT LEY thinks (see his letter in NATURE, vol. xv p. [illegible]3) that if the earth's atmosphere contained no watery vapour, the great currents of atmospheric circulation would be quite unlike what they are. I think, on the contrary, it is as certain as the established truths of physical astronomy, that if there were no watery vapour the great currents, though not the storms and other temporary disturbances, would be nearly what they actually are.

All winds belonging to the great currents, though not local winds, form part of a system of circulation between the equatorial and the polar regions, which is caused by the difference of those regions in temperature. Equatorial air is constantly flowing towards the poles, and polar air towards the equator; the equatorial air brings the greater rotatory velocity of the equatorial sented by Mrs. Mathews; a Common Kestrel (*Tinnunculus alaudarius*), European, presented by Mr. W. W. Hughes; a Rough-legged Buzzard (*Archibuteo lagopus*), European, presented by Lady Bunbury; a Passerine Owl (*Glaucidium passerinum*), European, presented by Mr. T. W. Evans; a Burrhel Wild Sheep (*Ovis burrhel*) from India; a Suricate (*Suricata zenik*) from South Africa; two Beautiful Parrakeets (*Psephotus pulcherrimus*) from Australia, deposited; a Common Rattlesnake (*Crotalus durissus*) from North America, purchased.

Section for Anthropology, Geology, and Anatomy: On the palates of *Ptenoglossa*, by Prof. Troschel—On a luminous beetle of the *Physodora* family from Java, by Herr Moknike.—On the fertilisation of the ova of *Araneida*, by Herr Bertkau.—On a stone sarcophagus found near Sechtem (on the Cologne-Bonn railway), containing well-preserved red hair of reddish tint, by Prof. Schaaffhausen.—On the various views of different naturalists on the reproduction of eels, by Prof. Troschel.—On the so-called *Cribellum* of L. Koch, by Herr Bertkau.—On some rare and remarkable *Arachnida* of the Rhenish fauna, by the same.—On stone implements and other objects found in the Klusenstein and Martin's Caves, by Prof. Schaaffhausen. Section for Chemistry, Technology, Physics, and Astronomy: On the separation of ethyl-bases by means of oxalic ether, by Prof. Wallach.—On converting amides into bromides, by V. von Richter.—On indium, by the same.—On some experiments with hydrobenzoines, by Herr Zincke.—On an apparatus for measuring very small fractions of time, by Herr Gieseler.—On a new electro-dynamical law, by Prof. Clausius. Physiological Section: On the functions of the spinal cord, by Dr Frensberg—On the structure of the tissues of blood-vessels and the inflammation of veins, by Herr Koster.—On santonine poisoning, by Herr Binz.—On the influence of salicylic acid upon the bones, by Herr Koster. The remaining papers are of purely medical interest.

Reale Istituto Lombardo di Scienze e Lettere. Rendiconti, December 28, 1876.—On some differential equations with algebraic integral, by M Brioschi.—On the electric theory of the radiometer, by M. Ferrini.—On the anti-fermentative action of boric acid, and its application in therapeutics, by M. Polli.—On the *sclerotium oryzæ*, a new vegetable parasite which has devastated many rice-fields of Lombardy and the Novarese during the past year, by M Cattaneo—Mildella, a new genus, type of new tribes of Polypodiaceæ—Graeco-Indian studies, by M. Cantor. Relating to geometry, algebra, astronomy; &c.

Morphologisches Jahrbuch, vol. ii. part 3—On the structure of the skin and dermal sense-organs of Urodela (Proteus, Menopoma, Cryptobranchus, Salamandra, Triton, Salamandrina), by F. Leydig, four plates.—On the metamorphosis of Echiurus, by W. Salensky, four stages figured.—On the exoskeleton of fishes, by O. Hertwig. Part 1, sixty-eight pages, six plates, relating to Siluroids and Accipenseroids. The placoid scales of Selachians, the dermal teeth of Siluroids, and the dermal scutes of Accipenseroids are shown to be homologous.—Contribution to the morphology of the limbs of vertebrates, by Prof. Gegenbaur.—The most ancient form of the carpus and tarsus of Amphibia, by R. Wiedersheim.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, February 8.—"On the Transport of Solid and Liquid Particles in Sewer Gases." By E. Frankland, F.R.S.

The suspension of vast aggregate quantities of solid and liquid particles in our atmosphere is the subject of daily remark. Cloud, fog, and smoke consist of such particles, and I have repeatedly seen at a distance of a few feet abundance of snow-crystals floating in the air, when the atmosphere was apparently perfectly clear and cloudless by placing the eye in shadow and then looking into the sunshine.

Prof. Tyndall has, I conceive, proved that a very large proportion of the suspended particles in the London atmosphere consists of water and other volatile liquid or solid matter by showing that the heat of boiling water is sufficient to dissipate them. That this is the true explanation of the disappearance of such particles by the application of a moderate degree of heat, and that it is not caused by the rarefied air from the heated body ascending and leaving behind the suspended matter, as suggested by Tyndall is, I think, conclusively proved by experiments in which

I found that suspended particles of sal ammoniac subsided in an atmosphere of hydrogen scarcely twice as fast as in atmospheric air.

Thus an atmosphere fourteen times as rare as that of London (and, as Prof. Stokes remarked, possessing only half the viscosity of air), still offers sufficient resistance to the subsidence of minute suspended particles to prevent them from falling more rapidly than one inch per minute. Such particles could not therefore be left behind by an ascending current of the slightly rarefied but more viscous air produced by an increase of temperature to 100° C.

In addition to these aqueous and other volatile particles which disappear by a gentle heat, there are also others which consist partly of organic and partly of mineral matters. But the organic seem greatly to preponderate in the air of towns, because such air becomes *apparently* perfectly clear after it has been ignited.

The processes of fermentation, putrefaction, and decay afford abundant evidence that zymotic and other living germs are present amongst the organic portion of the suspended matters, whilst many analyses of rain-water, made by myself and others, show that the salts of sea-water are amongst the mineral constituents floating in the atmosphere.

Of the zymotic matters, those which produce disease in man are obviously of the greatest importance. The outbreak of Asiatic cholera in Southampton in the year 1866, for instance, was traced by the late Prof. Parkes, F.R.S., to the dispersion of infected sewage through the air. The sewage became infected by the intestinal discharges from some cholera patients who landed from the Peninsular and Oriental Company's steamship *Poonah*.

In this case the dispersion was produced by the pumping of the infected sewage and its discharge, in a frothy condition, down an open channel eight or nine feet long. The effluvium disengaged from this seething stream was described as overpowering, and was bitterly complained of by the inhabitants of the adjacent clean and airy houses, amongst whom a virulent epidemic of Asiatic cholera broke out a few days after the sewage received the infected dejections. Nevertheless the discharge of the frothy liquid was kept up day and night for about a fortnight, and 107 persons perished. At length a closed iron pipe was substituted for the open conduit; from that day the number of cholera cases diminished, and within a week of the protection of the conduit the epidemic was virtually over.

In this example a potent cause of the suspension of the zymotic poison in the air was obvious, but in the many alleged instances of the propagation of typhoid fever by sewer gases, the condition of dispersion is not so evident. Does the flow of sewage in a properly constructed sewer produce sufficient agitation to disperse liquid particles through the air-space of the sewer? I endeavoured to answer this question by violently agitating a solution of lithic chloride in a glass cylinder three inches in diameter and thirty inches high, with a wooden rod, and ascertaining whether the atmosphere at the mouth of the cylinder became impregnated with the liquid, by testing it with the flame of a Bunsen burner; but no trace of lithium could be detected at the mouth of the jar, even after an agitation much in excess of what would ordinarily occur in a sewer.

There is, however, another kind of agitation to which sewage is subject that may produce a very different result—I allude to the development of gases during the processes of fermentation and putrefaction. It is well known that the bursting of minute bubbles of gas at the surface of an effervescing liquid causes the projection of visible liquid particles into the air to the height of several inches. Such visible particles are seen to fall back again immediately into the liquid; but it appeared to me not unlikely that other particles, too minute to be seen, might be simultaneously projected, and by reason of the smallness of their masses in relation to their sectional areas, might continue suspended in the air for a long time. To ascertain the fallacy or truth of this notion I made the following experiment:—

A quantity of a strong solution of lithic chloride was placed in a shallow basin and acidulated with hydrochloric acid; fragments of white marble were then added, and a paper tube five inches in diameter and five feet high was placed vertically above the basin. So long as the effervescence continued, abundance of particles of lithium were visible in a Bunsen flame held at the upper end of the tube. A tinplate tube three inches in diameter and twelve feet long was now placed in such a position as to bring one of its open ends over the top of the paper tube. The tin tube was nearly horizontal but slightly inclined upwards from the paper tube, so as to cause a gentle draught of air to pass through it, when it was slightly heated externally near its lower extremity. A Bunsen flame placed at the end of this tube furthest away from the effervescing liquid, showed that the suspended particles of solution of lithic chloride were not perceptibly less numerous than at the mouth of the paper tube; neither were they much diminished at the further end of the tin tube when the height of the paper tube was increased to nine and a half feet. There can, I think, be little doubt that these particles, which had thus been carried along by a gentle current of air for a distance of twenty-one feet, would be similarly conveyed to very much greater distances.

The following conclusions as to the behaviour of flowing sewage may be drawn from these experiments:—

1. The moderate agitation of a liquid does not cause the suspension of liquid particles capable of transport by the circumambient air, and therefore the flow of fresh sewage through a properly constructed sewer is not likely to be attended by the suspension of zymotic matters in the air of the sewer.

2 The breaking of minute gas-bubbles on the surface of a liquid consequent upon the generation of gas within the body of the liquid is a potent cause of the suspension of transportable liquid particles in the surrounding air, and therefore when, through the stagnation of sewage or constructive defects which allow of the retention of excrementitious matters for several days in the sewer, putrefaction sets in and causes the generation of gases, the suspension of zymotic matters in the air of the sewer is extremely likely to occur.

3. It is therefore of the greatest importance to the health of towns, villages, and even isolated houses, that foul liquids should pass freely and quickly through sewers and drain-pipes, so as to secure their discharge from the sewerage system before putrefaction sets in.

Linnean Society, February 1.—Mr. G. Bentham, F.R.S., vice-president, in the chair.—Messrs. G. Boulger, Alfred S. Heath, and William Meller, were elected Fellows of the Society.—Mr. A. W. Bennett exhibited, and made remarks on, certain specimens of insects illustrating mimicry; these had been captured in Syria by Mr. N. Godman.—An unusual form of double anemone, and some excessively large oak-leaves gathered near Croydon, were shown by Mr. S. Stevens, and they evoked discussion from the Chairman and other Fellows present.—Sir John Lubbock then proceeded with Part 4 of his contributions on the habits of ants, bees, and wasps. In this communication he illustrated by ingenious experiments his *modus operandi* of testing their faculties, dispositions, habits, &c., by something of a double F apparatus (Fi), whereby an interval of three-tenths of an inch, either by a drop from above or reaching upwards the distance from below, alone prevented ants from gaining access to a covered glass cell filled with larvæ. They evidently had not the acumen to surmount the three-tenths of open space, although they had for hours before been traversing the route and carrying off larvæ previous to the small gap being made. Industry was conspicuously shown by one specimen, which Sir John used to place in solitary confinement in a bottle for hours, and once for days, but the moment released it commenced its laborious larvæ-gathering propensities. It seems, from other experiments, that ants in difficulties within sight of their companions are by no means always assisted or relieved, other attractions, food and such like, possessing greater interest for them. On putting some specimens under the influence of chloroform, little or no notice was taken of those insensible by their companions, the tendency apparently being to let friends lie and throw over the edge of the board strangers thus chloroformed. It seems that to get ants properly intoxicated with spirit for experimental purposes is no easy matter, some recovering too quickly, and others remaining so thoroughly dead drunk as to come under the rank of impracticables; while between reeling friends and strangers the experimenter finds himself baffled. The sober ants are exceedingly puzzled at finding their friends in such a condition. As a general rule they picked up drunken friends and carried them to the nest, whilst they threw into the water and drowned strangers. In some instances confusion arose, for a few of the strangers were carried to the nest and friends tumbled into the water, but they did not return to the rescue of the friends, though strangers were afterwards expelled from the nest. Sir John expresses surprise that ants of one nest perfectly well know each other. Even after a year's separation old companions are recognised and amicably received, whereas strangers, particularly among the *Lasius flavus*, are almost invariably attacked and maltreated, even when introduced in the mixed company of old friends. Sight cannot be acute; for example, in experiments food was placed on a glass slip a few inches from the nest, the straight road to and from the nest being soon familiar to the ants; but when the food had been shifted only a short distance from its first position it was long ere it was discovered. Indeed they wandered from a few minutes to half an hour in the most extraordinary circuitous routes before finding out the direct road between the nest and food, and *vice versâ*. Slavery in certain genera is a positive institution, the Amazon ants (*Polyergus rufescens*) absolutely requiring slave assistants to clean, to dress, and to feed them, else they will rather die than help themselves, though food be close at hand. A curious blind woodlouse (*Platyarthrus hoffmansegii*) is allowed house room by the ants, it acts as a kind of scavenger, the ants taking little notice of the woodlice, and even migrate leaving them behind. Some new species of Diptera of the family Phoridæ he finds to be parasitic on our house ants; and Mr. Verrall has recently described these interesting forms.—A paper on the aspects of the vegetation of Rodriguez was read by Mr. I. Bailey Balfour, who accompanied as botanist the Transit of Venus Expedition in 1874. It seems that, like the flora of St. Helena, that of Rodriguez has undergone great changes, partly by human and other agencies. It is insular, dry, and temperate rather than humid, and tropical in character. The facies is predominantly Asiatic, though forms of Mascarene type, and even Polynesian and American forms, are sparsely met with. The leaves of many plants Mr. Balfour observed exhibited heteromorphism of a marked kind, and this he described with some fulness, remarking that while as a whole in degree and kind variable, yet among species the leaf variation is pretty uniform.—The fungi of the *Challenger* Expedition (third notice), by the Rev. M. J. Berkeley, and on Steere's collection of tropical ferns, by Prof. Harrington, U.S., were papers announced and taken as read.

Zoological Society, February 20.—Prof. Flower, F.R.S., vice-president, in the chair.—Mr. Osbert Salvin, F.R.S., exhibited a series of drawings taken during Hunter's voyage to Australia in 1788–92, wherein Duke of York Island as it then existed was depicted, together with various objects of natural history.—A communication was read from Prof. Owen, C.B., containing an account of some additional evidence recently obtained of the former existence of extinct birds allied to the genus *Dromornis* in Australia.—Mr. Sclater read a paper on the birds collected by the Rev. George Brown on Duke of York Island and on the adjoining parts of New Ireland and New Britain. Eleven species were described as new to science, amongst which were a new Kingfisher proposed to be called *Tanysiptera nigriceps*, and a new Pigeon to which the name of *Macropygia browni* was assigned.—Dr. G. E. Dobson read a paper on a collection of Bats collected by the Rev. George Brown in Duke of York Island and the adjacent parts of New Ireland and New Britain. Amongst these four were considered to belong to undescribed species, and one of these to a new genus of the Frugivorous Bats, proposed to be called *Melonycteris*.—Mr. Edward R. Alston read a paper on the Rodents and Marsupials collected by the Rev. G. Brown in Duke of York Island, New Britain, and New Ireland. The species, six in number, were either identical with New Guinea forms or nearly allied. For the three new species the names of *Mus browni*, *Uromys rufescens*, and *Macropus lugens* were proposed.—Messrs. O. Salvin and F. Du Cane Godman read the descriptions of a collection of Lepidoptera made by the Rev. George Brown on Duke of York Island and its neighbourhood. The series of Butterflies contained twenty-six genera and forty species, while in that of the Moths eleven genera were represented by fourteen species.—Mr. E. J. Miers read a description of the Crustacea collected by the Rev. G. Brown on Duke of York Island. The collection, with one exception (*Lysiosquilla armaria*), belonged to the Decapoda, and contained in all forty-four specimens representing sixteen species. Although none of the species were new to science, several were interesting and little-known forms.—Dr. A. Günther, F.R.S., read a paper on a collection of Reptiles and Fishes made by the Rev. George Brown on Duke of York Island, New Ireland, and New Britain. Of nine lizards represented in the collection one was described as new, and of eleven snakes three were considered to be hitherto unknown. Amongst the latter was a new genus and species of Erycidæ, proposed to be called *Erebophis asper*.—Mr. H. W. Bates read a paper on the Coleoptera collected by Mr. George Brown on Duke of York Island, New Ireland, and New Britain. The collection comprised forty-four species, and contained some of the finest species of the New Guinea Fauna. Amongst these were many examples of a new Longicorn, proposed to be called *Batocera browni*, after its discoverer.

Geological Society, February 7.—Prof. P. Martin Duncan, F.R.S., president, in the chair.—James Durham, Herbert William Harrison, William Hutchinson, H. M. Klaassen, Graeme Ogilvie, Joseph William Spencer, and Griffin W. Vyse were elected Fellows of the Society.—The following communications were read:—On the chemical and mineralogical changes which have taken place in certain eruptive rocks of North Wales, by John Arthur Phillips, F.G.S. In this paper the author described the felspathic rock of Penmaenmawr, which has been erupted through Silurian strata, and rises to a height of 1,553 feet above the level of the sea. The rock, which is composed of crystalline felspar with minute crystals of some hornblendic mineral, is fine-grained and greenish grey, divided into beds by joints dipping north at an angle of about 45°, and again divided by double jointings, sometimes so developed as to render the rock distinctly columnar. At the eastern end of the mountain the stone is so close in texture as often almost to resemble chert. In the next two quarries westward the rock is coarser, and its jointing less regular. In the most westerly quarry the stone is generally fresher in appearance, closer in grain, and greener in colour. All these stones are probably modifications of the same original rock. From the chemical analysis of the rocks the author concludes that, supposing them all to have had originally the same composition as the unaltered rock in the most westerly quarry, that at the extreme east of the mountain has lost about 3 per cent of silica, and the others have received respectively an increase of 1·35 and 0·77 per cent. of silica.—On a new species of *Belemnites* and *Salenia* from the Middle Tertiaries of South Australia," by Ralph Tate, F.G.S., Professor of Natural Science in the University of Adelaide. The author noticed the occurrence in deposits of supposed Miocene age in South Australia of a species of Belemnite (*Belemnites senescens*) and a *Salenia* (*S. tertiaria*). These fossils were obtained from Aldenga, twenty-six miles south of Adelaide, on the east coast of St. Vincent's Gulf, where the long series of sea-cliffs contains an assemblage of fossils identical with that of the Murray River beds. The *Salenia* is especially interesting on account of the discovery of a living species of the genus by the naturalists of the *Challenger*.—On *Mauisaurus gardneri* (Seeley), an Elasmosaurian from the base of the gault at Folkstone, by Harry Govier Seeley, F.L.S., F.G.S., *Professor* of Geography at King's College, London. The author described the skeleton of a great long-necked Saurian obtained by Mr. J. S. Gardner from the Gault of the cliff at Folkestone. The remains obtained included a tooth, a long series of vertebræ, some ribs, bones of the pectoral arch, the femur, and some phalanges, indicating a very large species, which the author referred, with some doubt, to the genus *Mauisaurus* of Dr. Hector, founded upon a Saurian from the Cretaceous formation of New Zealand. He gave it the name of *Mauisaurus gardneri* in honour of its discoverer. A small heap of pebbles was found in the neighbourhood of the ribs, and it was supposed that these had been contained in the stomach of the animal.

Anthropological Institute, February 13.—Mr. John Evans, F.R.S., president, in the chair.—Miss Buckland read a paper on primitive agriculture, in which the value of the study of the subject was explained, as determining migrations, &c., of nations in pre-historic times. It was observed that agriculture could only have been practised by peoples having settled habitats, and was probably carried on then, as often is the case now, by women; that agriculture was and is still unknown, to some of the lower races who confine themselves to the cultivation of indigenous roots and fruits, whilst the higher races cultivated the cereals. The origin of the cereals is still obscure, and maize, which has been considered indigenous to the New World, and unknown in Europe before the time of Columbus, was, in the opinion of Miss Buckland (based on the reports of recent travellers in Africa, Madagascar, New Guinea, China, &c.), cultivated by peoples which have never had intercourse with Europeans. In America, China, and Ancient Egypt there are traces of a time anterior to that of the cultivation of the cereals; and a similarity of myths, customs, &c., of China, Egypt, Peru, and Mexico leads to the conclusion that an allied pre-Aryan race introduced cereals into all these countries. In the discussion, Mr. Boyd Dawkins, the president, and others took part.—Mr. H. Hyde Clarke exhibited some weapons from the Amazon River, on which Mr. Franks and others remarked.—Lord Rosehill exhibited a collection of very fine and large flint weapons, objects, &c., from Honduras.

The president, Mr. Blackmore, Mr. Franks, and others spoke on the subject.

Society of Telegraph Engineers, February 5.—Prof. Abel, F.R.S., in the chair.—The paper read was on shunts and their applications to electrometric and telegraphic purposes, by Mr. W. H. Preece. Having briefly explained the laws of shunts, Mr. Preece referred to the use of shunts for measuring purposes as well as to their early employment in practical telegraphy. The author entered minutely into the question of electro-magnetic induction, and gave the results of the experimental investigations on the "extra" current upon which he has been recently engaged. The "extra" current which is received from a simple coil of insulated copper wire being selected as the *unit*, it was shown that by the insertion of a core as well as by varying the quantity of iron in the armature, the strength of the "extra" current might be increased no less than 2,238 times. The means which should be adopted in order to counteract the prejudicial effects of the extra currents upon the speed of working were then described at length, and the employment of electro-magnetic shunts in order to compensate for the *static* induction which proves so troublesome on long lines was also fully gone into.

Medical Microscopical Society, January 19.—Annual General Meeting.—Dr. J. F. Payne, president, in the chair.—The secretary's report for the year 1876 was read.—Twelve papers on important subjects were read during the year, of which four were illustrative of new forms of instruments applicable to medical histology.—The number of members in December, 1876, was 129.—The retiring President (Dr. Payne) then delivered his address, in the course of which he remarked that the Society was passing through a crisis, having outgrown its developmental stage, and that its sphere of usefulness was to be found rather among medical practitioners than among students, for whom it was first intended. After pointing out the special function of the Society to be the study of histology in its relation to medical practice and public health, the speaker passed in review the work done during the past year by the members of the Society.

Victoria (Philosophical) Institute, February 19.—Dr. C. Brooke, F.R.S., in the chair.—Mr. Morshead read a paper on comparative psychology.

BOSTON

Natural History Society.—Mr. Hyatt's important contribution on the life-history of the groups of Ammonites (*Proceedings*, December, 1876) develops and applies in detail to the Stephanoceras group (of which *A. humphresianus* is an important member), his doctrines as to the period in life at which specific peculiarities appear. He endeavours to prove that the species of a group inherit the characteristics of their ancestors at earlier and earlier periods, until they become present even in the very young forms. He further brings forward evidence of the inheritance of old-age or senile characters which forebode the extinction of the group. Thus the successive species of almost all large groups sooner or later inherit the senile features of their ancestors, so as to reproduce them at early stages. Further, there is a broad similarity between the senile characters in different groups.

PARIS

Academy of Sciences, February 19.—M. Peligot in the chair.—The following papers were read:—Meridian observations of small planets, at the Greenwich and Paris Observatories, during the fourth trimestre of 1876; communicated by M. Le Verrier.—The human species, by M. de Quatrefages. An outline of the views published in his new work on the subject.—Remarks of M. Chevreul on a recent note of M. Radziszewski relative to phosphorescence of organic bodies.—Properties common to canals, to conduit pipes, and to rivers with uniform flow (continued), by M. Boileau.—MM. Dumas, Milne-Edwards and Boussingault were appointed a Commission to give an opinion on the matter of discussion between Dr. Bastian and M. Pasteur.—On the air-jet in water, by M. de Romilly. When a steady jet is sent normally against the surface, and the tube gradually withdrawn, there is found a distance at which a smooth pocket, deeper than broad, is made at the surface, showing often a slow rotation, and giving a sound, which is strengthened if the same note be played on the violin. When a jet is sent upwards from an orifice near the bottom of a vessel of water, a spherical air-chamber forms about and under the orifice, becoming the base of an ascending air-column, which base is more than triple the diameter of the orifice. The column suddenly contracts near the orifice, then gradually widens. The author describes some other effects.—On Kepler's problem, by M. de Gasparis.—On orthogonal systems comprising a family of surfaces of the second degree, by M. Darboux.—Memoir on the methods employed for determination of the curves of astronomical objectives, accompanied with tables for abridging the calculation, by M. Martin.—On a means of varying the focussing of a microscope without touching either the instrument, or the object, and without altering the direction of the line of vision, by M. Govi. This is based on the fact that the interposition between objective and object of a medium more refringent than air, with plane parallel sides at right-angles to the axis of the microscope, will cause an apparent elevation of the object represented by $d = e\,\frac{n-1}{n}$, where d is the elevation produced, e the thickness of the medium, and n its index of refraction relatively to air or vacuum. He uses a vessel of liquid with glass bottom and varies the height of the surface either with a plunger or a communicating vessel.—New process of photomicrography, by M. Fayel. The upper end of the microscope catches in a wooden frame on colonnettes, the aperture of this corresponding with that of a dark chamber which can be placed or removed at will. In this chamber is a moveable plano-convex lens, and through it an image equal to that seen by the eye is thrown on sensitised glass.—On the microscope and the dark chamber, by M. Neyreneuf. This gives some theoretical results from examination of Dr. Fayel's method.—On the manufacture of carbon conductors for the electric lamp, by M. Carré. He reminded the Academy of his own experiments. Moistening carbon powder with syrups of gum, gelatine, &c., or fixed oils thickened with resins, he gets plastic and consistent pastes very suitable for making carbon points of. Even without other admixture, they give more light than the ordinary carbons, in the proportion of 1·25 to 1.—Study and determination of the principal colouring matters used to falsify wines, by M. Chanal.—On the action of alkaline sulphocyanates on chlorhydrates of alkalies of the fatty series, by M. De Clermont.—Action of electrolytic oxygen on glycol, by M. Renard.—On the discharge of the torpedo, studied with Lippmann's electrometer, by M. Marey. If the discharge of a torpedo, much weakened, be directed into the electrometer, the mercury moves in the positive direction, in a jerky way, progressing always more than it goes back. This shows a striking analogy to the phenomena of muscular contraction.—On the localisation of copper in the system, after ingestion of a salt of this metal, by M. Rabuteau. It would be rash to affirm poisoning with a salt of copper, because eight or even twelve centigrammes of the metal might be found in the liver. Salts of copper are less poisonous than hitherto supposed.—On the first development of a star-fish, by M. Fol.—On the hair of vine shoots, applied to manufacture of paper, by M. Boutin.—On the reconcilement of moral liberty with scientific determinism, by M. Boussinesq.

SCIENTIFIC WORTHIES

X.—HERMANN LUDWIG FERDINAND HELMHOLTZ

THE contributions made by Helmholtz to mathematics, physics, physiology, psychology, and æsthetics, are well known to all cultivators of these various subjects. Most of those who have risen to eminence in any one of these sciences have done so by devoting their whole attention to that science exclusively, so that it is only rarely that the cultivators of different branches can be of service to each other by contributing to one science the skill they have acquired by the study of another.

Hence the ordinary growth of human knowledge is by accumulation round a number of distinct centres. The time, however, must sooner or later arrive when two or more departments of knowledge can no longer remain independent of each other, but must be fused into a consistent whole. But though men of science may be profoundly convinced of the necessity of such a fusion, the operation itself is a most arduous one. For though the phenomena of nature are all consistent with each other, we have to deal not only with these, but with the hypotheses which have been invented to systematise them; and it by no means follows that because one set of observers have laboured with all sincerity to reduce to order one group of phenomena, the hypotheses which they have formed will be consistent with those by which a second set of observers have explained a different set of phenomena. Each science may appear tolerably consistent within itself, but before they can be combined into one, each must be stripped of the daubing of untempered mortar by which its parts have been prematurely made to cohere.

Hence the operation of fusing two sciences into one generally involves much criticism of established methods, and the explosion of many pieces of fancied knowledge which may have been long held in scientific reputation.

Most of those physical sciences which deal with things without life have either undergone this fusion or are in a fair state of preparation for it, and the form which each finally assumes is that of a branch of dynamics.

Many cultivators of the biological sciences have been impressed with the conviction that for an adequate study of their subject a thorough knowledge of dynamical science is essential. But the manner in which some of them have cut and pared at the facts in order to bring the phenomena within the range of their dynamics, has tended to throw discredit on all attempts to apply dynamical methods to biology.

We purpose to make a few remarks on a portion of the scientific work of Helmholtz, who is himself the most illustrious example not merely of extensive acquaintance with science combined with thoroughness, but of a thoroughness which of itself demands the mastery of many sciences, and in so doing makes its mark on each.

Hermann Ludwig Ferdinand Helmholtz was born August 31, 1821, at Potsdam, where his father, Ferdinand Helmholtz, was Professor of the Gymnasium. His mother, Caroline Penn, was of an emigrated English family. His father's means would not admit of his studying science otherwise than as a medical student. He therefore became a military surgeon, and continued in that position till the end of 1848, when he was appointed Assistant of the Anatomical Museum of Berlin, and Teacher of Anatomy at the Academy of Arts. In the following year he went to Konigsberg, in Prussia, as Professor of Physiology. In 1856 he became Professor of Anatomy and Physiology at the University of Bonn; in 1859, Professor of Physiology at the University of Heidelberg; and, in 1871, Professor of Natural Philosophy to the University of Berlin.

It was during his career as a military surgeon that he published his celebrated essay on "The Conservation of Energy."

The science of dynamics has been so long established, that it is hardly conceivable that any addition to its fundamental principles should yet remain to be made. But in the application of pure dynamics to actual bodies a great deal remains to be done. The great work for the men of science of the present age is to extend our knowledge of the motion of matter from those instances in which we can see and measure the motion to those in which our senses are unable to trace it. For this purpose we must avail ourselves of such principles of dynamics as are applicable to cases in which the precise nature of the motion cannot be directly observed, and we must also discover methods of observation by which effects which indicate the nature of the unseen motion may be measured. It is unnecessary here to refer to the labours of the different men of science who, each in his own way, have contributed by experiment, calculation, or speculation, to the establishment of the principle of the conservation of energy; but there can be no doubt that a very great impulse was communicated to this research by the publication in 1847, of Helmholtz's essay "Ueber die Erhaltung der Kraft," which we must now (and correctly, as a matter of science) translate *Conservation of Energy*, though in the translation which appeared in Taylor's "Scientific Memoirs," the word *Kraft* was translated *Force* in accordance with the ordinary literary usage of that time.

In this essay Helmholtz showed that if the forces acting between material bodies were equivalent to attractions or repulsions between the particles of these bodies, the intensity of which depends only on the distance, then the configuration and motion of any material system would be subject to a certain equation, which, when expressed in words, is the principle of the conservation of energy.

Whether this equation applies to actual material systems is a matter which experiment alone can decide; but the search for what was called the perpetual motion has been carried on for so long, and always in vain, that we may now appeal to the united experience of a large number of most ingenious men, any one of whom, if he had once discovered a violation of the principle, would have turned it to most profitable account.

Besides this, if the principle were in any degree incorrect, the ordinary processes of nature, carried on as they are incessantly and in all possible combinations, would be certain now and then to produce observable and even startling phenomena, arising from the accumulated effects of any slight divergence from the principle of conservation.

But the scientific importance of the principle of the conservation of energy does not depend merely on its accuracy as a statement of fact, nor even on the remarkable conclusions which may be deduced from it, but on the fertility of the methods founded on this principle.

Whether our work is to form a science by the colligation of known facts, or to seek for an explanation of obscure phenomena by devising a course of experiments, the principle of the conservation of energy is our unfailing guide. It gives us a scheme by which we may arrange the facts of any physical science as instances of the transformation of energy from one form to another. It also indicates that in the study of any new phenomenon our first inquiry must be, How can this phenomenon be explained as a transformation of energy? What is the original form of the energy? What is its final form? and What are the conditions of the transformation?

To appreciate the full scientific value of Helmholtz's little essay on this subject, we should have to ask those to whom we owe the greatest discoveries in thermodynamics and other branches of modern physics, how many times they have read it over, and how often during their researches they felt the weighty statements of Helmholtz acting on their minds like an irresistible driving-power.

We come next to his researches on the eye and on vision, as they are given in his book on Physiological Optics. Every modern oculist will admit that the ophthalmoscope, the original form of which was invented by Helmholtz, has substituted observation for conjecture in the diagnosis of diseases of the inner parts of the eye, and has enabled operations on the eye to be made with greater certainty.

But though the ophthalmoscope is an indispensable aid to the oculist, a knowledge of optical principles is of still greater importance. Whatever optical information he had was formerly obtained from text-books, the only practical object of which seemed to be to explain the construction of telescopes. They were full of very inelegant mathematics, and most of the results were quite inapplicable to the eye.

The importance to the physiologist and the physician of a thorough knowledge of physical principles has often been insisted on, but unless the physical principles are presented in a form which can be directly applied to the complex structures of the living body, they are of very little use to him; but Helmholtz, Donders, and Listing, by the application to the eye of Gauss's theory of the cardinal points of an instrument, have made it possible to acquire a competent knowledge of the optical effects of the eye by a few direct observations.

But perhaps the most important service conferred on science by this great work consists in the way in which the study of the eye and vision is made to illustrate the conditions of sensation and of voluntary motion. In no department of research is the combined and concentrated light of all the sciences more necessary than in the investigation of sensation. The purely subjective school of psychologists used to assert that for the analysis of sensation no apparatus was required except what every man carries within himself, for, since a sensation can exist nowhere except in our own consciousness, the only possible method for the study of sensations must be an unbiased contemplation of our own frame of mind. Others might study the conditions under which an impulse i propagated along a nerve, and might suppose that whil doing so they were studying sensations, but though such a procedure leaves out of account the very essence of the phenomenon, and treats a fact of consciousness as if i were an electric current, the methods which it has suggested have been more fertile in results than the method of self-contemplation has ever been.

But the best results are obtained when we employ all the resources of physical science so as to vary the nature and intensity of the external stimulus, and then consult consciousness as to the variation of the resulting sensation. It was by this method that Johannes Müller established the great principle that the difference in the sensations due to different senses does not depend upon the actions which excite them, but upon the various nervous arrangements which receive them. Hence the sensation due to a particular nerve may vary in intensity, but not in quality, and therefore the analysis of the infinitely various states of sensation of which we are conscious must consist in ascertaining the number and nature of those simple sensations which, by entering into consciousness each in its own degree, constitute the actual state of feeling at any instant.

If, after this analysis of sensation itself, we should find by anatomy an apparatus of nerves arranged in natural groups corresponding in number to the elements of sensation, this would be a strong confirmation of the correctness of our analysis, and if we could devise the means of stimulating or deadening each particular nerve in our own bodies, we might even make the investigation physiologically complete.

The two great works of Helmholtz on "Physiological Optics" and on the "Sensations of Tone," form a splendid example of this method of analysis applied to the two kinds of sensation which furnish the largest proportion of the raw materials for thought.

In the first of these works the colour-sensation is investigated and shown to depend upon three variables or elementary sensations. Another investigation, in which exceedingly refined methods are employed, is that of the motions of the eyes. Each eye has six muscles by the combined action of which its angular position may be varied in each of its three components, namely, in altitude and azimuth as regards the optic axis, and rotation about that axis. There is no material connection between these muscles or their nerves which would cause the motion of one to be accompanied by the motion of any other, so that the three motions of one eye are mechanically independent of the three motions of the other eye. Yet it is well known that the motions of the axis of one eye are always accompanied by corresponding motions of the other. This takes place even when we cover one eye with the fingers. We feel the cornea of the shut eye rolling under our fingers as we roll the open eye up or down, or to left or right; and indeed we are quite unable to move one eye without a corresponding motion of the other.

Now though the upward and downward motions are effected by corresponding muscles for both eyes, the motions to right and left are not so, being produced by the inner muscle of one eye along with the outer muscle of the other, and yet the combined motion is so regular that we can move our eyes quite freely while [illegible] during the whole motion the condition that the optic axes shall intersect at some point of the object whose motions we are following. Besides this, the motion of each eye about its optic axis is found to be connected in a remarkable way with the motion of the axis itself.

The mode in which Helmholtz discusses these phenomena, and illustrates the conditions of our command over the motions of our bodies, is well worth the attention of those who are conscious of no limitation of their power of moving in a given manner any organ which is capable of that kind of motion.

In his other great work on the "Sensation of Tone as a Physiological Basis for the Theory of Music," he illustrates the conditions under which our senses are trained in a yet clearer manner. We quote from Mr. Ellis's translation, p. 95 :—

> "Now practice and experience play a far greater part in the use of our senses than we are usually inclined to assume, and since, as just remarked, our sensations derived from the senses are primarily of importance only for enabling us to form a correct conception of the world without us, our practice in the observation of these sensations usually does not extend in the slightest degree beyond what is necessary for this purpose. We are certainly only far too much disposed to believe that we must be immediately conscious of all that we feel and of all that enters into our sensations. This natural belief, however, is founded only on the fact that we are always immediately conscious, without taking any special trouble, of everything necessary for the practical purpose of forming a correct acquaintance with external nature, because during our whole life we have been daily and hourly using our organs of sense and collecting results of experience for this precise object."

Want of space compels us to leave out of consideration that paper on Vortex Motion, in which he establishes principles in pure hydrodynamics which had escaped the penetrative power of all the mathematicians who preceded him, including Lagrange himself; and those papers on electrodynamics where he reduces to an intelligible and systematic form the laborious and intricate investigations of several independent theorists, so as to compare them with each other and with experiment.

But we must not dwell on isolated papers, each of which might have been taken for the work of a specialist, though few, if any, specialists could have treated them in so able a manner. We prefer to regard Helmholtz as the author of the two great books on Vision and Hearing, and now that we are no longer under the sway of that irresistible power which has been bearing us along through the depths of mathematics, anatomy, and music, we may venture to observe from a safe distance the whole figure of the intellectual giant as he sits on some lofty cliff watching the waves, great and small, as each pursues its independent course on the surface of the sea below.

"I must own," he says, "that whenever I attentively observe this spectacle, it awakens in me a peculiar kind of intellectual pleasure, because here is laid open before the bodily eye what, in the case of the waves of the invisible atmospheric ocean, can be rendered intelligible only to the eye of the understanding, and by the help of a long series of complicated propositions."—("Tonempfindungen," p. 42).

Helmholtz is now in Berlin, directing the labours of able men of science in his splendid laboratory. Let us hope that from his present position he will again take a comprehensive view of the waves and ripples of our intellectual progress, and give us from time to time his idea of the meaning of it all.

J. CLERK MAXWELL

THE UNIVERSITIES BILL

PEOPLE'S notions of "reform" differ very much according to their interest in or knowledge of the kind of thing to be reformed. At present there is much talk of university reform, but there is really no proposition before the public for reforming the universities. The Government Bill is simply intended to adjust certain parts of the machinery of the ancient corporations at Oxford and Cambridge and to oil the wheels which with the lapse of time have become rusty. There is no intention to make Oxford and Cambridge what they were three centuries ago—namely universities in the sense in which the word "university" is applied (excepting the cases of London and Durham) to every other institution claiming the title in civilised Europe. The historic process by which the endowed boarding-houses at Oxford and Cambridge known as colleges fell into the hands of the clerical party, and subsequently became possessed of the sole control of the university, suppressing the higher Faculties, with the exception of the Theological, and driving from the university all students but those who could afford to make a ruinous annual payment to the cooks, butlers, scouts, and tutors of one college or another in exchange for indifferent board and lodging and a "religious education" in a school-boy's horn-book, under the disciplinary system devised by the Jesuits, is *not* to be reversed. No re-constitution of the Faculties—the absolutely essential step in the reformation of decayed universities—is proposed, nor is the Bachelor-of-Arts curriculum to be relegated to its proper place—the preparatory schools. The colleges are still to have it all their own way, are to be allowed still to compete with one another in buying at the rate of 100*l.* a year the chances of distinction which a promising school-boy can give by entering his name on the college-books; they are still to pursue the fruitless task of training these youths so as to obtain for the college the largest possible number of "first classes" in an examination arranged and conducted by the colleges (whose representatives far outnumber the professoriate) in subjects and methods which the student should either have dropped at the threshold of the university or should pursue in a spirit and with a thoroughness incompatible with the conditions of these competitive examinations. Prize fellowships awarded by competitive examination are still to be the incentives to these mercenary studies on the part of the young men; the university professor, even though he may be multiplied by two, is still to occupy the ambiguous position which is at present his lot—by right the director of the studies connected with his chair, but, in fact, shorn of the privileges and functions of his office through the eager competition of colleges for examination honours and tutorial fees. Worse than all, the ridiculous "matriculation" examinations are *not* to be superseded by a thorough university matriculation examination—to the want of which the disgraceful inefficiency of school-teaching in all our public schools is due.

It is true that it is only within the last quarter of a century that the full supremacy of the Theological Faculty in Oxford has been attained by the practically complete effacement of the Medical Faculty, the Regius and Clinical chairs in which are now held by one professor, who appears to have acquiesced in the total cessation of medical study in Oxford. It is also true that within the same period the Faculty of Laws has made a partial reappearance, and musters a few non-professional students, whilst under the stimulus afforded by competitive examination and prize fellowships, something more in quantity than, but still identical in kind with, the class-work taught at school to boys of from fifteen to eighteen years of age, is now sedulously driven into the undergraduate's brain by his college tutors and lecturers. It will also be adduced by the apologists of the present university *régime*, that over 80,000*l.* have been spent at Oxford on a palatial edifice for the encouragement of the long-neglected studies which are ranked as physical science. It should, however, be thoroughly understood that the sum in question has been primarily devoted to the production of an architectural monstrosity, the University Museums, which though pleasing to the æsthetic persons who invented it, does not provide the accommodation which the subjects require, nor even so much as could, in the absence of æsthetic muddling, have been obtained for a fourth part of the sum quoted with so much assurance.

The actual facts which are given below show what is the constitution of the University of Oxford in the way of professors, college-teachers, and students, and to what studies they respectively devote themselves. These figures entirely refute Mr. Lowe's recent statements to the effect that whilst the honour-man at Oxford has a good education, and the pass-man a very bad one—the pass-men far outnumber the honour-men. Clearly Mr. Lowe had not troubled himself to ascertain the facts before making his attack, which was intended to show the danger of allowing the Owens College to become a university. Mr. Lowe's conception of a university is limited by the model of that which he represents, and accordingly there is little comfort to be derived from his attacks on Oxford for those who believe in "the university" as it exists in the great German home of universities.

All that has been written and said within the last three months on the university question shows that there is a most serious ignorance among our public men of what universities are, what they can do, are doing, and how they do it, both in Great Britain and abroad. Only two members of the House of Commons, Dr. Lyon Playfair and Mr. Grant Duff, appear to have so much as an elementary acquaintance with the subject on which they are about to legislate. Even Mr. Goldwin Smith, who has returned to England full of wisdom gained in the Far West, expresses his belief in the college system because, forsooth, certain mushroom institutions in America which are defective as universities, have no colleges or boarding-houses. Had Mr. Goldwin Smith travelled east instead of west, he might have formed other and sounder conclusions after a study of German universities.

Under these circumstances, though it is a matter of profound concern, it is not surprising that the Government Bill contemplates no change which will re-create Oxford and Cambridge as universities. They will remain each a congeries of finishing schools for the sons of the wealthier classes—where a man may learn, as Dr. Lyon Playfair has said—how to spend a thousand a-year, and to spend it with some discretion, but not how to earn a thousand a-year—how to make himself a useful member of society valuable at that rate.

To fit a man for a career in life, the task which is undertaken by every other university worthy of the name, is absolutely what Oxford and Cambridge refuse to do, and what legislators ought to force them to do. Poor men, or men of moderate means, can only afford to send their sons to an English university in order that they may become clergymen or schoolmasters, or on the chance that, as in the Chinese mandarin selection, they may, by submission to the tyranny of a competitive examination, win a prize fellowship.

Those who desire and see in the future a true university reformation—having nothing favourable to their views to expect from the action of the Commissioners appointed without definite instructions by the present Government Bill—have none the less much to fear and to combat. It is admitted on all hands that the powers of the Commissioners are very great, though they are not *definitely* instructed as to how they are to employ those powers. Practically it will come to this, that the Commissioners will simply empower the resident fellows of colleges to do what they have long wished and sketched out, namely, to marry and settle down permanently in the university as college lecturers and tutors. This boon will be granted to the colleges in exchange for an immediate ten and a prospective fifty thousand a year, which will go to paying for new university buildings and for some new (as well as additions to the stipends of some old) professorships.

The new professors will be in the same ignoble position as the old ones, since no change in the constitution of the government of the university is contemplated, and there is no reason to suppose that they will make the university more remarkable for research and less remarkable for apathy, than does the existing body. The clerical restriction on headships of colleges—sinecures varying in value from 1,000*l.* to 2,000*l.* a year—*may* be removed by the Commissioners, but is not necessarily to be so, nor is provision made for abolishing headships altogether. The nature of the duties of the college lecturers and tutors who will become a more formidable body than ever, when allowed to root themselves with family surroundings, will not be regulated by the Commissioners, nor the subjects which they shall teach. At the same time the non-resident fellows will have their term of tenure limited, and their influence in college government will be diminished, even if they are not altogether excluded from a share in it. The result of these changes will be greatly to strengthen the college system of preparing pupils for the examination race-course, and to render it more difficult than ever to remove the injurious antagonism which at present prevents any real co-operation among the colleges for the common good of the university. The cessation of this antagonism might have been effected once and for all by empowering the Commissioners to reconstitute the Faculties, and to combine in them equally all college teachers and professors, to be organised into a series of consentaneous teaching bodies, one in each Faculty.

In sketching what seems a possible and satisfactory scheme for the university reform of the future, it is desirable first of all to ascertain what sum of money can be spent with advantage in a single locality like Oxford; and, secondly, what can be reasonably done with the surplus funds now administered through Oxford. It appears that about 400,000*l.* a year may be reckoned as the immediate prospective revenue of the colleges and university of Oxford. Of this, 150,000*l.* a year would nobly endow a reformed Oxford, leaving 250,000*l.* a year for other purposes. The University of Oxford is generally regarded as a *place*, whereas it is essentially a *corporation*. Whilst the University could not with benefit dispense more than 150,000*l.* a year within the city of Oxford, there is no reason why it should not have a series of institutions connected with it in London, or even in other great cities. The universities founded in this way by the surplus revenues of Oxford and Cambridge in London, Birmingham, Manchester, Leeds, and Bristol, should be equally endowed with the parent universities, and might form as do the German universities a series of co-operating institutions from one of which to another the student could pass as the special direction of his studies might determine, and the professorial positions in which (of graduated value) would furnish a ladder to be climbed by those who devote themselves to the professorial career.

Leaving the question aside, as to the ultimate disposal of surplus revenues, there is no doubt that with the introduction of a system of professorial teaching, combined with a rigid pass examination, and the removal of the baneful "competition for honours," Oxford could be maintained in external appearance much as it is with 150,000*l.* a year of endowment. The college buildings would remain as boarding-houses and would have to compete as such with the ordinary lodgings in the city. There would be a limited number (two or three in each college) of domestic "tutors" or house-masters to preserve order and give advice to the students resident in colleges, whilst the entire teaching would be performed by the greatly-increased professorial staff.

With or without the more radical points of this change, any Bill professing to reform Oxford and Cambridge ought to embrace the following provisions, or some at least of them; none of them are comprised in the Government measure.

1. The creation of new professorships and their arrangement with the old ones in Faculties (say Theology, Law, Medicine, Physical Science, and Literature), on as complete a scale as the most fully-developed German university presents—say Leipzig—where with a total revenue of 50,000*l.* a year the University has 115 professors as against 43 in Oxford.

2. The giving of the sole control of the curriculum of study in each Faculty to the official members of that Faculty, together with the sole right to appoint examiners and to elect to vacant professorships. The existing "Boards of Studies" might without difficulty be developed into the required Faculties.

3. The exclusion of all non-resident graduates and of persons not officially recognised as teachers (members of Faculties) from participation in university government.

4. The imposition of a *thorough* matriculation examination (to embrace the elements of physical science and other modern studies) on all students seeking admission to the university; the subjects of examination and standard to be arranged and determined by a committee of the faculties in concert with other great national educational bodies.

5. The abolition of "college monopoly," and the introduction of free trade in the boarding and the teaching of undergraduates—firstly, by permitting an undergraduate (whether enjoying a college scholarship or not) to reside where he may find the cheapest and best accommodation either in or out of college; and secondly, by prohibiting any compulsory exaction from him of attendance on, or payment for, any teaching which he does not voluntarily select as the most likely to add to his knowledge, or to enable him to pass with credit the only examination he would have to undergo, viz., the "pass" examination of the faculty, admitting him to the degree of Bachelor or of Master.

6. The institution of a Doctor's degree to be given in the Faculty of Science, and in that of Literature after the degree of Bachelor, on presentation by the candidate of an original thesis to be approved by the Faculty, and *to be published* (publication being indispensable).

7. The annual assignment from surplus revenue of some thousands a year to each Faculty to be dispensed by them in special missions, explorations, travels, and researches.

8. The general control by the State Government of the finances and public acts of the university. The continual control of a richly-endowed corporation by the State is an indispensable safeguard.

9. The prohibition of the employment of any collegiate or university funds for any ecclesiastical purpose or for any other non-academic purposes.

10. The removal of all religious tests in connection with any office (professorial or other) held in the university or colleges, as well as the abolition of *all* compulsion in regard to religious observances such as are now exacted from undergraduates.

To make all or the major portion of the changes here advocated would be truly to change the character of our English universities. They would be restored to national uses as universities worthy of the name; they would cease to be the "Kindergarten" of the wealthy classes, to whom they belong by no right, and by whom they have long been appropriated and misused.

APPENDIX.

Facts with regard to Teachers and Students in the University of Oxford, derived from the "University Calendar" of 1875.

There are about 2,400 undergraduates, or persons *in statu pupillari*, on the College and University books; 400 of these graduate in each year, the average time spent in the University being over four years.

Of these 75 per cent. read for honours in the various schools or Faculties, whence it appears that there are about (probably less than) 1,800 students in Oxford reading for honours. Of these 1,800 it appears that 33 per cent. read for the school of Literæ Humaniores (Philosophy, Classical History, and Philology), 20 per cent. for the school of Modern History, 17 per cent. for the school of Theology, 15 per cent. for the school of Law, 7 per cent. for the school of Mathematics, and only 6·5 for the school of Physical Science.

Of the 2,400 undergraduates 24 per cent. hold college scholarships or exhibitions varying in value from 30*l.* to 100*l.* a year, exclusive of scholarships or exhibitions granted by external bodies.

There are at this moment 360 fellows of colleges, exclusive of heads and professors, of whom 140 (out of a total of 160 college lecturers and tutors) are resident and engaged in teaching. The average endowment of a fellowship is 250*l.*

There are thirty-seven University professors and six University readers or assistant professors, of whom nine give no definite courses and have no pupils. They are distributed in subjects thus: Theology, five; Medicine, two; Law, four, and a reader; Lit. Human. seven, and a reader; Mathematics, three; Physical Science, seven, and four readers; Modern History, three, and a reader; Fine Art and Modern Languages, seven.

Taking the total number of teachers, both collegiate and professorial, and the total number of honour-students, according to the subjects which they respectively teach and pursue (which subjects may be ascertained from the calendar), we find that in Literæ Humaniores the proportion of collegiate and professorial teachers to students is 1 : 5·5; in Mathematics, 1 · 6; in Physical Science, 1 : 7; in Modern History, 1 : 5; in Law, 1 : 15·5.

Estimating the average annual income of a college lecturer or tutor at 500*l.*, we find that 75,000*l.* is the sum required to pay at this rate for 150 such persons. This sum is exactly what the scholarship fund (40,000*l.*), plus 140 fellowships of 250*l.* each amounts to, so that, practically, the teaching in Oxford colleges is paid for, not by the parents of undergraduates, but by a portion of the collegiate endowments—to wit, the scholarship fund and two-fifths of the fellowship fund.

The statement recently made by Sir John Lubbock in the debate on the Universities Bill in the House of Commons, to the effect that Oxford practically has done nothing for the development of the study of physical science, is amply justified by the above figures; there are only seven professors and four readers of all the various physical sciences in Oxford; only one twenty-fourth of the undergraduate students in the place pursue the study of physical science; *and of all the three hundred and sixty fellowships in the various colleges only five* are held by persons (exclusive of professors) who have been elected to them in consideration of their attainments in physical science. In four more fellowships the application of mathematics to physics has been allowed to count in establishing a student's claim to such fellowship.

The public schools teach physical science to so few boys, and teach it so inefficiently, that there are quite as many scholarships for excellence in this subject offered to the matriculating students as there are worthy candidates. The fact that the public schools never teach physical science to all their pupils and only as a rule to the dullest study on account of their failure in classics and mathematics, is simply due to the fact that neither the colleges nor the university introduce any branch of physical science into any one of their compulsory examinations. And this fact is further explained by the fact that the college lecturers and tutors, and even the heads of houses, are, with few exceptions, men who have been schoolmasters, or who hope to be so, and who are identified in every way with the pedagogic profession.

In fact, using the term without any offensive implication, the College authorities, together with the schoolmasters, form a "ring" whose interest it is to suppress a class of studies of which they are themselves ignorant. The university professoriate, which should act as a higher body, to control and stimulate the pedagogic class of teachers, is, as already mentioned, a nonentity. There is no such higher power—the "University" is ridden over rough shod by the "Academy for Young Gentlemen."

AN OXFORD MAN

THE BASQUES

Essai sur la Langue Basque. Par F. Ribary. Traduit du Hongrois par J. Vinson. (Paris: F. Vieweg, 1877.)

Basque Legends. By W. Webster. (Griffith and Farren 1877.)

THE Etruscans perhaps excepted, there is no race that has had a greater attraction for the ethnologist and the student of language than the Basque. Defended by the mountain-fastnesses of the Pyrenees, with peculiar physiognomy, language, and manners, they seem to be the last waif and stray of a people and family of speech which have elsewhere disappeared. Whence did they come? and what is their kinship? are the two questions which have long been discussed warmly and to little purpose. Are we to regard them as the descendants of the ancient Iberi, and find their traces, with Wilhelm von Humboldt, in the local names of Spain, of Sicily, and of Southern Italy, or are we to bring them from Africa on the one side, or from America on the other, or finally let them drop from the clouds, or grow up spontaneously on their native soil? Certain it is that languages like Basque were spoken in the north of Spain under Roman rule; at least, the town called Graccuris, in honour of Tiberius Gracchus, is a genuine Basque compound of *iri* or *hiri* "city," like Iria Flavia, "the Flavian burgh." Exclusive of emigrants in South America, the present Basque population amounts to about 800,000, of whom 660,000 are Spanish, and 140,000 French. Their language has little resemblance to any other known tongue, whether ancient or modern. Erro claimed for it the privilege of having been spoken in Paradise; and Larramendi proudly named his grammar (1729) "El Impossible Vencido"—"The Impossible Conquered." The native works upon the language, however, were all tainted with mysticism and want of scientific method, and it is only of late years that this interesting speech has been examined in the light of science and exact scholarship, and grammars composed which treat it in a rational way. Materials for the work have been prepared by the researches of Prince Lucien Bonaparte, who has accurately mapped out the several dialects of the [illegible] noted their individual characteristics and peculiarities, and has actually discovered some fast-perishing dialects which had hitherto remained unknown. His magnificent work on the Basque verb has, it may be said, created the scientific philology of the language.

Basque, or Eskuara (probably meaning "mode of speaking"), as the Basques themselves call it, is an agglutinative tongue, postfixing, for the most part, the sounds which express the relations of grammar. The grammar would be simple were it not for the verb, at once the wonder of native writers and the despair of foreign linguists. The verb incorporates the pronouns, having a different form for "I have," "I have it," "I have it for you," &c., as well as (in some dialects) for addressing a woman, a man, a superior, and an equal. It possesses also three voices, two primary tenses, at least five moods, and more than one participle or infinitive. When analysed these forms turn out to be amalgamations of the verbal stem with various pronouns and modifying particles, but their origin is so obscured by phonetic decay, and their number is so immense, that we cannot much wonder if, according to the legend, the devil, having spent seven years at Burgos in the vain attempt to learn the language, was at last obliged to leave the Basques to their primitive simplicity and virtue. The eight principal dialects—Labourdin, Souletin, Eastern Bas-Navarrais, Western Bas-Navarrais, Northern Haut-Navarrais, Southern Haut-Navarrais, Guipuscoan, and Biscayan—differ a good deal from one another, and the three sub-dialects of Spanish Basque—Roncal, Aezcoan, and Salazarese, have yielded to Prince Bonaparte interesting archaic forms and words. It is unfortunate that our knowledge of Basque does not reach back further than 1545, when the first book in the language—the "Poems of Dechepare"—was printed, and a restoration of earlier grammatical forms must therefore rest solely upon a comparison of the existing dialects.

The grammar of the Hungarian professor, which M. Vinson has translated into French, is an extremely good one, and its value has been increased by the introduction he has prefixed to it, as well as by the notes he has added by way of supplement and correction, and by a very useful and almost exhaustive Basque bibliography he has appended at the end. These notes will form the subject of an article Prince Bonaparte is preparing for publication. Prof. Ribary's exposition of the intricacies of Basque grammar is singularly clear, and I know of no work from which the foreign student could gain a better insight into the machinery of the verb or a better key to its multitudinous forms. Certain of these are compared with corresponding forms in Magyar, Vogul, and Mordvinian, which, like the Basque, are able to incorporate the objective pronoun. The volume may be heartily recommended for both scientific and practical purposes.

While the Basque language has been attracting so much attention, the equally interesting and important folk-lore of the country has been almost wholly neglected. With the doubtful exception of Chaho, none of the Basque legends were "even noticed till within the last two years, when M. d'Abbadie read the legend of the Tartaro before the Société des Sciences et des Arts de Bayonne, and M. Cerquand his 'Légendes et Récits Populaires du Pays Basque,' before the sister society at Pau." Mr. Webster's book, therefore, is doubly welcome, consisting as it does of tales and legends written down from the lips of the narrators, and literally translated into English with the co-operation of M. Vinson. Mr. Webster has divided the stories into (1) Legends of the Tartaro, (2) of the Heren-Suge, or Seven-headed Serpent, (3) animal tales, which are neither fables nor allegories, (4) legends of Basa-Jauna, Basa-Andre, and other Lamiñak, or fairies, (5) tales of witchcraft, (6) Contes des Fées, and (7) religious legends. The Tartaro is a one-eyed Cyclops, and what is told about him will interest classical scholars. He lives in a cave among his flocks, and is blinded with a red-hot spit by the hero, who contrives to escape by the help of the unsuspecting sheep. In some versions the story of the talking ring is combined with that of the Cyclops, and in one form of the legend communicated to me by M. d'Abbadie, and alluded to by Mr. Webster, the hero is made to fight with a body without a soul. Grimm has quoted analogous stories to that of the Cyclops, among the Oghuzian Turks, Karelians, and others, and M. d'Abbadie heard an almost exactly similar one in Eastern Africa, while Mr. Moseley has pointed out to me that the Chinese also have their "one-eyed people who live to the east of Chuk Lung, and have one eye in the centre of the face." (See my "Principles of Comparative Philology," second edition, pp. 321-323, and for an account of a Mongolian Cyclops, Mr. Howorth, in the *Journal* of the R.A.S., vii., 2 (1875), p. 232.) It is within the bounds of possibility that the Greek myth of the Cyclops may have been borrowed by the colonists in Sicily or the voyagers to Tartessus from some ancient Basque population. However this may be, the legends of the seven-headed serpent connect themselves very strikingly with Western Asia. Accadian mythology had much to tell of "a seven-headed serpent," the dragon of Chaos, which tempted man to sin and waged war with Merodach, the Chaldean Michael. The Indian Vritra has but three heads, like the Orthros, the Kerberos, the Ekhidna, and the Khimæra of the Greeks, but it is at least curious that Orthros, with his master Geryon, was localised at Cadiz in the later days of Greek mythology. Basa Jauna, again, "the wild man of the woods," with his wife Basa-Andre, though once represented as a kind of vampire, is usually described as a sort of Satyr, reminding us not only of the classical Pan, but of the far older Chaldean Hea-bani, the friend and councillor of the Babylonian Herakles. Basa-Andre, says Mr. Webster, "appears sometimes as a kind of mermaid, as a beautiful lady sitting in a cave and 'combing her locks with a comb of gold,' in remote mountain parts."

On the whole, however, there is very little that is native in these Basque legends, at least so far as their origin and texture are concerned. As Mr. Webster has noticed, the resemblance of many of them to the Keltic stories of the West Highlands is too minute to be the result of accident, while a large part of them is familiar to us in a French or even a German form. How the Basques could have borrowed Gaelic stories is at present not easy to explain; it is more probable, however, that this took place through maritime intercourse at a comparatively recent period than at some remote date when the ancestors of the Kelts and the Basques may be supposed to have lived in close proximity. The impression left upon the mind by the legends Mr. Webster has collected is that the Basques are neither imaginative nor original, and this is borne out by what he tells us of their unreasoning "adherence to what they believe to be the text of these old tales. 'I don't understand it, but the history says so;' 'it is *so;*' 'the story says so;' was positively affirmed again and again." This conservatism accounts for the survival of so many pagan ideas and customs among the people, among which the legends themselves may be reckoned The latter are believed like "the histories of the Bible, or the 'Lives of the Saints.' In fact, the problem of reconciling religion and science presents itself to the Basque mind in this strange guise—how to reconcile these narratives with those of the Bible and of the Church. The general solution is that they happened before the time of which the Bible speaks, or before Adam fell. They are *lege zaharreko istorioak*—'histories of the ancient law'—by which is apparently meant the time before Christianity. 'This happened, sir, in the time when all animals and all things could speak,' was said again and again by the narrators at the commencement of their story;'" a statement which curiously fits in with a similar belief among the Bushmen Altogether Mr. Webster has produced a most interesting book, and we hope that the welcome given to it may induce him to make it but the first instalment of other researches among the folk lore of the Basques.

A. H. SAYCE

OUR BOOK SHELF

French Accent. By A. H. Keane. (Asher and Co, 1877.)

THIS is an excellent and useful little pamphlet, in which the author claims to have discovered and formulated for the first time the laws which regulate French accentuation. Putting aside the tonic accent which usually falls on the last syllable of a word, and corresponds with the toned syllable of the Latin or Italic original, we have three accents. the acute, the grave, and the circumflex, which Mr Keane terms respectively the euphonic, the grammatical, and the historical. The circumflex denotes the loss of a sound, as do also the acute when on initial *e*, and the grave when on final *e*. The grave is alone employed grammatically to indicate the grammatical changes of words, and Mr. Keane lays down the two rules that "*e* followed by grammatical *e* mute, one consonant intervening, takes the grave accent," and that "every unaccented *e* followed by one consonant not final is mute" Mr. Keane shows himself well acquainted with the latest philological researches into the French language, and both pupil and teacher will find great assistance from his attempt to introduce law and order into the nature and position of the French accents. However, he is not altogether the first in the field, and it must be remembered that the philological ignorance of those who have stereotyped the use of the accents has caused it to be somewhat arbitrary. The Neufchatel Bible of 1535 has no accents, and the first to employ them regularly, though somewhat capriciously, was Jacques Dubois, in the sixteenth century. In "An Introductorie for to Learn French trewly," published by Du Guez, in London, probably about 1560, the accents are written below the line.

Étude sur la Dégénerescence Physiologique des Peuples Civilisés. Par M. Tschourіloff. (Paris. Leroux, 1876.)

THIS is a careful and conscientious discussion of a class of statistics that have never been so carefully discussed before, and have in consequence been interpreted by different writers in very different senses. There are two questions, both of which M. Tschourіloff answers in the affirmative, but which perhaps he does not always separate as clearly as could be wished; the one is whether the French and other civilised nations are deteriorating in their *physique*, and the other whether their deterioration is due to the abstraction of able-bodied men to serve and perish in the army. He has no doubt as to the deterioration in France, Sweden, and Saxony; thus, in the latter country, the number of men too infirm to serve as conscripts has largely increased of late years; in 1832-36, one third of the men were rejected; in 1850-54, one-half. He quotes numerous medical authorities, whose opinions are printed in the article, "Recrutement," in the *Dictionnaire Médical*, to show the evil effects of industrial occupation on the health of factory workmen, and alludes to many other interesting facts of the same nature. But the bulk of the work is occupied in tracing the effects of the conscription on the French race. The statistical examination of the returns of the medical examiners is of a necessity very complex, allowances and corrections having to be made on many grounds Even so apparently simple a problem as that of determining the amount of vigour abstracted from a population by the absence of a given fraction of them during a limited period, such as that of the great war, is in reality very complicated, and requires the free use of tables of mortality and of fecundity for different ages. The upshot of the author's inquiries is to show that the amount so abstracted is much greater than appears at first sight to be the case. He therefore ascribes a very seriously damaging effect to the vigour of a population by the carrying on of great wars. It is truly sad to read the statistical tables of the increase in France of a long series of such hereditary diseases as scrofula, hare lip, varicose veins, paralysis, madness, and skin maladies, due in large part to the propagation of the race by men who had been rejected as too infirm to serve in the army, and to so many of the healthy men having been destroyed or displaced This treatise will become a standard work of reference, both in respect to its conclusions and to the statistical operations by which they have been attained.

F. G.

The Northern Barrier of India. A Popular Account of the Jummoo and Kashmir Territories. By Frederic Drew. With Map and Illustrations. (London Stanford, 1877)

THIS is a popular edition of Mr. Drew's valuable work on Jummoo and Kashmir, noticed in NATURE, vol. xii. p. 550. That work was perhaps too formidable for the general reader to undertake, and Mr. Drew has therefore done well in selecting from it those parts likely to be of general interest The selection has been judiciously made, and as the illustrations have been retained, and a map showing the races as well as the physical features, the work will be found of great value and interest by those who hesitate to undertake the larger volume. It deserves a wide circulation.

The Two Americas: an Account of Sport and Travel. By Major Sir Rose Lambert Price, Bart. With Illustrations. (London. Sampson Low, 1877.)

WE took up this book with little expectation of finding much in it either edifying or interesting, and have been most agreeably disappointed. The author, in one of Her Majesty's ships, touched at various places on the east and west coasts of South America, and although most of the ground has already been gone over, he has the faculty of seeing and describing the already known under new aspects. He also visited Mexico, California, and the Yosemite region. From beginning to end the narrative is thoroughly entertaining, and even those who are well read in American travel will find that Sir Rose Price is able to tell them much that is new.

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.]

Nebulous Star in the Pleiades

A SHORT paragraph in a recent number of NATURE (vol. xv., p. 244) on the nebulous star in the Pleiades appears to call for a few remarks. With reference to the supposed difficulty of seeing with very large instruments a faint nebulosity in close proximity to a bright star, I may say, that the words of my assistant, quoted in the paragraph referred to, viz., "The Merope nebula *is never* perceived with Lord Rosse's telescopes," are perhaps a little too strong.

The entries relative to this object are five in number. In February, 1871, "Examined under very favourable circumstances; no nebulosity seen." August, 1872, "Examined Merope for Tempel's nebulæ; not a trace of nebulosity visible." (Both the above with the 3-foot reflector.) October, 1872, "Tempel's variable nebula not found; sky clear." September, 1873, "Nothing seen; much false light in field." December, 1875, "Examined Merope in consequence of M. Tempel's letter (*Ast. Nach.*, No. 2,045); no nebulosity seen; only same little false light as around the other bright stars; sky very misty."

It may be expected *à priori* that imperfections of a certain class, such as dust and other opaque substances, will interfere more with the action of a speculum than of an object-glass in searching for faint nebulosity near a bright star, inasmuch as in the former they will throw back and disperse over the field light which would otherwise have contributed to form the image of the star; whereas in the latter they will cause a general darkening by intercepting a certain percentage of light from stars and sky alike. It may therefore still be possible that under peculiarly favourable atmospheric conditions, and with a speculum just re-polished, we may still be able to detect the nebulosity, but it appears far more probable that we must look for an explanation of the difficulty of seeing the nebulosity to the comparative smallness of field of so large an instrument, which in general prevents the simultaneous comparison of the star under observation with neighbouring ones, and of a nebulous sky with an adjacent part free from nebulosity, so well as with a smaller telescope, and to the greater brilliancy of the image of the star while the nebulosity about it is only as bright as in the smaller telescope. From D'Arrest's remarks, quoted in NATURE, it appears that such objects are seen with much difficulty with a large refractor also. I have myself noticed, particularly in working with the six-foot reflector on the great nebula in Orion, that the fainter parts of the nebulosity, whether or not in the vicinity of bright stars, could best be seen with a finding eye-piece of 26′ field, of too low magnifying power to utilise more than two-thirds of the diameter of the speculum, and with my eighteen-inch Newtonian, the very faint nebulosity on the preceding side of the nebula could be much better traced.[1]

The absence of symmetry of the nebulosity round the star, as of that round ι Orionis, should, however, enable real nebulosity to be more easily distinguished from false light than in other cases. The more southern position of M. Tempel's observatory probably gave him some slight advantage.

It appears to be in the detection of minute stars and the examination of small details, where they exist, rather than in the search for faint diffused nebulosity, or nebulosity round stars that a large aperture gives so great an advantage.

ROSSE

"The Movement of the Soil-cap"

UNDER the above heading Sir C. W. Thomson gives an interesting account of the "stone-rivers" of the Falkland Islands in a recent number of NATURE (vol. xv. p. 359), and attributes their origin to a general movement of the "soil-cap." Nothing can be clearer than his explanation of the mode in which the quartzites weather and break up on the hill-slopes, and one can quite understand how the resultant *débris* is gradually brought down into the valleys by the agents of change he refers to. But it is hard to see how these agents, after having got the *débris* down into the valleys, can subsequently spread it out into wide sheets, reaching "from a few yards to a mile or so in width," and resembling at a distance glaciers that seem as if descending from the adjacent ridges. The stones, as Mr. Darwin tells us, "are not thrown together into irregular piles, but are spread out into level sheets or great streams." Sir C. W. Thomson is apparently of opinion that these great streams of stones move *en masse* down the valleys, as "earth-glaciers," and he refers to the occurrence in Scotland of certain phenomena which seem to him to indicate similar movements of the "soil-cap." Geologists who have worked much in hilly countries, will readily recognise the truth of his descriptions—indeed the appearances to which he calls attention are quite common in such districts as the Northern Highlands and Southern Uplands of Scotland. The soil and rock-rubbish which are found resting upon our hill-slopes, and the bending-over of the truncated ends of the underlying vertical or highly-inclined strata are of course the results of atmospheric action. Rain or thawing snow filters into joints and crevices, and insinuates itself between bedding-planes, and frost tends to force these apart—the loosened rock moving in the line of least resistance, that is, *down hill*. At the same time both solid rock and detached fragments "weather," and thus grit and soil gradually form, while in like manner this gradually-forming "soil-cap" being itself acted upon by frost, is forced in the same way to move down the slope, a movement which is of course aided by a *vis a tergo*, the weight of the descending mass. Partly in this way, and partly by the direct action of rain, which not only washes the particles down, carrying away surface after surface, but sometimes soaks the loose "soil-cap" to such a degree as to cause the entire accumulation to "flow," whole hill-sides become swathed in mantles of soil and *débris*. But it is difficult to believe that an experienced observer would be puzzled to discriminate between such rubbish-heaps and true glacial moraines. Arrived at the foot of the slope, the rock-rubbish accumulates there, unless there be some stream at hand to denude it, and to sweep its materials, in the form of gravel, sand, and mud, down the valley. There are many good grounds, however, for believing that much of that "surface-wash" of soil and rock-rubbish which cloaks our hill-slopes to a depth sometimes of many feet, dates back to a time when our climate was considerably colder than it is at present, and that, while it was accumulating, local glaciers occupied many of our mountain-valleys. Putting aside "screes" and *débris*-slopes generally, I must say I have never seen any indication of that movement *en masse* of the soil-cap upon which Sir Wyville insists; and I hardly think many geologists will agree with him that it is "almost self-evident that wherever there is a slope, be it ever so gentle, the soil-cap must be in motion, be the motion ever so slow; and that it is dragging over the surface of the rock beneath the blocks and boulders which may be embedded in it," &c. Soil, as we all know, is always travelling from higher to lower levels, but this movement consists for the most part in the mere sweeping downwards of its component particles by rain and surface-drainage. It is true that the expansive power of frost, and the action of vegetation as described by Sir Wyville, may force a certain proportion of a soil-cap *en masse* down a gentle slope, but these influences will affect only an inconsiderable stratum; and, besides, the movement thus caused will be so trifling that the mere surface-action of rain would suffice to carry away the whole soil, particle by particle, long before the power of frost could have moved it bodily more than an inch or two. In reading the accounts of the wonderful "streams of stones" in the Falkland Islands, one is strongly reminded of the great moving masses of *débris* in certain valleys of the Rocky Mountains, as described by Dr. Hayden, and to surmise that the stone-rivers of the Falkland Islands may possibly be of the same nature. Dr. Hayden tells us that entire valleys are "covered thickly with earth, filled with more or less worn rocks of every size, from that of a pea to several feet in diameter. The snow melting upon the crests of the mountains, saturates these superficial earths with water, and they slowly move down the gulch much like a glacier. This is another process of grinding the underlying rocks, smoothing, and grooving them." But he apparently finds no difficulty in distinguishing between such "earth-glaciers," and the moraines left by those gigantic ice-rivers, which, according to him, flowed down the valleys of the Rocky Mountains during the glacial period. Suppose now that owing to some change of climate these earth-glaciers were no longer to be saturated with water to such an extent as to cause them to flow *en masse*, it is evident that the loose soil of which they are partly composed would then be gradually removed by the action of rain and running water, while the angular blocks and *débris* would remain for a very much longer time, until eventually they crumbled down and were carried away in the form of gravel, sand, and mud. As far as one can judge from descriptions, the "stone-rivers" of the Falkland Islands seem to present very much the appearance which such dessicated earth-glaciers might be expected to assume, after their finer materials have been abstracted. The possibility that considerable masses of loose materials, such as a "soil-cap," may have moved *en masse*, has before now attracted the attention of some observers. Mr. Robert Mallet contributed a paper on the subject a number of years ago to the Journal of the Dublin Geological Society (see vol. v.); and in the *Jahrbuch der k.k. geologischen Reichsanstalt*, vol. xxii. p. 309, will be found an article by Theodor Fuchs, treating of the same subject.

Government Grants to Science

IN that part of the article in last week's NATURE on "Government Grants" which relates to the grant which has been for some years annually voted for pathological inquiries under the direction of Mr. Simon, a statement is made concerning myself, which I fear may convey a false impression as to the relation in which I stand to the Medical Department of the Privy Council.

Will you allow me to say that that relation is limited to the fact that the pathological investigations in question are conducted at the Brown Institution by my friend and colleague, Dr. Klein, who derives his commission directly from their lordships. I may take the opportunity of adding that the directors of the institution, of whom Mr. Simon is one, are as anxious as I am myself that its resources should be available, not only for this, but for all other purposes connected with the advancement of pathological science.

In former years, as your readers no doubt know, I have myself undertaken numerous investigations for the department, the last occasion occurring in 1875, but for some time past other and equally important duties have rendered this impossible.

Tints and Polarisation of Moonlight in Eclipse

THE gradation of the coloured tints on the moon's surface during total eclipse was seen here most clearly last Tuesday. At the middle of the eclipse the surface seemed to be obscured by a dusky disc surrounded by a broad bright copper-coloured rim, of uniform width, following the outline of the moon's edge. Just before totality ceased the surface presented the appearance of a series of coloured crescents having the centres of their boundaries on the line joining the point where ordinary light would soon appear to the moon's centre.

The order of colour was bright sea-green at the edge, followed by a pale golden tint, then copper tints, deepening to a dusky red or peach-bloom.

The explanation of these effects of sunlight in its passage through the earth's atmosphere will be found in Herschel's Astronomy, §§ 421-4.

The sky generally was free from any but very transparent clouds, and the air keen and frosty with steady breeze.

Shortly before the middle of totality I examined the light from the moon's surface by means of a double image prism (made for solar eclipse work by Mr. Ladd) outside the eye-piece of a telescope with a $3\frac{1}{4}$ inch object-glass. On turning the prism round, with its front surface perpendicular to the axis of the telescope, the two images of the moon, in the parts where they did not overlap, appeared to brighten and darken alternately, interchanging intensities. The cycle was completed in course of revolution through 180°. This is conclusive as to the polarisation of the light received from the moon during total eclipse. I was unable to determine the character of the polarisation. There will be another total eclipse on August 23, for which I hope to be better prepared.

The Patenas or Grass Lands of the Mountain Region of Ceylon

EVERYONE who has travelled through the Central Province of Ceylon must have been struck by the occurrence, apparently without sufficient cause, of tracts of grass-land varying from a few perches to hundreds, and sometimes thousands, of acres in extent, in the midst of otherwise interminable jungle. This land is exceedingly poor; almost without exception it is worthless to the coffee-planter for purposes of cultivation, and incapable of supporting any vegetation except its own acrid mána grass (*Andropogon schœnanthus*) and a few stunted specimens of *Careya arborea* and *Emblica officinalis*. Yet on all sides of it will probably be found a rich forest vegetation that grows luxuriantly up to the very edge of the grass, where it terminates abruptly, without any dwarfed or stunted undergrowth on the border-line to show that the soil gradually changes from a fertile to a sterile character. Sir Emerson Tennant, in seeking for an explanation of this curious phenomenon, appears to have been completely baffled, for he suggests nothing beyond what is contained in a quotation from Humboldt in reference to the grassy plains of South America, where that great traveller speaks of the destructive custom of setting fire to the woods when the natives want to convert the soil into pasture. One reason, which seems to be quite conclusive against this explanation being applied to the grass-lands of Ceylon, is that cleared forest-land, however neglected and impoverished, does not run into grass such as is found on these Patenas, but into a dwarfish jungle called "chena," and then again, after a considerable period of time, into forest Besides, it very frequently happens that these grass-lands are the very last pieces of ground that one would expect the natives to select out of the forest to bestow labour on in clearing and burning. Another and minor argument against this view is that the natives, whose traditions extend back for a considerable period of time, can give no account of the origin of Patena-lands, as no doubt they would be able to do if their ancestors and themselves were the cause of their existence. Other causes, therefore, than that of human agency must be sought for. One of these I believe I discovered during my residence in Ceylon, and I should be glad to learn whether any of the readers of NATURE have noticed the same in any part of the gneiss formation of Southern India, or indeed in any extensive gneiss formation within or without the Tropics. How far this particular cause operates in other instances than the one presently to be mentioned I am unable to say, but I am inclined to the belief that although it does not hold universally, it nevertheless holds pretty generally in the case of the larger patenas. It must be remembered that the mountain region of Ceylon is entirely a gneiss formation, very much dislocated during upheaval, and consisting at the present time of exceedingly deep valleys and precipitous mountain ranges. In this gneissic series occurs a band of half-formed quartzite several hundreds of feet in thickness, to which my attention was first attracted by noticing that below it, *i.e.*, where its *débris* accumulated, nothing but patena was to be found, whilst above, where the ordinary gneiss rocks were in a state of disintegration, the jungle and coffee was of a most luxuriant character. This band of quartzite stands out from the ordinary gneiss cliffs in the valley leading from Pussellawa to Ramboda, about twenty miles south of Kandy. It extends for about five miles in the form of a cliff, broken through here and there by ravines. Its upper surface, beginning at an elevation of 4,500 feet on the Helbodde coffee estate, dips under the main waterfall at Ramboda, and disappears under the ordinary gneiss at an elevation of about 3,000 feet above sea-level. This rock weathers very black, and is distinguishable at a distance of several miles from the ordinary gneiss above it and in its neighbourhood. It seems to disintegrate into little else than a quartz sand impregnated with iron and entirely incapable of supporting the usual forest vegetation with which the district, except in this particular spot, abounds. I have been informed that in the extensive patena district of Ouvah, which, roughly speaking, is a plain almost surrounded by mountains, a few miles south of the district just mentioned, and separated from it by the loftiest mass of mountains in the island, the same quartzite formation occurs, but not having had an opportunity of visiting and examining it, I am unable to say how far this information is to be relied on. When one remembers how very extensively the gneiss is broken up throughout the whole of this mountain region of the Kandyan province, it seems not improbable that other patenas, especially the larger ones, owe their origin to the cropping out of this quartzite band, although it is difficult, probably impossible in many cases, to determine that such is the case.

Oxford

The Estimation of Urea by means of Hypobromite

ALLOW me to correct a slight mistake into which your reporter has fallen, no doubt inadvertently.

Knop was the first to propose (in 1870) the use of a strongly alkaline solution of hypobromite for the estimation of urea in place of the hypochlorite previously employed by Davy. Every chemist who since 1870 has worked with the process has, as far as I am aware, retained the exact composition of Knop's hypobromite solution.

The modifications in details which I have proposed are therefore for the purpose of facilitating the working of Knop's process. This process is, I believe, the one best suited for general use. Certainly no other process as yet devised equals it in rapidity and ease of working, and few, if any, surpass it in accuracy. If, then, it should be deemed desirable to attach any names to this process, I would suggest that it be called the Knop-Davy process.

Colœnis Julia in Texas.—Venomous Snakes devouring each other

IN Chapter xv. of his "Geographical Distribution of Animals," Mr. Wallace mentions *Colænis* (belonging to the Nymphalidæ) as one of the South American forms, which do not pass north of Costa Rica or Nicaragua. I have taken, though only once during nine years, a female of *Colænis julia*, Hubner, here at Bastrop, on the Colorado, in about 30° N. latitude, but I believe this to be the first time where said species has been captured in temperate America.

I do not know whether the fact has been observed before, that one venomous snake will devour another belonging to even the same genus. Some time ago I captured, on the Guadaloupe River, a large and very thick *Ancistrodon pugnax* (Water Moccasin), one of the Crotalidæ, and upon opening it, found inside a large and quite well preserved specimen of *Ancistrodon contortrix* (Copperhead).

Although I have examined many venomous snakes since, I never found a similar case, and the stomachs contained only mice, frogs, &c.

Bastrop, Texas, February 7

Lowest Temperature

THE temperature experienced during the night between February 28 and March 1 was so exceptional, that it may be thought worthy of a passing remark. The minimum reading at this observatory was 9·1° F., which is the lowest recorded during the last sixteen years; that of December 24, 1860, was, however, lower, being 6·7°. The lowest readings for February and March during the past twenty-eight years were respectively 10·1° on February 1, 1855, and 14·5 on March 4, 1866.

Stonyhurst Observatory, March 2

S. J. PERRY

Meteor

I SAW the meteor described* by Mr. Ingleby on February 26, about 6.20 P.M., Greenwich, from the railway platform at Gloucester. It was moving very slowly from right to left parallel with the horizon to the right of the moon, and a good deal below her; I should think two or three degrees at least. A bright track was left behind. The size must have been considerable for it was a very brilliant evening, and still almost daylight. No stars were visible in that part of the sky. I could not then see the position of Sirius, however. It was tolerably bright twenty minutes later. Gloucester is nearly due west of Ilford, and about 100 miles distant in a straight line.

Westbury-on-Severn, March 3

ALBERT J. MOTT

REPORT ON THE GOVERNMENT METEOROLOGICAL GRANT

THE following is the Report to the Lords Commissioners of her Majesty's Treasury by the Committee appointed in November, 1875, to inquire into the conditions and mode of administration of the annual grant of 10,000*l.* in aid of meteorological observations. That Committee consisted of the following:—Sir W. Stirling Maxwell, Chairman, Mr. T. Brassey, Mr. T. H. Farrer, Mr. Francis Galton, Mr. David Milne Home, Dr. J. D. Hooker, Mr. R. R. W. Lingen, C.B., and Lieut.-Gen. Rd. Strachey. We hope to make a few comments on the Report in our next number.

1. We have, in accordance with the Treasury Minute of November 2, 1875, made the inquiries therein mentioned. In doing so we have asked for the opinion of the President and Council of the Royal Society, who have favoured us with an elaborate report. We have also taken evidence from members and officers of the Committee which has hitherto administered the grant; and from many other persons whose opinions appeared to us to be important, either on account of their scientific eminence, their official position, or their practical knowledge and experience of the subjects in respect of which, and the classes to whom, meteorological knowledge is specially useful. To this report and evidence, which are contained in the Appendix to our Report, we desire to refer in support of the following conclusions:—

2. The business of the Committee may be considered under two heads, viz.:—

(1) The Meteorology of the Ocean.
(2) The Meteorology of the British Isles.

And the business relating to the latter of these may again be subdivided as follows, viz.:—

(*a*) That branch which by the use of the telegraph collects material for, and issues daily weather charts and storm warnings.

(*b*) That branch which collects, digests, and publishes meteorological statistics. This last branch depends on two sources of information, viz. (1) on observations taken at a limited number of stations which are provided with self-recording instruments, and which furnish continuous observations; and (2) on observations taken by the eye at stated daily periods at more numerous intermediate stations.

3. All these divisions and sub-divisions of the business have produced results of value, and should be continued. For more specific information on these points we beg to refer to the evidence, and especially to the report of the President and Council of the Royal Society.

4. Ocean meteorology should, we think, be transferred to the Hydrographical Department of the Admiralty. The reasons for this are, first, that whilst this department is equally able with the present Committee to collect observations from merchant ships, it must be better able to collect similar observations from her Majesty's ships; and, secondly, that from its experience in chartography and in nautical wants, it is specially competent to put the results in a form useful to navigators.

5. In performing this new duty the Hydrographical Department should be in such relation with the office or department which manages land meteorology, as to insure that the observations taken at sea will be so made and digested as to be available for scientific purposes in connection with those made on land.

6. Every effort should be made to act in concert with other nations in ocean meteorology, so that labour may be economised, and the utmost possible use be made of all available materials.

7. In recommending the above transfer we assume that the Lords of the Admiralty will be willing that the Hydrographical Department should undertake the duty; that that department will be organised and made in all respects adequate for the purpose; that the observations from merchant ships which have been hitherto successfully collected by the present Committee, and which are necessarily more numerous and more varied than any which can be obtained from the Royal Navy, will continue to be collected; and that the advancement of science, so far as the ocean is concerned, will be no less an object with the Hydrographical Department of the Admiralty than it has hitherto been with the present Committee.

8. As to land meteorology we have considered the alternative proposals of appointing one permanent head, as was the case before 1866, and of leaving matters to be managed by a Committee in the same manner in which they have since been managed. But we cannot recommend either of these proposals. As regards the first, although it may be desirable at some future time to create a permanant meteorological establishment on some such footing as that of the Astronomical Observatory at Greenwich, with an officer of scientific eminence at its head, we think that matters are scarcely ripe for such a step at present. As regards the second, it cannot be expected that the gentlemen who now constitute the Meteorological Committee, and who have by way of experiment given much valuable time to the work in its

initial stages, will continue to do so under the existing conditions.

9. We think, however, that the Royal Society should be invited to continue to recommend to the Government persons eminent in science to superintend the work, under the title of a Meteorological Council. They should be appointed for limited periods and should be eligible for re-appointment. They should be fewer in number than the present Committee, and the means should be provided of remunerating them in the shape of fees for attendance. They should have and exercise complete control and supervision over and be responsible for the business, expenditure, and staff, the chief officer of which would be more appropriately designated by the title of secretary than by his present title of director. The important duty of selecting a chairman, would rest with the Royal Society or with the members of the Council.

10. The present system of collecting daily information by telegraph and of issuing storm-warnings should continue. There is evidence that it is of real value to the seafaring population, and that it leads them to thought and observation on the subject of weather. The want of communication by telegraph on Sundays causes a serious defect in the system, which ought to be remedied.

11. An endeavour should be made to put into clear shape, and to issue, for public information, the maxims or principles upon which storm-warnings are in future to be given. This information should be revised from time to time so as to embody the latest results of experience.

12. The process of issuing daily weather-charts, with explanations, should continue, with such improvements as experience may from time to time suggest. The information thus given not only creates a general interest in the subject, but is of value to persons who are disposed to engage in the discussion of scientific meteorological problems.

13. A certain number of continuously self-recording stations should be retained. But it may deserve consideration by the Council whether some at any rate of the existing stations may not be discontinued, and others obtained on more eligible sites. Doubts have also been expressed whether in the present state of meteorological science the minute exactness of the observations now taken at these stations is of sufficient comparative value to justify the whole of the costs which they involve, when there are so many other objects of meteorological inquiry which call for increased expenditure.

14. The present system of supplementing self-recording observations by returns from eye-observers at intermediate stations should be continued. The positions of these latter stations should, however, be revised, and their number increased, especially in Ireland (where at present there are but few of them); so that the returns may exhibit a fair representation of the different climates and weather of the British Isles. Every possible endeavour should be made to secure the co-operation and assist the efforts of the different societies or other local bodies engaged in meteorology, and to further the adoption of uniform methods.

15. The evidence of the Astronomer-Royal and of other scientific witnesses contains some important observations on the form and extent in and to which the results of the observations should be published. This is a subject which deserves the careful attention of the Council with a view to saving all unnecessary expense on the one hand, and on the other to publishing the results in such a form as may render them most available for use by men of science.

16. There is evidence to show that the system adopted in the United States by which observations are taken over the large area of the North American continent and are communicated by telegraph to Washington, is of great value both for the immediate practical purposes of agriculture and navigation, and also as throwing light on the general movement of the atmosphere. The position and extent of the United Kingdom do not admit of any similar system of equal value. But it is desirable in the general interests of science as well as for practical purposes, that by means of co-operation between the different European nations synchronous observations should be made throughout Europe and the adjacent seas, so as to afford all possible facilities for synoptic charts of the weather in Europe. To this end this country should give all the help it can.

17. There is important evidence that the science of meteorology at the present moment stands in need of hypothesis and discussion at least as much as, if not more than, of observation. It is not easy to lay down any rule concerning the method by which such investigations may be promoted. But we think that the Council should be at liberty to appropriate a part of their annual grant to the purposes of any special researches which they may think important, and in such cases it should rest with them to select the investigators, and fix the remuneration.

18. There is evidence of a connection between weather and health; but it does not appear that any special meteorological observations are wanted at present, or are likely to be wanted in future for this special purpose, other than the observations, which, under the scheme we have recommended, the Council should collect for general purposes.

19. Again, the importance of meteorological data to the agriculturist and dealer in agricultural produce is clearly established. But neither do their requirements demand other observations than should be included in the general returns and information obtained by the Meteorological Council.

20. As regards the forms in which the information thus collected can be made most available for sanitary and agricultural purposes, it appears desirable that the Meteorological Council should place themselves from time to time in communication with the Registrars General, and with such bodies as the Medical Council, and the Agricultural Societies of the United Kingdom.

21. The expense of the scheme we have suggested may be estimated as follows:—

The following return has been prepared by members of our Committee who are also members of the Meteorological Committee of the approximate present cost of the Meteorological Office:—

	£
Director's office and general control	2,500
Ocean meteorology, excluding supply of instruments	1,500
Land meteorology including self-recording observations and supply of instruments	3,500
Telegraphy and storm-warnings	2,500
Total	£10,000

The modifications that have been proposed would lead to certain additions to the necessary outlay, among which may be specified—

	£
Remuneration of Council, say	1,000
Special scientific researches	1,000
Extension of telegraphy on Sundays . .	500
New land stations	1,500
Inspection of stations	500
Total	£4,500
Deduct for ocean meteorology transferred to Admiralty	1,500
Net increase	£3,000

This sum being added to the present grant of 10,000*l.* would bring the whole sum to be placed at the disposal of the Council up to 13,000*l.* yearly. Assuming the expense of ocean meteorology transferred to the Admiralty to remain under the new arrangement at its old figure, 1,500,[1] the whole additional annual burden on the National Exchequer proposed in the above suggestions is 4,500*l.* or 14,500*l.*, instead of the existing grant of 10,000*l.*

22. With reference to the Scottish Meteorological Society, the representations of which have been specially referred for our consideration, we desire to offer the following remarks:—

It seems essential that any grant of public money for the purposes that have been indicated in our recommendations, should be applied under the immediate responsibility of the Council, and that no expenditure should be incurred which those purposes do not absolutely require. There is evidence to show that a large and trustworthy amount of co-operation may be obtained in all parts of the United Kingdom, from observers who do not require remuneration for their service, and it seems very important that such co-operation should be fostered to the utmost. Any system of payment for meteorological registers which was not very strictly limited, would necessarily involve the concession of payments to all observers, and might entail a very large outlay which has hitherto been avoided, and which there is reason to believe is not at present really called for.

We are of opinion, therefore, that only such payments should be made from the grant placed at the disposal of the Meteorological Council to the Scottish Meteorological Society, as are necessary for obtaining observations at stations required for the purposes of the Council; for securing the proper inspection of stations the registers from which are required for the general purposes of the Council; for the needful compilation and check of such registers; and for meeting other charges directly arising from these services; or for special researches conducted by the Society with the approval of the Council; but that no grants should be made to ordinary observers, nor for any general purposes of the society which lie beyond the scope of the operations to be placed under the Council.

---

[1] See paragraph 25 of this Report.

23 We think that the same principle should be applied to all similar local bodies interested in the study of Meteorology, so that, in fact, no payments should be made to them except for results sought for by the Council

24. We have indicated above in very general terms the functions of the proposed Council, and we do not think it desirable to fetter their discretion by further details. We append, however, to this report a paper by a member of the present Committee of the Royal Society, who is also a member of our Committee, stating what, according to present experience, are, in his opinion, likely to be their duties

25 The later stages of the inquiry in relation to the transfer of oceanic meteorology to the Admiralty have raised some serious questions of expense, which the Government will, doubtless, require time to consider We think it only just to the Committee which has heretofore had the administration of the annual grant to report our opinion that very good and valuable work is being done by it, and that if funds were provided to admit of the more responsible and more extended action of the Council, as suggested in paragraphs 9 and 22 of our Report, and if, at least provisionally, some assistance were given to the Scotch Meteorological Society, the more immediate objects referred to our Committee would be met, and there need be no interruption of the Committee's operations pending the delay, if any, which may occur, whilst the feasibility of transferring oceanic meteorology to the Admiralty is being maturely considered by her Majesty's Government

It is important in connection with this part of the subject to bear in mind the strong claims which the Superintendent and other members of the existing staff have to continued employment.

26. In recommending the above changes we feel bound to express our sense of the great value of the disinterested services which, at the cost of much time and labour have been rendered during so many years by the Committee appointed by the Royal Society

27 We are aware that what we are proposing is still tentative only, and we recommend, in conclusion, that there shall be a further inquiry and report at the end of (say) five years

---

RESEARCHES ON THE SPECTRA OF METALLOIDS[1]

THIS paper was published by Mr. Thalen after Mr Angstrom's death. Mr Thalen states, in the introduction, that only the first sheet was printed during Mr. Angstrom's life, who in the remainder would have liked to alter some passages and add others Yet we take it that such alterations only would have referred to matters of detail, and that as far as the general conclusions are concerned the paper represents fairly Mr Angstrom's opinion on the important questions discussed therein Mr. Thalen has made the measurements, while the experiments were made by him in conjunction with Mr. Angstrom

After a few historical remarks the authors give the following judgment on the question of double spectra —

"We are far from denying that the lines of an incandescent gas may come out in greater number as the temperature, or perhaps only the quantity of radiating matter increases, or that some rays may increase much quicker than others in intensity But it is certain that the assertion of various physicists that the lines originally seen may disappear altogether, and that in this way the spectrum may change completely in appearance is as unlikely from a theoretical point of view as it is contrary to experience If such properties were real all spectroscopic researches would be rendered impossible as each element could play as far as its spectrum is concerned the parts of a Proteus.

"We do not deny that an elementary body may in certain cases give different spectra The absorption spectrum of iodine, for instance, is quite different from its emission spectrum obtained by means of the electric spark. All bodies existing in different allotropic states will give different spectra corresponding to these different allotropic states provided that the allotropic states still exist at the temperature of incandescence.

. . . .

"Oxygen, for instance, would present two different absorption spectra, one belonging to oxygen the other to ozone But as ozone is destroyed at a high temperature, only one spectrum of incandescent oxygen can exist

"Sulphur in the solid state exists in different allotropic states, and some observations lead us to believe that even as a gas it may exist in different states. Supposing this to be true, sulphur will give us several absorption spectra, while the possibility of a single or several emission spectra depends on the question whether the more complicated allotropic states support the temperature of incandescence.

"It is evident that the above cases do not form an exception to the general law which we have given, that an elementary body can only give one spectrum In fact, if we suppose that the allotropic state is due to molecular constitution, it will possess from a spectroscopic point of view, all properties of a compound body, and in consequence it will be decomposed in the same manner by the disruptive discharge of electricity."

The paper then goes on to discuss the difference which is noticed in the electric spark, between the aureole and the spark itself Messrs Angstrom and Thalen sum up what they have said on the subject in the following words —

1 There are two kinds of electric discharge, one of tension, which takes place by explosion, or disruptively, the other of quantity, which takes place by conduction, or continuously.

2 By the disruptive discharge which always takes place when the tension is sufficiently great, the body is, as a rule, torn into its smallest particles, and thus decomposed into its elements if the body is compound. The phenomenon of incandescence which accompanies both the mechanical disruption and chemical decomposition, cannot be considered as a consequence of the augmentation of temperature, but we ought rather to say that the high temperature is an effect of the mechanical and chemical force which disintegrated the body In addition to the decomposition produced directly by the disruptive discharge, we may have chemical actions, which are, however, of a secondary nature

3 When the electricity is conducted by conduction we must distinguish between two actions We have actions which are entirely due to heat, and which belong to the conductors themselves. They increase with the square of the intensity of the current. We have, secondly, actions which make themselves perceptible at the surface of bodies, and which are proportional to the intensity of the current These latter actions are confined in elementary bodies to a variation in temperature, but if the body is compound they may consist in chemical effects, which we call electrolytic actions. These two phenomena, the Peltier effect and the phenomenon of electrolysis, must be considered as different manifestations of the same force, one or other of the actions takes place according as the body is simple or compound.

These laws, which are demonstrated to hold for solid and liquid bodies, must also be applied to gaseous bodies, where we must therefore expect electrolytic actions as well as chemical ones of a secondary nature

Our authors then go on to discuss the spectra of carbon and their compounds. They begin again with a historical statement of the work done in this respect, and as this part of the paper does not contain anything new to those who are interested in the matter we pass to the question which they propose to solve: "How are we to explain all these different spectra of carbon compounds?" They draw attention to the fact that all these spectra have a common characteristic, as they consist of bands which can be resolved into fine lines There is, however, one spectrum which must be attributed to carbon, while the authors attribute all other spectra to carbon compounds. This spectrum is a line spectrum It is obtained from carbon poles by means of a powerful jar[1]

If we allow a spark to pass between carbon electrodes, the lines are not seen in the middle of the field, but only close to the poles similar to the metallic lines. If the discharge pass through some carbon compound, one obtains not only these carbon lines, but also those of oxygen, hydrogen, or nitrogen, that is, all lines belonging to the elements entering into the carbon compound.

---

[1] Abstract from a paper in the "Nova Acta Regiæ Societatis Scientiarum Upsaliensis," vol. ix., 1875, by A. J. Angström and T R Thalen

[1] It is the spectrum marked by Watts No IV.—A S

Round the electrodes of carbon we observe during the disruptive discharge an aureole, which indicates a continuous discharge. The spectrum of the aureole depends on the nature of the medium in which the discharge passes; in nitrogen we find the blue and violet groups which characterise cyanogen; in hydrogen it is the spectrum of the hydrocarbons[1] which we observe; in oxygen we get the spectrum which a Geissler tube, filled with carbonic oxide, shows.

The shaded bands of cyanogen which are situated in the blue and violet part of the spectrum, are also seen if the spark passes the luminous part of a gas flame, or in the voltaic arc between the carbon electrodes of a powerful battery. In the spectrum of the voltaic arc, however, the brilliant lines of cyanogen are mixed with those of hydrocarbons, the splendour of which is still more magnificent.

After these observations we may consider it to be a demonstrated fact that the aureole gives respectively the spectra of cyanogen, hydrocarbon, oxide of carbon, or carbonic acid, according as the gas which surrounds the electrodes consists of nitrogen, hydrogen, or oxygen. The most natural supposition is, therefore, that the spectra belong really to the compound bodies, which is the more probable as the general appearance of these spectra suggests at once an origin of compound bodies rather than of elementary bodies.

It is well known that carbonic acid is decomposed by the electric current, and that the spectrum which is observed belongs exclusively to carbonic oxide, which is formed. One might therefore imagine that carbonic acid would not have any spectrum of its own. If, however, carbonic acid is formed, as, for instance, while cyanogen burns, it appears probable that lines belonging to carbonic acid can appear, and this opinion has been confirmed by an observation of Plucker. He has found that the shaded red bands of cyanogen burning in air or in oxygen become stronger and wider as the combustion becomes stronger. An experiment made by us with a spark passing in cyanogen gas, circulating in a glass tube and freed therefrom by degrees of every trace of oxygen, has taught us that these red bands only extended to the first band of hydrocarbon, and even vanished during some instants of the experiment. The probable cause of the appearance of the spectrum of hydrocarbon in this case must be looked for in the impossibility of drying the gas completely, if it is prepared with cyanide of mercury.

It seems to us that it is much more difficult to explain the appearance of the spectrum of hydrocarbons in the combustion of any compound of carbon and hydrogen, and also, according to Mr. Attfield, in the flame of carbon disulphide. Though this spectrum was considered by some observers to be due to carbon, we cannot accept this view, and for this reason: If we employ a condensator the spectrum of coal gas shows not only the spectrum in question, but also the lines of carbon and hydrogen. The appearance of the shaded bands, being similar to those of cyanogen, shows at once, as we have repeatedly said, that the body is compound.

The difficulty, it seems to us, must in great part disappear if we could show that the same chemical compound is always formed in the combustion of any hydrocarbon. M. Berthelot has shown this to be true. According to him acetylene is formed whenever an incomplete combustion of any hydrocarbon, ether, &c., takes place, and even if the electric spark passes between carbon electrodes in hydrogen gas. It is therefore very probable that the spectrum which is formed for all carbon compounds is due to acetylene.

As far as the observation of Mr. Attfield is concerned, that oxide of carbon gives the ordinary spectrum of the hydrocarbons, we must observe that this does not agree with our own experiments. In a Geissler's tube, containing carbonic acid or carbonic oxide, one can certainly find traces of the spectrum of hydrocarbon, as the gas is never altogether dry, but according to Plücker's observation, the particular spectrum of oxide of carbon has no resemblance to it.

To the left of the Fraunhofer line G one sees generally a very strong line which really belongs to carbon. We find here the same thing which we have mentioned speaking of the spectra of the metallic oxides, that often the spectrum of the oxide is mixed with some of the lines of the elementary body.

As a second example Messrs. Angstrom and Thalen take the spectrum of nitrogen. The so-called line spectrum of nitrogen was first observed by Angstrom, while v. d. Willigen observed a different spectrum seen in the aureola when the discharge takes place in air. The two spectra which Plücker observed were therefore not new, though he gave a new way of obtaining them. The following is a translation of the author's remarks on the origin of the two spectra:—

As to the interpretation of these two spectra we think that they only depend on the way in which the electric discharge takes place, and belong to two different bodies. The spectrum of lines caused by the disruptive discharge must be attributed to nitrogen as it appears in Geissler's tubes under the same circumstances, which accompany the disruptive discharge, but the shaded bands belong doubtless to some combination of nitrogen formed by the discharge of quantity or by conduction.

. . . .

In the aureole at the positive pole we find a great number of shaded bands in which we distinguish two different series, one situated in the least refrangible part of the spectrum, and another in the green, blue, and violet parts. The appearance of these two series is different and gives rise to the suspicion that they belong to two different bodies. Whether this be true or not it is certain that their intensity varies much according to circumstances and in different ways.

At the negative pole we observe a bluish violet sheet the spectrum of which, situated in the green, blue, and violet, does not change with the nature of the electrodes.

In Geissler's tubes, containing rarefied nitrogen, we find for the continuous discharge the same spectra as in the aureoles in the atmosphere. But the positive light, which is very intense, is not only seen near the pole but also in the capillary parts of the tube. At the negative pole the bluish violet sheet gets larger and more brilliant as the exhaustion proceeds.

We now ask which combinations of nitrogen can cause the spectra of the continuous discharge? As far as the negative light is concerned we are in complete ignorance on the subject. As to the gas which is found at the positive pole one can prove by means of a solution of sulphate of iron that nitrogen dioxide is formed. It is well known that the electric spark passing through air produces the red fumes which indicate the existence of nitrous acid. It follows that nitrogen combines under these circumstances with oxygen. The only question therefore is, where does the oxygen come from in a tube filled with nitrogen? We must remember that in making nitrogen we can never entirely get rid of air, or at least there will always be a trace of aqueous vapour present, as is shown by the hydrogen line C. This fact sufficiently explains the possibility of the presence of a compound of nitrogen and oxygen. As the luminous spectrum bears no resemblance to the absorption spectrum of nitrous acid fumes, we conclude that the dioxide of nitrogen causes the shaded bands at the positive pole or in the aureole, and in the capillary part of Geissler's tube containing nitrogen. Several experiments are mentioned which have been made by the authors. Those on the spectrum of carbon run as follows:—

1. Spark between carbon electrodes in oxygen with condensator. The lines of oxygen and carbon are seen.

2. Spark between platinum electrodes, 35 mm., apart in a current of carbonic acid. Two jars used as condenser. The revolving mirror showed that the spark was instantaneous. The lines of platinum, carbon, and oxygen, were seen.

3. Same as 2. Distance of electrodes 5 mm. The aureole gave the spectrum of carbonic acid.

4. Spark between aluminium electrodes 10 mm. apart, in a current of coal gas. The lines of hydrogen, carbon, and the bands of carburetted hydrogen are seen.

5. Spark without condenser in a current of cyanogen. The lines of hydrogen, nitrogen were seen, besides the bands of carburetted hydrogen, and some bands of cyanogen.

The experiments on the spectrum of nitrogen have been made with atmospheric air. A solution of sulphate iron was used to show the presence of dioxide of nitrogen. The appearance of Geissler's tubes at various pressures are given.

Exact measurements of all the spectra discussed in the paper are given, not only for the more intense lines or bands, but exact micrometer measurements of some of the band. The names of the authors are a sufficient guarantee of the accuracy of these measurements. Excellent plates with drawings of the spectra are added. A copy of the measurements will be found in the first number of the *Beiblätter zu Poggendorff's Annalen*.

ARTHUR SCHUSTER

---

[1] Messrs. Angstrom and Thalen call Swan's spectrum of the candle the spectrum of hydrocarbons.

SIR WILLIAM THOMSON ON NAVIGATION[1]

POPULAR lectures rarely contain much that deserves repetition or notice in a review. But when the lecturer is Sir William Thomson and his subject navigation, we may be sure that we shall hear something that we have not heard before, and that we should hear, if we wish to keep abreast of the advance of nautical science. When a reformer contents himself with merely making suggestions and leaving it to others to test them, his work is comparatively easy and its results are proportionally valueless. The suggestions of Sir W. Thomson have the very special merit that they are submitted to a practical test before he gives them utterance, and after he has done so he is far from considering his connection with them over. Every part of every crude idea or novel appliance is submitted to a searching process of natural selection which must cost the author as much labour as to watch it gives the onlooker pleasure, and those who see only the final survival of the fittest cannot form anything like a just conception of the time and pains which have been bestowed on the rejection of the less fit.

We cannot here find space to notice those parts of the lecture which are the reproduction of old and received truths, interesting though these are by virtue of their skilful dressing. We must pass on at once to mention one or two points which are either in themselves new, or which have as yet failed to secure the recognition they deserve.

The first important novelty we come to is the discovery by Mr. Hartnup, astronomer to the Harbour Board of Liverpool, of a system of rating chronometers, which gives an almost perfect means of compensating for change of rate due to change of temperature. It had long been known that no compensation balance could be made to keep time correctly through wide ranges of temperature:—

"Thus the best chronometers of the best makers in modern times are practically perfect only within a range of 5° or 10° Fahrenheit on each side of a certain temperature, infinitely near to which the compensation is perfect in the individual chronometer.

"The temperature for which the compensation is perfect, and the amount of deviation from perfection at temperatures differing from it are different in different chronometers. Mr. Hartnup finds that at the temperature for which the compensation is perfect, the chronometer goes faster than at any other temperature, and that the rate at any other temperature is calculated with marvellous accuracy (if the chronometer be a good one) by subtracting from the rate at that critical temperature the number obtained by multiplying the square of the difference of temperature by a certain constant coefficient."

Two chronometers recently carried from Liverpool to Calcutta, when rated on Mr. Hartnup's plan, gave a mean error of six seconds, while by the ordinary method the reckonings of Greenwich time from them differed by 4 minutes 35 seconds. The navigator could easily secure the advantages of Mr. Hartnup's system by noticing the temperature of his chronometer-case daily, and entering a few figures in a note-book. His work would be much facilitated if the thermometer used were graduated to squares of numbers of degrees from the temperature of maximum rate.

The lecturer discusses at considerable length various modifications of the pressure-log, the invention of Mr. J. R. Napier and Mr. Berthon, the principle of which is to measure the speed of the ship by observing to what height a column of water rises in a vertical tube, the bottom end of which dips into the sea and faces forwards. It shows the ship's velocity through the water at any instant, instead, like all other logs, of telling the distance run during a known length of time. The latter piece of information is what is chiefly wanted for the purposes of ordinary navigation, but the former could not fail to be of immense use in the navy when ships are sailing in squadron. Even now, a rough approximation to a knowledge of velocity is got in the navy by the use of indicators showing the number of revolutions per minute made by the screw, and these satisfy very imperfectly the requirements of the case, as appears from the evidence given at the court martial on the loss of the *Vanguard*. The Admiral signalled to the squadron that his ship was about to go at thirty-three revolutions, which he afterwards explained to mean that he desired the squadron to go as nearly as possible at a speed of seven knots. Had each of the ships been provided with a pressure log, he might at once have given an order of whose meaning there could have been no possible doubt, and which it would have been perfectly easy for every ship to obey.

The taking of soundings to determine the depth is one of the most important of nautical operations. In surveys of the ocean's bed and for guidance in cable laying, soundings have to be made in great depths, often of several thousand fathoms. The trouble and time involved in taking a deep-sea sounding have been greatly reduced by Sir W. Thomson by the substitution of a single steel pianoforte wire for the hemp rope formerly used as a sounding line. The advantage of the wire is the comparatively small resistance it meets with in passing through the water. When hemp rope is used for sounding in deep water a weight of three or four hundred pounds must be attached to it, and even then it descends very slowly. When it reaches the bottom the weight is detached by a trigger and is therefore lost. When wire is used a weight of about thirty pounds suffices; it descends very much more rapidly, and there is nothing to prevent its recovery each time. For very small depths such as are met with in the immediate neighbourhood of land, the hand lead is convenient and sufficient, but there is a third class of soundings, those which are (or should be) made in depths of about twenty fathoms and upwards when a ship is approaching land. To be able to take "flying" soundings—that is, to find the depth without stopping the ship—in any depth from 20 to 150 fathoms, is a matter of the greatest possible importance in ordinary navigation. Sir W. Thomson has succeeded in making it easy to do this, by the aid of his pianoforte wire in combination with another apparatus which he described at the recent meeting of the British Association. This consists of a pressure gauge of very simple construction, which is attached close to the end of the sounding-line, and which, by registering the maximum pressure to which it has been subjected during immersion, registers the maximum depth it has attained. This indication is of course quite independent of the length of wire out, and is not affected by the fact that the ship is in motion. The pressure gauge consists of a small glass tube, of about $\frac{1}{10}$ inch bore, open at the lower end, but closed at the top. As this descends, the water rises in the tube compressing the column of air. In order that a permanent record may be left of the maximum height to which the water rises, the interior of the tube is coated along its whole length with starch, in which red prussiate of potash has been dissolved, and just at the mouth of the tube are placed a few crystals of sulphate of iron, which are held in position by an outer guard tube. The water which rises in the tube carries with it a little sulphate of iron in solution, and so leaves a permanent record of its height by staining the tube with Prussian blue. The system of sounding by wire has now had abundant trial, and its success is thoroughly established. Its author was, no doubt, quite within the limits of safe prophecy when he declared to the British Association in Glasgow that the old system of deep-sea sounding by hemp rope had done its last work on board the *Challenger*.

---

[1] Navigation. A Lecture delivered under the auspices of the Glasgow Science Lectures Association. By Sir William Thomson, D.C.L., LL.D., F.R.S., Professor of Natural Philosophy in the University of Glasgow, and Fellow of St. Peter's College, Cambridge. (London and Glasgow: William Collins, Sons, and Company, 1876.)

In proceeding to speak of astronomical navigation the author begins by giving a series of definitions which differ from those commonly given, by being based on no assumption as to the figure of the earth, so that they "designate in each case the thing found when the element in question is determined by actual observation." Thus the latitude of a place is defined as the altitude there of the celestial pole. After a flying shot at the British Statute mile, whose existence "is an evil of not inconsiderable moment to the British nation," he goes on to describe the various means of deducing a ship's place from observations of the heavenly bodies, giving the place of honour to Sumner's method, of the merits of which we had recent occasion to speak (NATURE, vol. xiv. p. 346).

To communicate information from ship to ship by signals is an object of first importance to the sailor. By day, in clear weather and with skilful men, the system of flag and semaphore signals at present in use in the navy is very complete and effective. By night, in clear weather, Capt. Colomb's method of flashing signals has been successfully used in the British navy for nearly twenty years, but its adoption has not been nearly so general as properly to meet the requirements of the case. On this point Sir W. Thomson says:—

"The essential characteristic of Capt. Colomb's method, on which its great success has depended, consists in the adoption of the Morse system of telegraphing by rapid succession of shorts and longs, 'dots' and 'dashes,' as they are called; and, I believe, its success would have been still greater, certainly its practice would have been by the present time much more familiar to every officer and man in the service than it is now, had not only the general principle of the Morse system but the actual Morse alphabet for letters and numerals been adopted by Capt. Colomb. A modification of Capt. Colomb's system, which many practical trials has convinced me is a great improvement, consists in the substitution of short and long eclipses for short and long flashes. In the system of short and long eclipses, the signal lamp is allowed to show its light uninterruptedly until the signal commences. Then groups of long and short eclipses are produced by a movable screen, worked by the sender of the message, and read off as letters, numerals, or code signals by the receiver or receivers. . . . Whenever the light of a lamp suffices, the eclipse method is decidedly surer, particularly at quick speeds of working, than the flash method, and it has besides the great advantage of showing the receivers exactly where to look for the signals when they come, by keeping the signal lamp always in view in the intervals between signals, instead of keeping it eclipsed in the intervals as in Colomb's method."

Is it too much to hope that before very long a knowledge of the Morse alphabet may form part of the elementary education of every boy and girl in the kingdom? Only then can the public awaken to a sense of the many uses to which such a knowledge could be put.

But there is a third set of conditions where signalling is more necessary as well as more difficult than in either of the other two. In fogs, by day or night, visible signals have to be given up as useless, and audible ones take their place. We may utilise Colomb's code or the Morse alphabet by giving short and long blasts on a steam whistle or fog-horn.

"But here again a very great improvement is to be made. Use instead of the distinction between short and long the distinction between sounds of two different pitches, the higher for the 'dot,' the lower for the 'dash.' Whether in the steam whistle or the fog-horn a very sharp limitation of the duration of the signal is scarcely attainable. There is, in fact, an indecision in the beginning and end of the sound, which renders *quick and sure* Morse signalling by longs and shorts impracticable, and entails a painful slowness, and a want of perfect sureness, especially when the sound is barely audible. Two fog-horns or two steam-whistles, tuned to two different notes, or when the distance is not too great, two notes of a bugle or cornet may be used to telegraph words and sentences with admirable smartness and sureness. Five words a minute are easily attainable. This method has the great advantage that, if the sounds can be heard at all, the distinction between the higher and the lower, or, as we may say for brevity, 'acute' and 'grave,' is unmistakable: whereas the distinction between long and short blasts is lost, or becomes uncertain, long before the sound is inaudible."

To produce powerful blasts of sound differing from each other in pitch the Americans have devised an instrument which is much more effective than the fog-horn or steam-whistle. By the irony of fate sirens are now enlisted in the service of humanity, and no longer lure sailors to destruction. The reform in their morals, however, has been fatal to their romantic charm, for now they are "driven at a uniform rate by clockwork, and the blast is supplied from a steam boiler." But is the change to be regretted when we hear that:—

"Short and long blasts of the siren might be advantageously substituted for short and long blasts of the steam whistle, but *much more advantageously* short blasts of two sirens on the same shaft, or on two shafts geared together, sounding different notes, acute note for the short, grave note for the long. The rapidity and the ready distinctiveness of character of the two notes will then be such that every officer and man will habitually recognise evolutional signals and signals for course and speed, just as in skirmishing every officer and private knows the bugle calls; and the signal-book will be no more needed on the bridge of a ship of war than on the saddle of a field officer. When the admiral desires to alter speed or course for the fleet, his order will be given to the whole fleet simultaneously, and very nearly as fast as he can speak it to his flag captain, and then instantly (without waiting to open signal-books) the other ships will, one after another in order, each in replying give the 'understand,' repeat the numbers expressing course and speed, and make her pennant. In as many quarter-minutes as there are ships under his command, the order will have been thus securely acknowledged by every one of them, and the admiral will sound his signal announcing that the order commences to take effect. Nothing short of this in quickness and sureness of ordering the movements of a fleet ought for a moment to [illegible]ught of as tolerable, when it is certain (as it assu[illegible]s) that so much is *readily* attainable."

We have quoted this part of t[illegible]ure at considerable length, for we have a strong conv[illegible] of its high practical value. The collision betwee[illegible] *Monarch* and the *Raleigh* in Besika Bay, which has h[illegible]ned since the lecture was published, serves to point Si[illegible] Thomson's moral. W[illegible] that when the squadro[illegible]s in three lines stea[illegible] [illegible]bout five knots an hour, [illegible] signal was made to alter [illegible]rse, which "from some unexplained cause" was m[illegible]stood by two of the ships—the *Triumph* and the *Inv*[illegible] This brought the latter across the bows of the *M*[illegible] which then stopped and reversed engines, but the [illegible] astern of the *Monarch*, kept on her course, the[illegible]ing a collision, which was fortunately much less [illegible] in its consequences than the costly *Vanguard* ex[illegible]ent, of which this one bid fair to be a repetition. That the signal was misunderstood, not by all the ships, and yet by two of them, seems to prove that much blame cannot be attached either to those who made it, or to those who read it; it is, in fact, the system that is at fault.

TYCHO BRAHÉ

BY the kindness of Dr. Crompton, of Manchester, we are able to publish this week a copy from a photograph of what there is every reason to believe is a contemporary portrait of the great Danish astronomer, Tycho Brahé. This picture is on canvas, and is 3 feet 3¾ inches high, and 2 feet 6½ inches wide. It represents a man of ruddy complexion, standing and looking forwards. He is bareheaded, has little hair, and that short, of a yellowish colour verging to red. He has very long moustaches and a short beard. In the right upper corner of the picture (that is, to Brahé's right) there is a curious emblematic design, consisting of a round tapering column springing from a square base, around which at its foot are waves. Over the monument is a canopy suspended by a strong chain, a few links only of which are visible, the top being lost in clouds, and the chain itself has flames playing round it. Two Æolic heads (one on each side) are represented as blowing towards the canopy and column. Lower down, and to the right and left of the column, are two hands (one on each side) holding each a jug from which water flows. Clouds and lightning surround the background, the wrists of the hands holding the jugs, and also the Æolic heads. Round the monument is a label not entirely decipherable with the words: "Stans (tectus?) in solido;" then follows an indistinct word and "igne e. tunda" (*sic*). "Igne et unda" was, no doubt intended. In the left upper corner, in large and distinct letters, is this inscription: "Effigies Tychonis Brahe, Otton. Da. anno 50 completo quo post diutinum in patria exilium libertati desideratæ divino provisu restitutus est."

Dr. Crompton thinks, correctly we believe, that the inscription referred to Brahé's departure from Denmark, and that the "exilium *in* patria" was an allusion to his residence on his island of Huenna, in his observatory, away from the court for twenty years. The emblematic picture evidently implies that nothing (not all the elements) could destroy the monument he had erected to his reputation by his observations, and that they would be protected by Providence.

The portrait then shows Brahé as he was in his fiftieth year, and Dr. Crompton thinks the tenor of the emblems and the inscription seem to be conclusive that the picture was painted after Brahé had left Denmark, most probably between the end of October and the 13th of December, 1597, and Dr. Crompton conjectures that the portrait may have been painted to be engraved for Brahé's "Mechanica."

In connection with this interesting portrait, it may not be inopportune to remind our readers of the main events in Tycho Brahé's life, and of the work on which his fame is grounded.

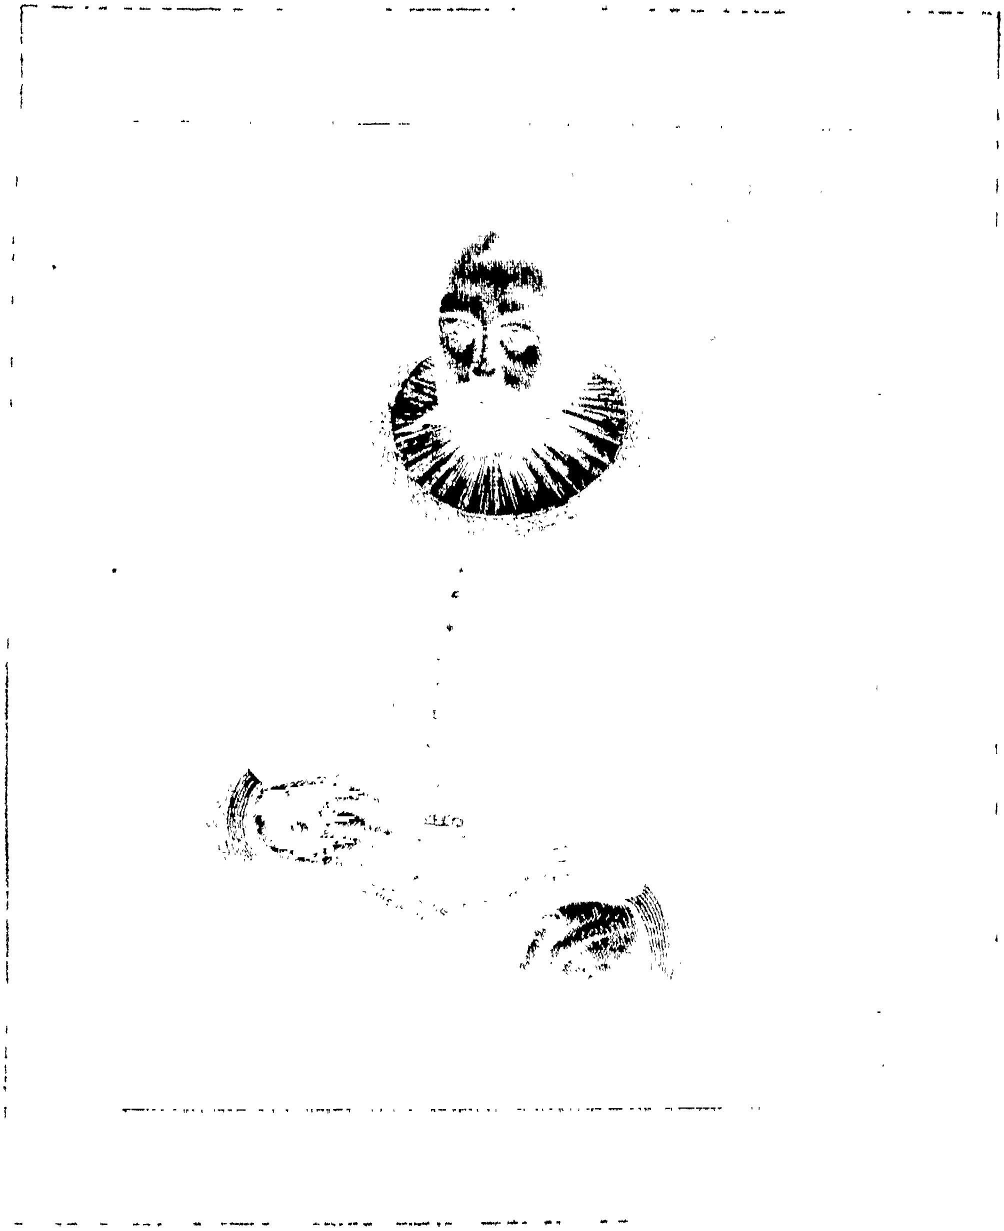
Tycho Brahé was born at Knudsthorp, an estate of his ancestors, near Helsingborg, in Sweden, on the Sound, December 14, 1546. Copernicus had been dead two years and a half, Galileo was not born till eighteen years after, and Kepler, with whom Tycho was latterly associated, was about twenty-five years his junior. Tycho's father, Otto Brahé was descended from an ancient Swedish family, and Tycho was the second eldest child, there being altogether five sons and four daughters in the family. Tycho, evidently much against his will, was destined for a military career. After the birth of another son, the father being in straitened circumstances, Tycho was adopted by his uncle, George Brahé. Until 1559 he appears to have been educated at home at his uncle's, learning reading and writing and Latin, with occasional instruction in poetry and belles-lettres. As it had now been decided that he should qualify himself for some political office in the kingdom of Denmark, Tycho, in April, 1559, was sent to the University of Copenhagen to prepare for the study of law. It seems to have been while pursuing his studies at Copenhagen that Tycho's mind was first strongly attracted to the study of astronomy. An eclipse of the sun was to happen on August 21, 1560, and Tycho was so struck by the precision with which the various details of the phenomena had been predicted by the astrological almanacs of the time that he was fascinated by, and resolved to master, so wonderful a science as astronomy, more especially, it would seem, that phase of it then universally believed in and cultivated, astrology. The planetary motions seem first to have claimed his attention, and these he studied by means of the *Tabulæ Bergenses* of John Stadius.

In February, 1562, Tycho was sent to Leipsic, under care of a tutor, to study law. For this, however, he had not the smallest inclination, and devoted all his spare time, when not in presence of his tutor, or when the latter was asleep, and all his pocket-money, to becoming master of the science for which he had contracted a passionate devotion. By means of what books he could command, and with a celestial globe about the size of an orange, he studied the heavens nightly, and soon came to discover that the results obtained by himself differed greatly from those of Stadius. "From that moment," says Brewster, "he seems to have conceived the design of devoting his life to the accurate construction of tables, which he justly regarded as the basis of astronomy." For this purpose he set himself to get up a knowledge of mathematics.

So rapid was Tycho's progress in mastering the astronomy of the day, and so skilful already had he become as an observer, that by means of a simple pair of compasses he discovered that both the Alphonsine and Copernican Tables had erred considerably as to the time of the conjunction of Jupiter and Saturn, which took place in August, 1563. His first instrument seems to have been constructed at the time, a wooden radius, which he got a Leipsic artisan, Scultetus, to devise for him in the manner recommended by Homelius, the professor of mathematics in that city. With this instrument he continued his observations. On his uncle's death, Tycho returned to Denmark about May, 1565, to take possession of the fortune which had been left him. His continued devotion to astronomy greatly offended his friends and relations, who considered such a pursuit as degrading to a noble as trade used to be in this country, and still is in most continental countries. Tycho was so annoyed at the attitude of his friends, that he left Denmark after staying a short time at Wittenberg, took up his residence at Rostock, where he stayed during the years 1566-68, steadily pursuing his celestial observations. It was in a duel at this place that he lost his nose, which was so ingeniously replaced by a substitute of silver and gold, that few could have detected it to be artificial.

From Rostock Tycho proceeded to Augsburg, where with the help of the brothers Hainzel, he constructed a magnificent quadrant of fourteen cubits radius. It was made of beams of oak bound with iron bands, the arcs being covered with plates of brass, divided into 5,400 lines. To enable him to observe distances, a sextant on a similar scale was constructed, and a wooden globe six feet in diameter was begun; hitherto his only instrument was the simple radius made at Leipsic. With his new instruments he continued his observations at Augsburg, with renewed enthusiasm. Tycho returned to his native country in 1571, and found a warm friend in an uncle Steno Bille, who had always taken his nephew's part against the taunts of his other friends, and who assigned him a part of his own house as an observatory. It was while living thus that one of the most notable events in the life of this great astronomical observer occurred, his discovery, November 11, 1572, of a new star in the constellation of Cassiopeia. This wonderful body probably made its first appearance in the heavens on November 5, and continued visible for sixteen months, rapidly increasing in brightness till in the second month it surpassed that of Jupiter, and was visible at noonday. It then slowly declined, and finally disappeared in March, 1574. It is curious that in the years 945 and 1264 something similar was observed in Cassiopeia, so that in fact the star observed by Tycho Brahé may be a variable one of long period, and if so may be expected to reappear about the year 1885. The colour of this star, moreover, changed; it was at first white, then yellowish, then reddish; afterwards bluish, like Saturn, getting duller and duller as it decreased in apparent size. After much persuasion Tycho, in 1572, published an account of his observations on the new star in a work "De Nova Stella."

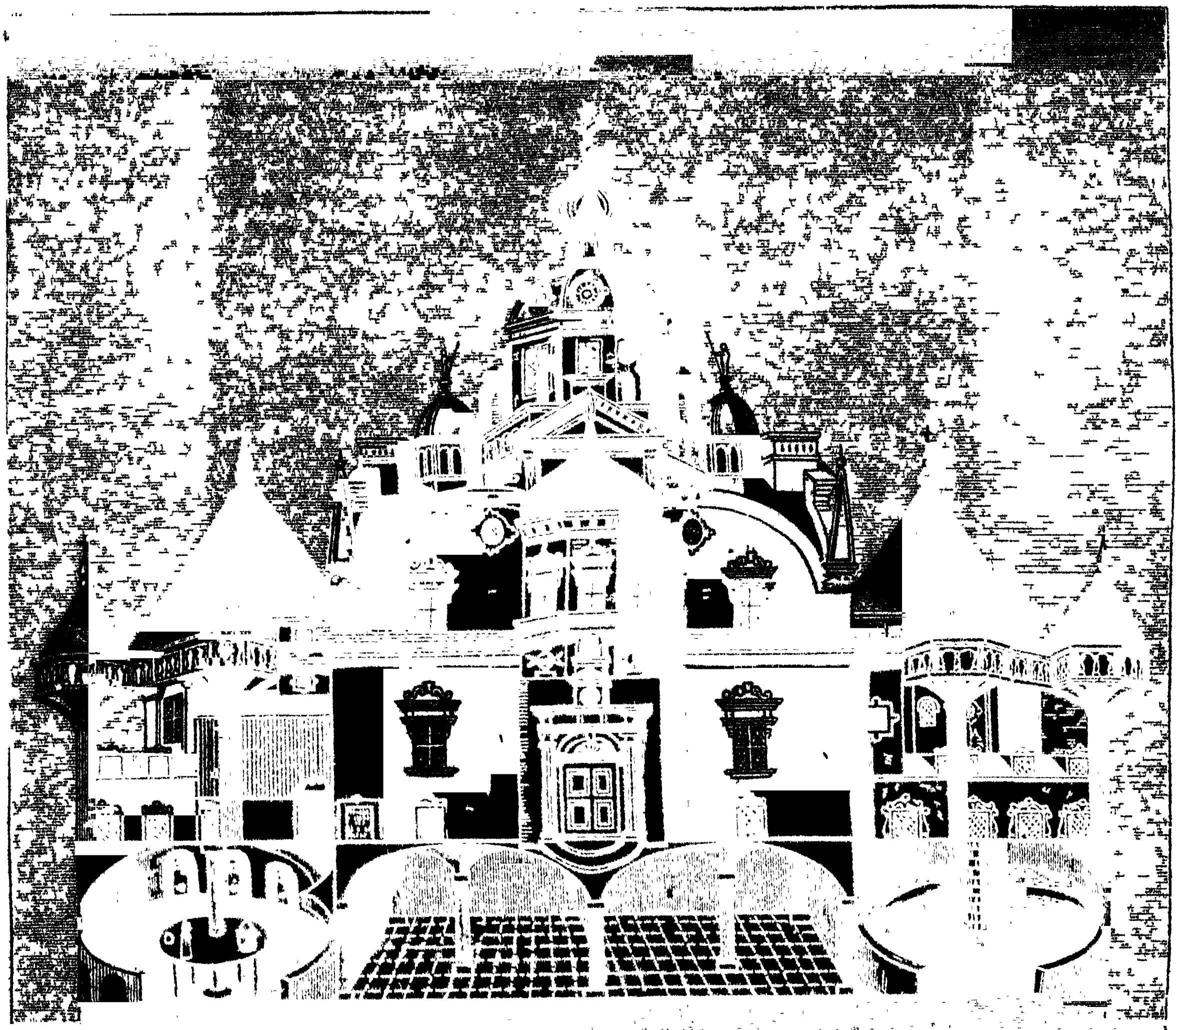
Tycho still further offended his relations by marrying a peasant girl in 1573, and shortly after, at the request of the King of Denmark, delivered a course of lectures on astronomy both in its observational and astrological aspects, for in astrology he still continued to believe. After travelling in Germany and Switzerland in 1575, Tycho returned to Denmark and received from the King, Frederick II., an offer which ought to immortalise the name of that monarch. The King seems always really to have admired the astronomer and estimated highly the pursuits to which he had devoted his life, and now realized it to be his duty, as head of the state, to put the man of science in the most favourable position to carry on researches which were then, as now, essentially unremunerative. In fact, in Frederick's treatment of Tycho Brahé we have an early and munificent, and in its results most successful, instance of the endowment of research.



Portrait of Tycho Brahé (from original painting in possession of Dr. Crompton, of Manchester).

The island of Huen lies in the Sound between Denmark and Sweden, about six miles from the latter and three from the former, and fourteen north-east from Copenhagen. It is somewhat rounded in form, six miles in circumference, and rises from the coast to its centre, where is formed a broad and level table-land. This island the King granted for life to Tycho Brahé, and on it erected a spacious observatory with every convenience for astronomical work and ample accommodation for Tycho's family and servants. A wide space around the central building was inclosed by high substantial walls in the form of a quadrangle, each angle corresponding to one of the cardinal points, and the centre of each wall extending outwards in the form of a semicircle. At the north and south angles were erected turrets of which one was a printing-office and the other the residence of the servants.

This main building was carefully and elaborately planned. It was about 60 feet square, had on the north and south points two round towers for observations, with windows opening to any part of the heavens. Besides a museum and a library there was in a subterranean crypt a laboratory with sixteen furnaces, for we ought to say that Tycho devoted much of his time to the alchemical pursuits of the time, mainly, it would appear, in the hope of being able to find in his crucible the fortune he was prepared to spend on his astronomical pursuits. Tycho Brahé needs neither to be defended nor blamed for his belief in astrology and alchemy; it was a universal belief in his time, a belief only got rid of by slow degrees and the thraldom of which no one man could shake off while at its very height, least of all a man with so much reverence for established beliefs as was Tycho Brahé.



Tycho Brahé's Observatory on the Island of Huen

A well forty feet deep distributed water to the building by means of syphons. An instrumental workshop stood outside the rampart to the north, and a sort of farmhouse on the south. The foundation-stone of Uraniberg ("the City of the Heavens"), as Tycho called his establishment, was laid on August 6, 1576.

Large as was Uraniberg, it was found insufficient for the accommodation of all the astronomer's instruments, and he therefore erected another, partly underground, for the sake of steadiness and solidity, on a hill a little to the south of the former; to this he gave the name of Sternberg ("City of the Stars"), which, by an underground passage, was connected with Uraniberg. Both buildings were in a handsome and regular style of architecture, as contemporary pictures testify, and cost the King of Denmark 100,000 rix dollars (20,000*l.*), and Tycho, it is said, an equal sum. Indeed, Tycho's expenses had so reduced his income, that the king gave him an annual pension of 2,000 dollars, an estate in Norway, and a canonry in the church of Rothschild worth 1,000 dollars per annum. Considering the difference between the value of money then and now, these sums for such a purpose may almost be considered munificent beyond example.

The magnificent set of instruments with which Tycho stocked the buildings were all made under his own superintendence, and according to his own designs, many of them having the merit of original inventions. For number, workmanship, and design, they were unequalled at the time. The following is a list of these instruments as given in Sir David Brewster's excellent memoir of Brahé, in "Martyrs of Science," on which the present notice is mainly based:—

In the South and greater Observatory.

1. A semicircle of solid iron covered with brass, four cubits radius.
2. A sextant of the same materials and size.
3. A quadrant of one and a half cubits radius, and an azimuth circle of three cubits.
4. Ptolemy's parallactic rules, covered with brass, four cubits in the side.
5. Another sextant.
6. Another quadrant, like No. 3.
7. Zodiacal armillaries of melted brass, and turned out of the solid, of three cubits in diameter.

Near this observatory there was a large clock with one wheel two cubits in diameter, and two smaller ones which, like it, indicated hours, minutes, and seconds.

In the South and lesser Observatory.

8. An armillary sphere of brass, with a steel meridian, whose diameter was about four cubits.

In the North Observatory.

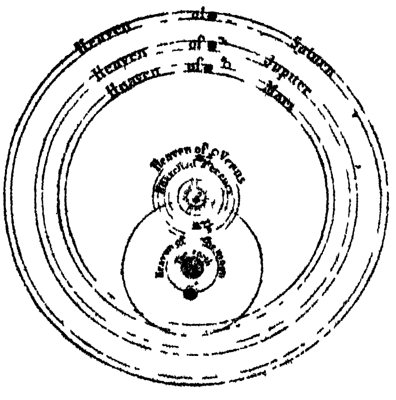
9. Brass parallactic rules, which revolved in azimuth above a brass horizon, twelve feet in diameter.
10. A half sextant, of four cubits radius.
11. A steel sextant.
12. Another half sextant with steel limb, four cubits radius.
13. The parallactic rules of Copernicus.
14. Equatorial armillaries.
15. A quadrant of a solid plate of brass, five cubits in radius, showing every ten seconds.
16. In the museum was the large globe made at Augsburg.

In the Sternberg Observatory.

17. In the central part, a large semicircle, with a brass limb, and three clocks, showing hours, minutes, and seconds.
18. Equatorial armillaries of seven cubits, with semi-armillaries of nine cubits.
19. A sextant of four cubits radius.
20. A geometrical square of iron, with an intercepted quadrant of five cubits, and divided into fifteen seconds.
21. A quadrant of four cubits radius, showing ten seconds, with an azimuth circle.
22. Zodiacal armillaries of brass, with steel meridians, three cubits in diameter.
23. A sextant of brass, kept together by screws, and capable of being taken to pieces for travelling with. Its radius was four cubits.
24. A movable armillary sphere, three cubits in diameter.
25. A quadrant of solid brass, one cubit radius, and divided into minutes by Nonian circles.
26. An astronomical radius of solid brass, three cubits long.
27. An astronomical ring of brass, a cubit in diameter.
28. A small brass astrolabe.

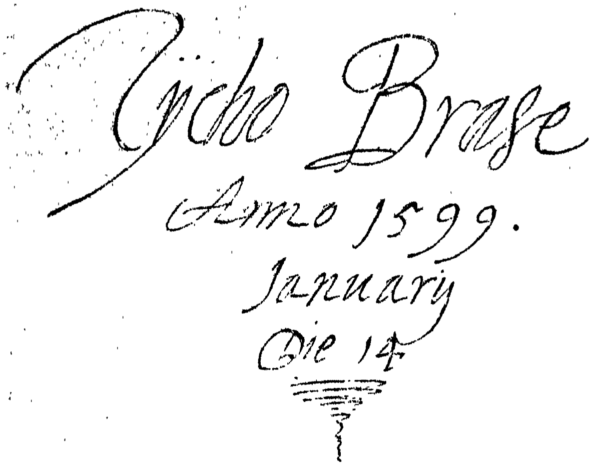
In the island of Huen Tycho resided and carried on his astronomical work for twenty-one years. The island itself was at the time fertile and well cultivated. The astronomer was virtually monarch of all he surveyed. He seems to have been loved by his subjects, and to have led a life of peaceful research and healthy contentment which any man of science of the present day might envy. Teaching was no condition of his tenure of the island and observatory, but his fame, which spread far and wide, attracted numbers of pupils eager to study under the great astronomer. Some of these were trained at the expense of the king, others were sent by different academies and cities, and several were maintained by the astronomer himself. Distinguished visitors were constantly arriving to do homage to the great man, and among these was our own James I., then, however, only James VI. of Scotland. This was in the year 1590, when the king was in Denmark to wed the Princess Anne. He spent eight days at Uraniberg, discussing various subjects with Tycho, and carefully examining all the instruments. He was so much surprised by what he saw and heard, that he granted the astronomer liberty to publish his works in England during seventy years.

Tycho Brahé might have peaceably ended his days in his pleasant island home, had his great patron Frederick II. lived; he died in April, 1588, and a new king, Christian IV., arose "who knew not Joseph," or at least cared nothing for him and his work. While Frederick reigned his courtiers of course, and many of them sincerely, professed to be passionately fond of astronomy; but as might be expected, Frederick's munificent kindness to Tycho made him many envious enemies. He continued to be tolerated for several years after the death of Frederick, but at last the young king's mind became so poisoned against Tycho by some of the courtiers, that he was deprived of his pension, his estate in Norway, and his canonry. With a wife, five sons, and four daughters, it was scarcely possible for him now to continue his work, but he stayed on till the spring of 1597, when he removed to Copenhagen. His persecution was brought to a crisis by a personal attack made on himself at the instigation of his chief enemy, the President of the Council, Walchendorp, in which one of his servants was injured. Tycho had the spirit to retaliate on his assailants, but almost broken-hearted he resolved to leave a country which had got tired of the glory of its greatest citizen, and which had nothing for him but persecution and insult. Fortunately he had many friends abroad among the nobles and princes of Europe. Among these was Count Henry Rantzau, who lived at the Castle of Wandesburg, near Hamburg, and who invited Tycho to take up his abode with him. Here then, with all his family, he went in the end of 1597, and here he wrote his "Astronomiæ instauratæ Mechanica," containing an account, with illustrations, of his various



Tycho Brahe's System

instruments and their uses, and also of his chemical labours. This work also contains views and plans of his observatory at Huen, and in the British Museum is an original copy presented by Tycho to his friend, Dr. Thaddeus Haggecius ab Hayck, Chief Physician to the Kingdom of Bohemia, and bearing the fine autograph which we here reproduce (one-half the size of the original). The work was printed at Wandesburg in 1598, and a copy, along with a MS. catalogue of 1,000 stars, was sent to the Emperor Rudolph II., a great lover of alchemy and astronomy. The result was an invitation to Tycho to go to Prague, with an assurance that he would receive the warmest welcome. Thither he went with his family in 1599, and most of his fine set of instruments followed soon after. An annual pension of 3,000 crowns was bestowed upon him, and the castle of Benach given him for residence, though in the beginning of 1601 he removed into Prague, to the house of his late friend Curtius, which the Emperor had purchased and presented to the astronomer. It was at this period that Kepler, then about twenty-nine years of age, lived and worked with Tycho, who procured for him the post of imperial mathematician, for which, however, Kepler never seems to have received any income.



Tycho Brahe
Anno 1599.

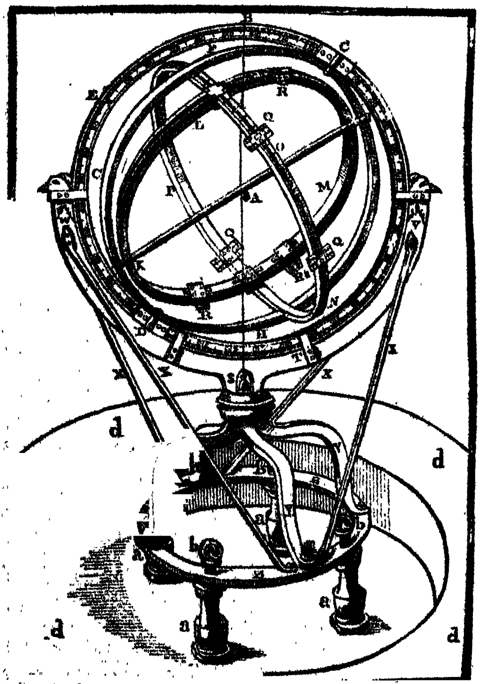
Die 14

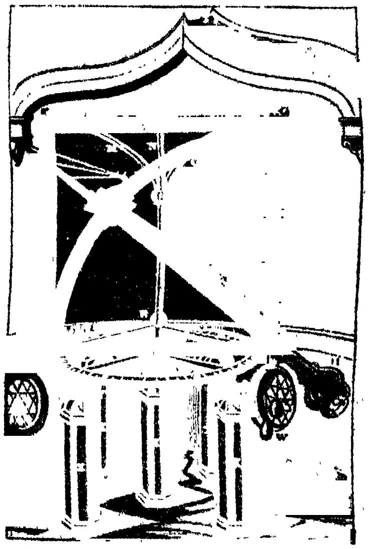
ARMILLÆ ZODIACALES.



Ecliptic Astrolabe (Tycho Brahé) similar to that used by Hipparchus.

Notwithstanding the munificent treatment of Rudolph, Tycho's misfortunes in Denmark must have told seriously on his health, and his end was near. He had a serious attack on October 13, which so told on his weakened constitution, that although the immediate cause was removed, his strength failed him, and he expired on the 24th of the same month, within two months of completing his fifty-fifth year.

QVADRANS MAXIMVS CHALIBEUS QVADRATO INCLUSUS, ET horizonti Azimuthali chalybeo inſiſtens.



Alt-azimuth of Tycho Brahé.

As to Tycho Brahé's work, we cannot do better than give the following summary by Sir David Brewster:—

"As a practical astronomer, Tycho has not been surpassed by any observer of ancient or of modern times. The splendour and number of his instruments, the ingenuity which he exhibited in inventing new ones and in improving and adding to those which were formerly known, and his skill and assiduity as an observer, have given a character to his labours, and a value to his observations, which will be appreciated to the latest posterity. The appearance of the new star in 1572 led him to form a catalogue of 777 stars, vastly superior in accuracy to those of Hipparchus and Ulugh Beig. His improvements on the lunar theory were still more valuable. He discovered the important inequality called the *variation*, and likewise the annual inequality which depends on the position of the earth in its orbit. He discovered, also, the inequality in the inclination of the moon's orbit, and in the motion of her nodes. He determined with new accuracy the astronomical refractions from an altitude of 45° down to the horizon, where he found it to be 34′; and he made a vast collection of observations on the planets, which formed the groundwork of Kepler's discoveries, and the basis of the Rudolphine Tables."

MINIATURE PHYSICAL GEOLOGY

THERE have appeared from time to time in the columns of NATURE, interesting and instructive letters on the subject of Miniature Physical Geology. May I be allowed to continue this subject, by pointing out a few lessons which may be learnt during spare half-hours on Ramsgate Sands.

Not far to the east of the harbour, there bubbles up a little stream, which, when the tide is low, flows for a considerable distance over the sands before it reaches the sea. Small as it is, this offers an excellent miniature example of a large river, and from it several things may be learnt. In the first place the river, when carefully watched, is seen repeatedly, and with more or less rapidity, to change its course. This is effected by the deflection, from some cause or other, of the main course of the stream against one bank; the result of which is that the bank is forced to recede, and, as it does so, it ceases to be a shelving slope, and becomes a tiny cliff of greater or less relative height. This bank continues to be rapidly undermined by the action of the stream, and the upper portions, now and again, topple over, with a little splash, into the water, in a manner with which those who have travelled on the Mississippi are well acquainted. In this way a bold curve is formed, which *increases in length downstream.*

In the meanwhile, on the opposite shore of the river, sand is deposited, and, as the river cuts its way downwards, this portion is left high and dry.

But, ere long, the deep water channel shifts—often rapidly, and without apparent cause—and the miniature river tends to resume a straight course; it recedes from its bank cliffs, and soon a tract of comparatively level dry land separates these banks from the stream. After advancing, however, for a while in this direction, until it there forms a curve similar to the one described above, it once more swings in the direction of its former course, until, by a continuance of the same processes, a broad valley is formed, with beautifully-marked river terraces on either side, showing the length of swing of the river on each occasion that it oscillates to and fro.

In the midst of the stream sand islands are from time to time formed, partly by the deepening of the main channel on one side or the other; but, no sooner has the sand of which they are composed become dry, than the treacherous stream commences the destruction of that which itself had produced.

This is exactly what is continually taking place in the Delta areas of most great rivers. In the Pará branch of the Amazons a large island (Parraqueet Island) has, within the last quarter of a century, completely disappeared. The Ihla Nova has arisen, and is now covered with a luxuriant vegetation.

During the repeated changes in the course of our miniature river, it is possible to watch the deposition of a layer of coarse sand on the partially-eroded surface of a bed of finer material, and it is interesting and instructive to notice how great a body of the coarse material is *dragged* along the bottom. Even in the most sluggish of my miniature streams the sand-grains might be seen rolling over and over each other as they travelled seawards.

In the more muddy flats of Pegwell Bay, I, on one occasion, had an opportunity of witnessing the formation of that which is known on the Mississippi as a "cut-off." The miniature stream bent round in a great loop, and as the flow of the water caused the concave banks to recede, the loop was gradually converted into a circle of water, and, the main stream flowing through the shortest course, left a "horse-shoe" lake, which was in time almost completely shut off from the miniature river.

Perhaps one of the most interesting of these spare half-hours may be spent in watching the formation of deltas. Numbers of these miniature rivers flow into pools, which are miniature seas or lakes. I have often seen one of the streams in the course of an hour fill up a considerable bay, and push its delta far out to sea. The grains of sand, when they come to rest in the pool, form a slope of very constant angle, which, by a number of measurements, I found to be 40° for coarse sand, and 34° for fine sand, the average angle being 36°. By watching the advance of the delta, the formation of false bedding may be seen in actual progress. But these pools, or miniature seas, which lie in depressions in the chalk, offer a field for the study of marine denudation. One may see, for instance, the waves advancing over a newly-formed delta, planing off the upper portion, and forming tiny cliffs of delta material, but leaving the deeper parts of the slope of the deposit intact.

Again, during gentle and steady breezes one may see the formation of drift-currents. I remember watching with interest such a current, which flowed between tiny chalk cliffs through the straits which separated two miniature seas; the most instructive point being that the finer grains of sand at the bottom of the straits, where the water was some 7 inches deep, were rolling over each other in such a manner as to prove the existence of an under-current setting *in the opposite direction* to that in which the surface-current was flowing.

There are many other lessons which may be learnt—such as the formation of fan-deposits (similar to those so plentiful in the Rhone valley and elsewhere in Switzerland), which are formed at the foot of the miniature chalk mountains that stand out from the sand; and the stoppage of the sand ripples, or miniature sand dunes, by the tiniest stream, reminding us of the way in which the Nile has preserved Egypt from total obliteration by this material; but I have already occupied enough of your space.

My object in drawing attention to such matters of ordinary observation is to induce students of physical geology to go out and observe these things for themselves. If, after a morning's study of Lyell's "Principles," the young geologist will devote an hour's careful observation to miniature physical geology, with sketch and note-book in hand, he will find that his conceptions have a reality and a solidity which could not have been evolved in the study at home, while at the same time he will find it more easy to follow, when he shall have the opportunity, the workings of nature on a grander scale.

C. LLOYD MORGAN

TESTIMONIAL TO MR. DARWIN.—EVOLUTION IN THE NETHERLANDS

WE have great pleasure in printing the following correspondence:—

To the Editor of NATURE.

Utrecht, February 20, 1877

On the sixty-eighth birthday of your great countryman, Mr. Charles Darwin, an album with 217 photographs of his admirers in the Netherlands, among whom are eighty-one Doctors and twenty-one University Professors, was presented to him. To the album was joined a letter, of which you will find a copy here inclosed, with the answer of Mr. Darwin.

I suppose you will like to give to both letters a place in your very estimable journal, and therefore I have the honour to forward them to you.

P. HARTING,
Professor, University, Utrecht.

Rotterdam, 6th February, 1877

SIR,—In the early part of the present century there resided in Amsterdam a physician, Dr. J. E. Doornik, who, in 1816, took his departure for Java, and passed the remainder of his life for the greater part in India. His name, though little known elsewhere than in the Netherlands, yet well deserves to be held in remembrance, since he occupies an honourable place among the pioneers of the theory of development. Among his numerous publications on natural philosophy, with a view to this, are worthy of mention his "Wijsgeerig-natuurkundig onderzoek aangaande den vorspronkelijken mensch en de vorspronkelijke stammen van deszelfs geslacht" ("Philosophic Researches concerning Original Man and the Origin of his Species"), and his treatise, "Over het begrip van levenskracht uit een geologisch oogpunt beschouwd" ("On the Idea of Vitality considered from a Geological Point of View"). The first already appeared in 1808; the latter, though written about the same time, was published in 1816, together with other papers more or less similar in tendency, under the title of "Wijsgeerig-natuurkundige verhandelingen" ("Treatises on the Philosophy of Natural History"). In these publications we recognise Doornik as a decided advocate of the theory that the various modifications in which life was revealed in consecutive times originated each from the other. He already occupies the point of vantage on which, shortly afterwards, Lamarck, with reference to the animal kingdom, and in his wake, Prévost and Lyell, with respect to the geological history of our globe, have taken their stand.

Yet the seeds scattered by Dr. Doornik did not take root in fertile soil. It is true that a Groningen professor, G. Bakker, combated at great length some of his arguments regarding the origin of man; it attracted but little public attention, and they soon passed into oblivion.

A generation had passed away ere the theory of evolution began to attract more attention in the Netherlands. The impulse was given by the appearance of the well-known work, "Vestiges of the Natural History of Creation," of which a Dutch translation was published in 1849 by Dr. T. H. van den Broek, Professor of Chemistry at the Military Medical College in Utrecht, with an introductory preface by the celebrated chemist, Prof. G. T. Mulder, as well known in England as elsewhere. This work excited a lively controversy, but its opponents were more numerous than its partisans. Remarkably enough, it found more favour with the general public, and especially with some theologians of liberal principles, than with the representatives of the natural sciences. The majority of zoologists and botanists of any celebrity in the Netherlands looked upon the writer's opinions as a chimera, and speculated on the weaker points rather than on the merits of the work. Notwithstanding, this presented no obstacle to a comparative success, and in 1854, even a third edition of the translation was published, enriched by the translator with numerous annotations.

Among the few Dutch *savants* to recognise the light which the theory of development spreads over creation, must be mentioned two Utrecht professors, viz., F. C. Donders and P. Harting. The former, in his inaugural address pronounced in 1848, "De Harmonie van het dierlijk leven, de openbaring van wetten" ("The Harmony of Animal Life, the Revelation of Laws"), expressed his opinion that, in the gradual change of form consequent upon change of circumstances, may be the cause of the origin of differences which we are now wont to designate as species. The latter, in the winter of 1856, delivered a series of lectures before a mixed audience, on "The History of Creation," which he published the following year under the title of "Voorwereldlijke Schoppingen" ("Antemundane Creations"), with a diffuse supplement devoted to a critical consideration of the theory of development. Though herein he came to a standstill with a "non liquet," yet it cannot be denied that there gleamed through it his prepossession in favour of a theory which several years later his famed and learned colleague, J. van der Hoeven, Professor at Leyden, making a well-known French writer's words his own, was accustomed to signalise as an explanation, "de l'inconnu par l'impossible."

In 1858 your illustrious countryman, Sir Charles Lyell, was staying for a few days in Utrecht. In the course of conversations with this distinguished *savant* on the theory of development, for which Lyell himself, at least in his writings, had shown himself no pleader, the learned of this country were first made observant of what had been and what was being done in that direction in England. He attracted attention to the treatise of Wallace in the Journal of the Linnean Society, and related how his friend Darwin had been occupied for years in an earnest study of this subject, and that ere long a work would appear from his pen, which, in his opinion, would make a considerable impression. From these conversations it was evident that Lyell himself was wavering. In the following edition of his "Principles of Geology," he declared himself, as we know, a partisan of the hypothesis of development, and Prof. Harting speedily followed in the same track. In his "Algemeene Dierkunde" ("General Zoology"), published in 1862, he was able to declare himself with full conviction a partisan of this hypothesis. Also another famous *savant*, Miquel, Professor of Botany at Utrecht, who had previously declared himself an opponent of the Theory of Development, became a convert to it in his later years, for although this is not expressed in his published writings, it was clearly manifest in his private conversation and in his lectures. To what must this conversion be attributed? With Harting and Miquel, as well as with Lyell and so many others in every country of Europe, this was the fruit produced by the study of your "Origin of Species," published in 1859, which first furnished one vast basis for the theory of development. That work, translated into Dutch by Dr. F. C. Winkler, now conservator of the Geological, Mineralogical, and Palæontological collections in "Feyler's Foundation" at Haarlem excited great and general interest. It is true that a theory, striking so keenly and so deep at the roots of existing opinions and prejudices, could not be expected at once to meet with general approbation. Many even amongst naturalists offered vehement opposition. Prof. J. van der Hoeven, bred up as he was in the school of Cuvier, endeavoured to administer an antidote for what he regarded as a baneful poison by translating into our tongue Hopkins' well-known article in *Fraser's Magazine*. However, neither this production nor the professor's influence over his students could withstand the current, especially when, after his death, the German zoologist, Prof. Emil Selenka, now Professor of Zoology at Erlangen, was appointed at Leyden. A decided advocate of your theory, he awakened in the younger zoologists a lively enthusiasm, and founded a school in which the conviction survives that the theory of development is the key to the explanation of the History of Creation.

In Utrecht, Prof. Harting, with convictions more and more decided, was busy in the same direction; and Selenka's successor in Leyden, Prof. C. K. Hoffmann, did not remain in the rear. Other names, among which are Groningen and Amsterdam professors, might here be cited. By the translation of your "Descent of Man" and "The Expressions of the Emotions in Man and Animals," with copious explanatory notes and by various original papers and translations treating on your theory, Dr. Hartogh Heys van Zouteveen has also largely contributed to the more general spread of your opinions in the Netherlands.

To testify how generally they are held in esteem among the younger zoologists and botanists, and more and more obtain among professors of analogous branches in this country, we might refer to a multitude of less important papers and articles in the periodicals.

This, however, we deem superfluous, since by offering for your acceptance an album, containing the portraits of a number of professional and amateur naturalists in the Netherlands, we offer a convincing proof of our estimation of your indefatigable endeavours in the promotion of science and our admiration of you, Sir, as the cynosure in this untrodden path. We recognise with pleasure Dr. Hartogh Heys van Zouteveen as the primary mover of such a demonstration of our homage. The execution, however, devolved upon the directors of the "Netherland Zoological Society," who reasoned that, with the presentation of this unpretending mark of esteem, a few words on the History of the Theory of Development in the Netherlands would not be entirely unacceptable, the more so, since this historic sketch clearly shows that, albeit some ideas in that direction had already been suggested here, yet to you alone reverts the honour of having formed by your writings a school of zealous and convinced partisans of the theory of development.

Among the names in the accompanying list you will observe several professors of Natural History, Anatomy, and Physiology at the three Dutch Universities, the "Athenæum Illustre" of Amsterdam, and the Polytechnical Academy of Delft, the Conservators of the Zoological Museums, the Directors of the Zoological Gardens, and several lecturers on zoology and botany at the High Burghal Schools.

Accept, then, Sir, on your sixty-ninth birthday, this testimony of regard and esteem, not for any value it can have for you, but as a proof, which we are persuaded cannot but afford you some satisfaction, that the seeds by you so liberally strewn have also fallen on fertile soil in the Netherlands.

We are, Sir, &c.,
The Directors of the Netherlands
Zoological Society,
(Signed) President, A. A. VAN BEMMELEN
Secretary, H. T. VETH

The following is Mr. Darwin's reply :—

Down, Beckenham, February 12

SIR,—I received yesterday the magnificent present of the album, together with your letter. I hope that you will endeavour to find some means to express to the 217 distinguished observers and lovers of natural science, who have sent me their photographs, my gratitude for their extreme kindness. I feel deeply gratified by this gift, and I do not think that any testimonial more honourable to me could have been imagined. I am well aware that my books could never have been written, and would not have made any impression on the public mind, had not an immense amount of material been collected by a long series of admirable observers, and it is to them that honour is chiefly due.

I suppose that every worker at science occasionally feels depressed, and doubts whether what he has published has been worth the labour which it has cost him ; but for the remaining years of my life, whenever I want cheering, I will look at the portraits of my distinguished co-workers in the field of science, and remember their generous sympathy. When I die the album will be a most precious bequest to my children. I must further express my obligation for the very interesting history contained in your letter of the progress of opinion in the Netherlands, with respect to evolution, the whole of which is quite new to me. I must again thank all my kind friends from my heart for their ever-memorable testimonial, and

I remain, Sir,
Your obliged and grateful servant,
(Signed) CHARLES R. DARWIN

THE NORWEGIAN NORTH-SEA EXPEDITION OF 1876[1]

Zoological Researches

AMONG the various scientific objects of our expedition the examination of the biology of those parts of the ocean which we traversed was one of the most important. We had with this view equipped ourselves in the best way with all the apparatus required for the purpose (dredges, trawl-nets, swabs, sieves, &c.), chiefly after the newest English models, a considerable quantity of ropes of various kinds, and heavy iron weights to hold the apparatus to the bottom were also stowed away in the hold of the vessel. There was besides procured a large quantity of glass vessels of different sizes and kinds, from small test-tubes to cylinders a foot in diameter, and a considerable stock of spirits for preserving the specimens that might be collected.

That the zoological material that might be brought up with the apparatus we have named might be arranged and the preliminary examinations made, which would be of great importance for the later working out, we considered it indispensable that as many zoologists as possible should accompany the expedition ; we also thought it right that a skilful artist should always be at hand. The zoological party consisted of Overlæge Danielssen, Grosserer Friele, and myself, and as artist we were fortunate enough to engage Herr Schiertz, landscape-painter, whose practised pencil and keen, all-embracing faculty of observation were exceedingly useful to us. There is a series of masterly-coloured pictures from his hand which will be a true ornament to the zoological treatises, which in course of time will be published on the work of the expedition.

The zoological work was divided in this way :—Overlæge Danielssen and Dr. Koren undertook the Echinodermata, Gephyreerna, and Corals ; Grosserer Friele, the Mollusca ; Dr. Hansen, the Annelida ; and I myself the other classes, the Crustacea, Pycnogonida, Polyzoa, Hydroida, Spongia, together with the lowest organisms standing on the boundary line between the animal and vegetable kingdoms (Foraminifera, Radiolaria, and Diatomacea), and that department of the researches which eventually concerns our salt-water fisheries. We have all been occupied for a considerable time in working out each his own portion of the collected material. But as this has been extraordinarily abundant, it has not been possible for any of us to bring his examination to a conclusion so that a detailed account of it can be given. As, besides, the more special results will be reserved for the collective work, which it is proposed to publish when the expeditions are concluded, it will be sufficient here to state some of the most important results of the expedition. It may also here be mentioned that these researches, carried on far out in the open sea from a comparatively small vessel, and at depths approaching 2,000 fathoms, are, even under the most favourable circumstances, attended with extraordinary difficulties, and occupy a comparatively long time. That we, notwithstanding the exceedingly unfavourable state of the weather during the expedition, were able to obtain such an abundance of zoological material, is due to the skilful and intelligent way in which the work was carried out by Lieut. Petersen, to whom Capt. Wille's command was given over.

During our expedition we had in all employed the dredge from the vessel sixteen times, the trawl-net twelve times, both these together twice, and the swabs but once ; there were thus no fewer than thirty-one separate casts, and of these only a few were unsuccessful, while most of them gave very satisfactory results. A net was also employed for examining the marine animals occurring in the upper stratum. Boat dredgings were also undertaken in Sogne Fiord, at Husoe, at Thorshaven in the Færoe Islands, and in the harbour at Reykjavik. Without entering on any detailed specification of the numerous animal forms thus brought from the depths of the sea, I will merely state that there are interesting species, new to science, of nearly all classes, of which complete descriptions and drawings will by-and-by be published

The greatest depth reached during the expedition was about 2,000 fathoms, almost half-way between Norway and Iceland ; there were several casts at depths of over 1,000 fathoms. The zoological researches were begun in Sogne Fiord, where the considerable depth of 650 fathoms was reached, the greatest depth which up to that time had been examined on our coasts. We found here the common deep-sea fauna known from earlier researches, viz., of Hardanger Fiord, and various rarities were collected ; among others a well-preserved specimen of the remarkable family, Brisinga, discovered by Asbjœrnsen (*B. coronata*, G. D. Sars), several specimens of the *Priapuloides bicaudata*, Danielssen, and great numbers of the beautiful haired *Munida tenuimana*, G. D. Sars, of which previously only very few specimens had been found.

Our researches, however, first attained their peculiar interest when we reached the extended barrier that lies along our coast on the west, the uttermost limit of which forms the so-called Havbro. Here below 300 fathoms begins the yet little examined cold area, with a bottom-temperature of from 0° to 1·6° C., and the fauna now, in correspondence with this temperature, exhibits a very peculiar character, totally different from that on our south and west coasts. Seventeen of our casts were in the cold area, and we have thus some idea of the peculiar physical and biological conditions prevailing there.

Over the extensive depression which occupies the greater part of the expanse of sea between Norway on the one side, and the Færoe Islands and Iceland on the other, the bottom below 1,000 fathoms appears everywhere to consist of a very peculiar, loose, but very adhesive, exceedingly light, nearly greyish white clay, which is very strongly calcareous, and, on being washed or passed through a sieve, appears to consist almost exclusively of shells of a little, low organism, belonging to the Foraminifera, Biloculina. We have therefore named this deep-sea clay Biloculina clay, to distinguish it from the kind of clay which occurs in the warm area at a great depth in the Atlantic Ocean, and which is called, after a very different Foraminifer, Globigerina. The Biloculina clay of the cold area contains a larger quantity of lime than the Globigerina clay of the Atlantic. It gives off, when treated with an acid, an uncommonly large quantity of gas, and when it is pressed and dried, it is converted in a short time into a very hard and compact sort of limestone. We have here a complete chalk or limestone formation coming into existence, and the fauna occurring here also bears a considerable impress of its ancient origin and close alliance with the organic remains preserved in the fossilliferous strata from the close of the Secondary period. First of all may here be named a fine, probably new Crinoid, over a span long, which was here obtained in numerous living specimens, and which shows an unmistakable resemblance to a few of the oldest fossil forms of this, in our time, almost extinct animal group; next a very peculiar and interesting holothuroid animal, colossal chalk sponges, and large numbers of a new and very peculiar Pycnogonide, also a remarkable blood-red coloured Crangon (*Reke*) with integuments thin as paper (Hymenocaris), besides several lower crustacea, for the most part new; the mollusc commonly occurring here is that which is so characteristic of our older glacial clay, the *Siphonodentalium vitreum*, M. Sars, which on our coast is first found living in the most northerly part of Finmark. The fauna in these great depths, though peculiarly interesting, both with reference to zoology and geology, appears however as a whole to be rather poor and without variety. The contrary is the case where the bottom begins to rise towards the sea banks. Here we find at a depth of 400 to 900 fathoms, but still within the cold area, an uncommonly abundant and varied animal life. Quite contrary to what we might be inclined to expect from the prevailing low temperature, so far is there from being any trace of hindering or preventing the development of animal life, in comparison with our coast fauna, that we find the rather as we go downwards an exceedingly remarkable luxuriance in the development of the fauna expressed both in the numerous and varied animal forms occurring here, and in the comparatively colossal dimensions which several of these here reach; indeed, one of the marine animals taken up here, belonging to the Umbellularia, had a length of quite eight feet. From the specimens which we got up with the help of dredges, trawl-nets, and swabs, we have been able, if only approximately, to form a sort of idea of the peculiar physiognomy which the sea-bottom here presents.

---

[1] [illegible] January [illegible] and [illegible]

Forests of peculiar Cladorhiza, with tree-like branches, here deck the bottom for long stretches. Between the branches sit fast beautiful medusa heads (Euryale), and variegated *fjær-stjerner* (Anteüon), and various crustacea, among them the marvellous object, Arcturus Baffini, known from the Polar Sea, and slow-moving Pycnogonida, partly of colossal size (up to a span between the extremities of the feet), creep along between their branches and with the help of their enormously-developed proboscis suck out their organic juices; a whole world of more delicate plant-like animals (Polyzoa and Hydroida) having at the same time fixed their dwellings on the branches and stems of the sponges when dead and deprived of their organic bark substance. In the open spaces between the sponge forests creep along beautiful purple sea-stars (Astropecton) and long-armed Ophiurids, together with numberless Annelids of various kinds, and round about swarm different sorts of Crustacea, long-tailed, bristly Decapoda (Crangon), finely-formed Mysida (Eyrthrops, Panerythrops, Pserdomma), masses of Amphipoda (Anonyx), and Isopoda (Munnopsida). Above all project, like high mast timber in a coppice, the predominating Umbellularia with their delicate straight stems and elegantly-curved crowns set full of fringes of polyps. The light of day does not, properly speaking, penetrate to these great depths, but as a compensation there is produced, by the animals themselves, a splendid illumination of the whole, inasmuch as almost all are strongly phosphorescent, or have the power to produce from their bodies an intense light, by turns bluish, greenish, and reddish.

So often as our bottom-scraper or trawl-net found bottom in that region which, after the animal type that was undoubtedly the most prominent and characteristic, we named the region of the Umbellularia, we were certain to have a rich zoological prize, and the day was indeed in most cases unfortunately quite too short for the proper examination and preservation of all those treasures fetched up from the depths of the sea.

Higher up, in a depth of 300 to 100 fathoms, and at a distance from the coast of from ten to twenty Norwegian miles (about 70 to 140 English), begins that extensive barrier which forms, as it were, the foundation on which our land rests, and by which the cold Polar Sea depths are shut off from it. This barrier begins in most cases with a hard, stony bottom, so that our dredgings were here attended with great difficulties. Numerous rolled stones, whose smooth rounded forms and worn edges clearly enough show that they had at one time been subjected to the powerful action of ice, lie here strewn on the sometimes very uneven bottom, consisting of solid rock, and prevent the dredge from acting properly, or fill up its mouth so that only incomplete specimens of the animal world living here can be obtained. The fauna has here quite altered its character, and more resembles that common on our coasts; but it appears to be a rule that below this point at the border of the barrier it is considerably richer than that nearer the shore, a fact which also stands in full agreement with the long known great abundance of fish at these places.

When we finally survey what here can only in a general way be pointed out concerning the physical and biological relations of the tract of sea we traversed we may, both in a physiographic and a zoological respect, divide the depths of the sea surrounding our country into two regions differing greatly in character, namely, the warm and the cold areas. The first occupies the whole Skagerak and the North Sea, and farther north the sea along our coast to a distance of ten to twenty Norwegian miles, including herein all the fiords cutting deeply into the land, and stretches towards the north to the northernmost point of Finmark. The cold area commences where the bottom begins to sink from the sea-banks towards the great deeps lying beyond them, and towards the south reaches nearly to the latitude of Stadt, and towards the south-west extends in the form of a narrow wedge in between the Færoe and the Shetland Islands as far as the 60th degree of latitude. Towards the north the cold area extends to the Pole, which properly is its central point. We have examined it at one of the points where it extends farthest to the south, where it has shown itself to be everywhere very sharply and distinctly defined from the warm area. As we proceed farther north, the boundary between the two becomes less distinctly marked, inasmuch as the cold area little by little raises itself from the depths, until in the Polar Sea it finally rises to the surface, and thus also occupies the littoral region, the warm area being at the same time greatly diminished in extent. The close correspondence with the above-described peculiar physical conditions in the sea surrounding our country has been to a very considerable degree explained by the experience obtained during our expedition, and thus a very important contribution has been made to the meteorology of the sea in general. A fuller explanation of these purely physical phenomena is also of the greatest importance to us zoologists for the right understanding of the different biological conditions in the sea; but as such an explanation belongs properly to the physical-meteorological researches, I will not here enter farther upon it, but keep to the more purely zoological side of the matter.

With regard to the character of the fauna in the cold area, it is purely arctic or glacial without any southern mixture whatever; and we have already been able to identify several of our species with types before collected in the Polar Sea during the various North Polar expeditions fitted out in Sweden, Germany, England, and America. In higher latitudes those animal types, which in that part of the sea which we examined are only found below the 400 fathoms' line, live in comparatively shallow bands, indeed even in the upper stratum of the sea, which interesting fact appears still further to confirm the view held by several men of science that the distribution of animal life in the sea is mainly dependent on temperature, depth having only a comparatively limited influence upon it. The purely Arctic fauna which prevailed on our coasts during the Glacial period, and which has left behind its traces in the glacial clays and in the older glacial shell banks, has, under altered meteorological conditions, little by little drawn down to the depths, where the effect of these conditions was less sensible, while the places which it inhabited have been occupied by more southern, immigrating types. At great depths in our fiords which run far into the land, a remnant of the original Arctic fauna has been able to maintain itself. But this is clearly only a fortuitous circumstance, as clearly enough appears from the generally small size and stunted appearance of these animal types, and their complete extinction is probable. This we are now, after having acquired an accurate acquaintance with the temperature of the sea, able to explain on purely physical grounds. For even to those deep pools in our fiords the influence of the milder climatic conditions has at last reached, so that at depths of 650 fathoms there is a temperature of 6° C., which may be supposed to have a prejudicial influence on the growth of these types. On the other hand, the temperature off our sea-banks at a much smaller depth remains unchanged, such as it was in the Glacial period, both here and close to our coast, and therefore we find also here, even at a remarkably southern latitude, no impoverished and stunted, but as luxuriantly developed an Arctic or glacial fauna as high up in the north in the Polar Sea.

The very important light which from the side of meteorology may be thrown on several yet obscure phenomena in the development and distribution of organic life as on the other hand the often considerable aid meteorological researches may obtain from purely biological facts, render it desirable that these two sciences, which may appear very different, do not become strangers to each other but mutually come into closer alliance with the object in view, to contribute to the scientific solution of the many yet unsolved physical and biological problems.

(*To be continued.*)

OUR ASTRONOMICAL COLUMN

THE BINARY STAR ξ BOOTIS.—Dr. Doberck, of the Markree Observatory, has published elements of this revolving double-star, which appear to represent very satisfactorily the measures up to the present time, allowance being made for some obvious errors of observation. The orbit, which differs materially from those calculated upon shorter series of measures by Mädler, Herschel, and Hind, is as follows:—

Peri-astron passage, 1770·44. Period, 127·97 years.
Node ... 12° 1′ Inclination ... 37° 53′
Node to peri-astron, on orbit ... 130° 54′
Eccentricity ... ... 0·6781
Semi-axis major ... 4″·813

At the epoch 1782·28 these elements give the position 24°·1, distance 3″·64; and for 1804·25, position 352°·5, distance 6″·53; for Dembowski's epoch 1870·87 the errors are + 0°·3 and − 0″·11. The following figures are deduced from Dr. Doberck's elements:—

1876·0,	Pos.	283°·7	Dist.	4″·29	1892·0,	Pos.	224°·7	Dist.	2″·35
1880·0,	,,	274·5	,,	3·84	1896·0,	,,	188·2	,,	1·82
1884·0,	,,	262·8	,,	3·36	1900·0,	,,	111·9	,,	1·31
1888·0,	,,	247·1	,,	2·86					

Dr. Doberck has now investigated elements of σ Coronæ Borealis, τ and λ Ophiuchi, μ^2, 44 and ξ Bootis, γ and ω Leonis, η Cassiopeæ, and several other stars, thus greatly adding to our knowledge of the orbits of the binaries, his discussions being at the same time conducted in a very exhaustive manner, to date.

VARIABLE STARS.—In No. 2,119 of the *Astronomische Nachrichten* are observations of a number of variable stars, made in 1875 by Mr. Chandler of New York. There was a well-marked minimum of that irregular variable α Herculis on August 21; the observations of W and X Sagittarii are worthy of note, as they support the results previously given by Prof. Schmidt, of Athens, and are stated to have been made without any "pre-occupation of mind in the observer," who had no previous knowledge of the character of the light variations. Schmidt's period for W, is 7·5933 days, and for X, 7·0119 days; another star in the same constellation, U Sagittarii of the last catalogue by Prof. Schönfeld, is assigned a period of 6·7452 days. The three stars were added to the variable star list by the indefatigable director of the Observatory at Athens, in the summer of 1866.

Mr. J. E. Gore (Umballa, Punjab) writes, suggesting the variability of Lalande 42360. The place in the catalogue depends upon an observation made August 7, 1793, when the star was rated 7m. Argelander ("Bonn Observations," vol. vii. p. 181) identifies this star with No. 42383 of the catalogue, observed as an 8m., September 29, 1791. Considering that there is an error in the record of the time of transit; the declinations closely agree.

DAMOISEAU'S TABLES OF JUPITER'S SATELLITES.—Independent extensions of these Tables, which run out in 1880, have been made in Europe and America. Prof. Coffin, superintendent of the American Ephemeris, notifies an extension to 1900, which has been carried into effect by Mr. D. P. Todd, we believe under the superintendence of Prof. Newcomb. The work will be sent to any library or astronomer possessing a copy of the Tables, on application to the office at Washington. Before the time named it may be hoped that both as regards theory and observation, the laborious operation of forming new Tables may be justified by the certainty of obtaining results which will enable us to predict the phenomena of the satellites, with considerably greater accuracy than can be effected by the use of Damoiseau's Tables. And we may also express the hope that as regards systematic observations, the Astronomer-Royal's urgent recommendation will not be lost sight of.

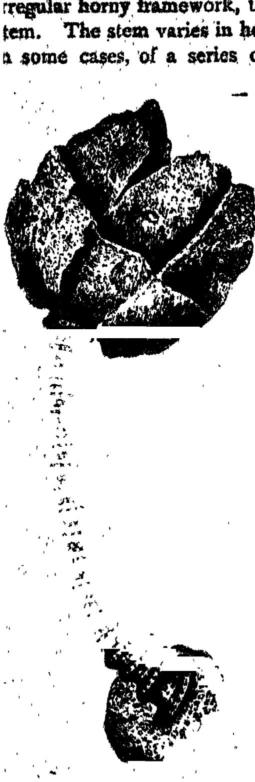
BESSEL'S TREATISES.—Volume iii. of the reprint of the more important of the many papers by Bessel on astronomical and other subjects, which completes the work, was issued a short time since by Dr. Engelmann, and comprises geodesy, physics, and general astronomical subjects, as the libration of the moon, shooting-stars, the mass of Jupiter, and the theory of eclipses. Speaking of the work as a whole, it will prove a very valuable aid to the student of Astronomy, affording him without the labour and difficulty of consulting a number of publications, the means of acquainting himself with the principal memoirs of the illustrious Professor of Königsberg, who may be said to have revolutionised the practice of astronomy. Dr. Busch's "Verzeichniss sämmtlicher Werke, Abhandlungen, Aufsätze, und Bemerkungen, von F. W. Bessel," printed in vol. xxiv. of the Königsberg observations, and subsequently in a separate form, contains 385 articles, and we believe, with only one or two exceptions, Dr. Engelmann's three volumes will be found to contain all that are of more permanent interest and value.

BIOLOGICAL NOTES

THE ELECTRIC EEL.—Since Humboldt's discovery of the electric eel and his observations of its peculiar properties, carried out unfortunately before the discovery of the voltaic pile, strange to say, no attempt has been made to study this remarkable reptile in its natural surroundings. In view of this fact, the Berlin Academy of Sciences sent the well-known histologist and physiologist Dr. Carl Sachs, last September, to the scene of Humboldt's former activities, well equipped with an ample supply of electro-physiological apparatus, and means for carrying out an extensive series of observations. In the last session of the Academy a letter dated December 7 was read from Dr. Sachs, in which he stated that he had safely performed the journey from Caraccas, over the Cordilleras, to the *Llanos*. The gymnotus had disappeared from the neighbourhood of Rastro, where Humboldt's investigations took place, but at a distance of a few miles from the city of Calabozo, a river was found fairly alive with the dreaded *temblador*. In the five days which had elapsed since the discovery of the locality, many valuable results had been afforded by the observations, and there was every prospect that the expedition would yield a large number of new and important additions to our knowledge of the electro-motive organs.

EARLY DEVELOPMENT OF SPONGES.—At a meeting, on February 8, of the Société Vaudoise des Sciences Naturelles, Prof. Forel spoke on an interesting occurrence o an early development of sponges in the Lake of Geneva, due to the unusually mild winter of this year. The fluviatile sponge of the lake consists of a horny skeleton with very fine siliceous spiculæ, covered with a sheet of soft, perforated anima matter. Usually, in autumn, this soft matter leaves the exterio ramifications and condenses under the form of small gemmule half a millimetre in diameter, in the deepest interior parts of th horny skeleton. There it remains until the spring, when expands anew upon the ramifications, and covers them with sheet of living animal matter. But this year M. Forel observe on February 2, besides many sponges in their hibernal state, colony of other sponges which had already reached their fu summer development, differing only by a somewhat paler colo rom the usual summer appearance. The occurrence is perfectly xplained by the circumstance that the temperature of water in he Lake of Geneva was this year higher by two degrees than he average temperature for many years, which is 6°·3 Cels. for December and 4°·9 for January.

A NEW SPONGE.—Prof. E. Perceval Wright describes (*Proc. R. Irish Acad.*, vol. ii., ser. 2, part 7) a beautiful little sponge ound growing on the fronds of some species of Red Seaweeds rom the coasts of Australia, of which we give the accompanying illustration. The largest specimens measure not three millimetres in height. The sponge consists of three distinct and well-marked portions: firstly, a small basal disk; secondly, an elonated stem, on the summit of which expands the third portion, or apitulum. The disk is button-shaped, flat, and is formed of an irregular horny framework, twice to three times as broad as the tem. The stem varies in height, and presents the appearance, n some cases, of a series of margined rings, some twenty in number, fastened together one on the top of the other; in others the margins of the rings will be more prominent, and the bodies of the rings will be, as it were, more deeply sunk. In both these cases the horny framework is of a more or less evenly latticed character, the longitudinal lines of the lattice being very prominent. The head portion, in its natural state, probably presents a more or less spherical form, perhaps slightly flattened on the summit, with an indication of being divided into four nearly equal parts, the open space between these leading into the body-cavity of the sponge. In some of the specimens the head portion nearest to the stem seems to have been formed of a somewhat denser framework than the upper portion, so that while being pressed this upper portion has been fractured across. The framework here is of a densely-reticulated kind, in appearance reminding one of the reticulated network of the intracapsular sarcode in Thalassolampe, or of the tissues met with in some Echinoderms. This sponge has been called *Kallispongia archeri.* The wonderful mimetic resemblance which it bears o some Crinoid-forms can scarcely be overlooked. Leaving the exture and composition of the skeleton mass for the moment out f view, and simply looking at its outline—the circular disc-like ase, the stem—the profile of which is absolutely the same, xcept as to size, as that of the pentacrinoid stage of *Antedon osaceus*, and the slightly cleft head, the resemblance is very reat. So far as is known, this is a unique case among the ponges, and one is left to wonder what may be the tiny enemies rom which *Kallispongia archeri*, by this complete disguise, conceals itself.



Kallispongia.

WILD DOGS ON THE OBI.—An interesting occurrence of dogs hich have reverted to the wild state is reported by M. Poliakoff rom the neighbourhoods of Soorgoot on the Obi, and Tobolsk. The size of these animals is somewhat larger than that of he dogs of the locality, but less than that of wolves; their abits being rather remarkable the inhabitants would not acknowledge them to be common dogs, and the hunters preserved he skins of the individuals they happened to kill, as rare samples of unknown animals. M. Poliakoff could not, however, detect in the skins he describes any deviations from the common dog type, except the larger size, and perhaps a somewhat greater length of body, with comparatively shorter legs (at Tobolsk). But the habits of these animals are certainly wolf-like; they inhabit woods and live by hunting, which they carry on in companies. Ten individuals were thus well-known at Soorgoot as hunting in company the wild reindeer, and latterly they approached the settlements, causing a panic among the inhabitants by the ravages they made among cattle. They hunted always together, assailing their prey simultaneously. They are reported also to be far more voracious than wolves, and their habits, M. Poliakoff observes, resemble much those of the red highland wolf (*Canis alpinus*) of Eastern Siberia.

THE WOODPECKER.—At the session of the German Ornithological Society, on February 8, Prof. Altum gave an interesting address on the ordinary woodpecker, embodying a portion of the results of over seven years' observation. With regard to the question of how the woodpecker finds the trees inhabited by insects, he had noticed that it almost invariably resorted to such trees as bore the diseased look consequent upon the presence of insects, manifested by the smallness and fewness of the leaves, the absence of the usual fresh colour of the bark, &c. In some cases it is deceived, especially where new varieties of trees have been set out. When it has detected a hole bored in the bark by insects, it follows the course of the passage under the bark by a gentle tapping with its bill, until it reaches the place where the larvæ are situated, when, by tearing off large portions of bark, its food is laid bare. Among the insects not eaten by the woodpecker are such as the *Cerambyx heros*, which bores too deep into the wood, or small insects such as the *Bostichidæ*, living in the bark of the pine tree, which is difficult to penetrate. The presence of the woodpecker is good for a forest, in so far as it destroys the insects upon the trees. It however injures the latter frequently by tearing off large pieces of bark, and indirectly by eating the useful wood-ants. The statement that woodpeckers made incisions in trees free from insects, for the purpose of sucking the sap, was disproved by Prof. Altum, on ground of repeated observations.

SAGACITY OF A LOBSTER.—A few days ago, at the Rothesay Aquarium, a tank containing flat fishes was emptied, and a flounder of eight inches in length was inadvertently left buried in the shingle, where it died. On refilling the tank it was tenanted by three lobsters (*Homarus marinus*), one of which is an aged veteran of unusual size, bearing an honourable array of barnacles; and he soon brought to light the hidden flounder, with which he retired to a corner. In a short time it was noticed that the flounder was *non est.* It was impossible the lobster could have eaten it all in the interim, and the handle of a net revealed the fact that, upon the approach of the two smaller lobsters the larger one had buried the flounder beneath a heap of shingle, on which he now mounted guard. Five times within two hours was the fish unearthed, and as often did the lobster shovel the gravel over it with his huge claws, each time ascending the pile and turning his bold defensive front to his companions.

THE INFLUENCE OF TEMPERATURE ON THE NERVE- AND MUSCLE-CURRENT.—M. Steiner has proved (*Reichert's Archiv*) that the electromotive force of the nerve-current from 2° upwards, is greater the higher the temperature, that it reaches a maximum between 14° and 25°, and at higher temperatures decreases again. The force of the muscle-current is likewise, from 5° upwards, greater the higher the temperature; it has its maximum between 35° and 40°, and at higher temperatures becomes less again, till, when rigidity sets in, it is almost *nil*. Thus, for the nerve and muscle-current, as well as for other functions of living organic forms, there is a *temperature optimum*; which is as distinctly marked when, by heating, we rise to it from lower temperatures, as when we descend to it by cooling from higher temperatures.

FERTILISATION OF FLOWERS BY BIRDS.—In an interesting article by Prof. Asa Gray, in the *American Journal of Science and Arts*, on Darwin's recent work the writer notices what Darwin says about the fertilising of flowers by birds, chiefly humming-birds. The frequenting of the flowers of *Impatiens* is the only case cited from the United States; and Dr. Gray asks: "Can it be that there are no references in print to the most familiar fact that our humming-bird is very fond of sucking the blossoms of trumpet creeper (*Tecoma radicans*) and of honeysuckles? Both these are, in size and arrangement of parts, well adapted to be thus cross-fertilised."

A NEW PARASITIC GREEN ALGA.—Not very long since it was thought that the want of chlorophyll determined the parasitism of plants, and it is still true that the want of this green colouring substance serves to distinguish between fungi and algæ. It is also true that the former need already-formed carbon compounds, but it is still thought that chlorophyll-bearing plants not only do not require to find these compounds ready formed, but that they are absolutely unable to assimilate them. It was therefore a fact of great interest when Prof. Cohn described some years since (1872) a perfectly new chlorophyllaceous alga ("Ueber parasitische Algen" in *Beit. zur Biol. der Pflanzen*, Bd. i. Heft 2; see also W. Archer, *Quart. Journ. Mic. Science*, N.S., vol. xiii.), which he found living as a bright emerald green parasite in the thallus of duck-weed gathered at Breslau. For this the genus Chlorochytrium was established, and *C. lemnæ* was the only species until at a late meeting of the Dublin Microscopical Club, Prof. E. Perceval Wright exhibited and described a second species found growing and developing itself in the mucilaginous tubes of a species of Schizonema, collected on rocks at Howth, near Dublin, between high and low water-marks. There can be no question as to the parasite on the diatom being different from that on the duck-weed, while there is but little difficulty in placing it in Cohn's genus. Smaller in size its emerald lustre is scarcely if at all less than the fresh-water species, and like it its development has not been traced farther than the production of zoospores.

FLORA OF TURKESTAN.—We notice a very interesting communication on the Flora of Turkestan, made by Prof. Regel, the director of the St. Petersburg Botanical Garden, at the last meeting held on January 20, by the Russian Society of Gardening. The special aim of the communication being to advocate the introduction into European gardens of representatives of the flora of Turkestan, Prof. Regel described the numerous, original, and most beautiful species belonging to the *Compositæ*, *Caryophyllæ*, *Umbelliferæ*, *Papilionaceæ*, *Malvaceæ*, and *Campanulaceæ*, which grow in Turkestan, and which could rank among the best ornaments of our gardens by their variety and beautiful forms and colours. Most of these species are already cultivated with complete success in the St. Petersburg Botanical Garden, and they might be thus introduced in the gardens of Russia and Western Europe. Concluding his communication, Prof. Regel pointed out the remarkable circumstance that in Turkestan, even in hilly tracts, the *Ericaceæ* are totally wanting, whilst they are so common in the highlands of the Alps, of the Caucasus, and even of the Altai.

NOTES

METEOROLOGISTS everywhere will learn with much satisfaction that Dr. Julius Hann, the eminent meteorologist, was appointed, February 10, successor to the late Dr. Jelinek, as Director of the Central-Anstalt für Meteorologie und Erdmagnetismus, Vienna.

FIFTY-SEVEN candidates for election into the Royal Society have offered themselves during the present session.

PROF. A. OPPENHEIM, of Berlin, has accepted the chair of chemistry in the newly-organised Philosophical Faculty at Münster.

PROF. PFEFFER, of Bonn, has accepted the ordinary professorship of Botany in the University of Basel.

THE Treasury have agreed to recommend votes from the Consolidated Fund for 80,000*l*. towards the new buildings devoted to the Science Schools of the University of Edinburgh, in four yearly instalments of 20,000*l*. each. This vote is to supplement a like amount subscribed by the public.

THE marble statue of Sir W. Fairbairn is in the hands of Mr. Geflowski, who obtained the Commission in competition with other eminent sculptors. Besides the statue, which is to stand in the New Town Hall, Manchester, facing the entrance, a Fairbairn scholarship is founded in Owens College, Manchester, out of the funds subscribed. The statue is eight feet high, representing Sir W. Fairbairn standing with papers in his hand as if delivering an address to a scientific audience, the head bare and inclined slightly, and an admirable likeness in the features as well as in the thoughtful expression and quiet energy characteristic of the man.

THE University of Tübingen is making preparations to celebrate its 400th anniversary during the coming month of August. Various historical addresses are in course of preparation, and a work will be issued commemorative of the occasion.

A PUBLIC meeting of the Sanitary Institute of Great Britain will be held at the rooms of the Society of Arts, John Street, Adelphi, on Wednesday, March 14, at 3 P.M., to consider the report recently issued by the Committee appointed by the President of the Local Government Board upon the disposal of town sewage.

HIS Majesty, the Emperor of Brazil, observed the eclipse of the moon on the evening of the 27th, at the Arcetri Observatory. The Emperor took a very lively interest in the phenomenon and discussed with acuteness the hypothesis with which Prof. Tempel, the astronomer, and Prof. Echert tried to explain the varying shades and colours in which the moon appeared during the different phases of obscuration. On Monday last his Majesty assisted at a meeting of the Anthropological Society, when Prof. Mantegazza made some interesting remarks on several Maori skulls, and Prof. Giglioli read an elaborate paper on the ethnology of Brazil.

THE general expenses of the seven Russian universities in 1876 were as follows:—The University of St. Petersburg, 43,500*l*.; of Moscow, 52,850*l*.; of Kieff, 38,375*l*.; of Kazan, 39,500*l*.; of Kharkof, 38,125*l*.; of Odessa, 25,375*l*.; and of Dorpat, 26,625*l*.

WE notice the following more important papers on natural science, among those published by professors of the Moscow University in 1876:—"Observations de Jupiter en 1876," "Profil spectroscopique du Soleil en 1876," and "Sur la Queue de la Comète de 1874," by Prof. Bredikhin, in the *Annales* of the Moscow Observatory; a paper, by Prof. Babukhin, "Ueber die Structur und Verhältnisse elektrischer und pseudo-elektrischer Organen," in the *Archiv für Anatomie und Physiologie*; "Théorie des Dérivées," and "On the Numerical Equations of the Second Degree," by Prof. Bagaieff, in the Moscow *Mathematical Review* (Russian); the papers of Prof. Markovnikoff on Theine (NATURE, vol. xv. p. 167). An interesting popular lecture on Unicorns, and on the origin of the myths on them, was delivered at the last anniversary of the University by Prof. Usoff.

M. DUMAS has been nominated president of the Société d'Encouragement pour l'Industrie Nationale. At the last meeting of the Society M. Moutenat exhibited metallic tubes which emit sounds when burning coal is placed in the interior. The sound is modified when the place occupied by the coal has been changed. A copper tube into which metallic gauze has been introduced also emits musical sounds. M. Moutenat is preparing to build large tubes for the International Exhibition of 1878. He hopes the sounds may be heard at a great distance, and if successful he intends to propose this method instead of steam whistles for warning on the sea-coasts.

THE Bradford Scientific Association purpose holding a conversazione and exhibition of scientific instruments and objects on the evenings of April 11 and 12. Exhibits will be arranged under various sections and sub-sections, and contributions will be welcomed.

FROM the Annual Report of the Geologists' Association we learn that the number of members on January 1 was 390.

VOL. I. Part 6, of the *Transactions* of Watford Natural History Society contain papers on the Hertfordshire Bourne, by Mr. John Evans, F.R.S.; on the Hertfordshire Ordnance Bench Marks, by Mr. John Hopkinson, F.L.S.; and on the Polarisation of Light, by Mr. J. N. Harford.

MR. RUDKIN has given notice of his intention to move, at the next meeting of the Court of Common Council, that it be referred to the Gresham Committee to confer with the Mercers' Company as to whether and how the Gresham College foundation can be utilised and extended in connection with the scheme which is now being prosecuted by the Livery Companies for establishing a Central Technical University, with affiliated colleges and institutes, not only in the metropolis and its suburbs, but in the chief centres of industrial life throughout the United Kingdom.

THE Russian Government announces the discovery of valuable silver deposits in several islands of the White Sea.

GRAF WALBURG, a member of Dr. Brehm's expedition to Siberia, is now studying the botanical and palæontological collections at Dorpat. He proposes to undertake this year another journey to Asia and to explore the Caucasus.

THE St. Petersburg papers announce the return of Lieut. Onatsevitch, who has spent two years in the survey of the Northern Pacific shores of Siberia. After having observed the Transit of Venus, Lieut. Onatsevitch engaged in a full and thorough survey of Behring's Strait, extending his soundings into the glacial ocean as far as the ice barrier over a surface of about sixteen square degrees. Further, having at his disposal fourteen chronometers, he has determined many longitudes, and has brought into connection the longitudes formerly determined in the north-east with those recently determined with great accuracy before the Transit of Venus in south-eastern Siberia. The work done by M. Onatsevitch will be the subject of communications at the next meeting of the St. Petersburg Geographical Society.

THE map of the mouth of the Obi, prepared by M. Dahl (who made last summer a detailed survey and soundings when descending the river on board the schooner *Moscow*, built in Tiumen), will appear in the course of a month or two.

THE *Afrikanische Gesellschaft* of Berlin received a few days since news from Dr. von Bary, who at the end of December was on the point of leaving the city of R'hat to penetrate into the mountain region of the Tuaregs, in the central part of the Sahara. Hostilities had just ceased between the tribes inhabiting this territory, and there was every probability of his successfully accomplishing the aims of the journey, viz., a careful geological study of this scarcely-known region.

IN the last session of the Berlin Geographical Society, the president, Dr. Bastian, announced that the well-known African traveller, Dr. Gustav Nachtigal, intended to undertake a new journey of exploration into the interior from the coast of equatorial Africa. This field, now rendered vacant by the death of Edward Mohr at Molange, has always been the favourite territory of the German explorers. Dr. Nachtigal's peculiar qualifications for the undertaking, as well as his six years' varied experience in the hardships of African travel, will lend an important character to this new new attempt to penetrate into the unknown interior of the continent.

AT the meeting of the French Geographical Society M. Charles Velain read a paper on the volcanic lakes of the island of Nossi Bé, near Madagascar. The formation of the island is generally volcanic, the north and south parts being of ancient formation, while the central part is of much more recent origin. Besides a number of true volcanic craters, not very high, M. Velain found a great number of crater-lakes or circular troughs, level with the ground and filled with water. These troughs, M. Velain thinks, must have been formed by subterranean explosions, which did not last long enough to enable the lava to reach the surface. These lakes abound in fish, many of which are probably new species; it is impossible, however, to catch them, on account of the number of crocodiles that swarm on the banks.

ERGÄNZUNGSHEFT No. 50 of Petermann's *Geographische Mittheilungen* contains the first part of a narrative of M. E. de Pruyssenaere's Travels in the Region of the White and the Blue Nile. M. de Pruyssenaere was a young and accomplished Belgian who spent most of the time between 1859 and 1864 in the exploration of the above region, and after much difficulty the editor of the narrative, K. Zöppritz, obtained possession of his journals and notes. Notwithstanding the length of time that has elapsed since M. de Pruyssenaere traversed the region, it will be found that his narrative adds considerably to our knowledge of it. He made many botanical notes, which, we believe, will be published at a future time. Accompanying the narrative is a map of the region, showing the traveller's routes, prepared from his astronomical and trigonometrical observations. M. de Pruyssenaere died in the midst of his travels in 1864, at the early age of thirty-eight years.

PROF. C. JARZ, of Vienna, formerly an artillery officer under the Emperor Maximilian of Mexico, has recently issued a short work on "Ocean Currents of the North Atlantic," with especial reference to the Gulf Stream, embodying much of individual observation. The rotation of the earth is excluded from among the causes producing these phenomena. His theory is essentially that each current has its own particular causes, and that a number of independent compensating forces occasion the character, speed, and direction of the currents.

THE last session of the Hungarian Natural History Society was devoted to a detailed account, by M. von Hantken, of the results of his extensive microscopic researches on the Hungarian limestone formations. The old Tertiary deposits near Ofen were found to consist almost entirely of organic remains, principally Algæ, Foraminifera, and Bryozoa. The Algæ form the chief part of several strata and belong to the genus *Lithothamnium*. Microscopic investigation showed a regular structure of successive layers of cells. In the interstices between the cells of the plants carbonate of lime was gradually deposited, and they were petrified entire. The presence of the remains of Foraminifera and Bryozoa showed a contemporaneous zoogenous and phylogenous growth of the rocks. As the Lithothamnium of the present day grows only on the sea-shore, it is probable that these Hungarian limestone deposits are coast formations.

In the February session of the Hungarian Geological Society, Prof. Krenner displayed a lately-discovered mineral from Nagyág, which consisted of pure telluride of gold. As is well known, gold does not occur in nature in combination with any member of the sulphur-group except tellurium. A mixture of the tellurides of silver and gold was found recently in California, but this is the first instance of the occurrence of the pure auric telluride in a crystalline state. In view of the fact that gold is the noblest metal, and tellurium one of the rarest elements, the new mineral has been called *Bunsenite*, in order to give a fitting expression of the gratitude of the great chemist's admirers in Hungary for the services rendered to mineralogy by his analytical methods.

A remarkable piece of coral taken off the submarine cable near Port Darwin, is spoken of in a Melbourne paper. It is of the ordinary species, about five inches in height, six inches in diameter at the top, and about two inches at the base. It is perfectly formed, and the base bears the distinct impression of the cable and a few fibres of the coil rope used as a sheath for the telegraphic wire still adhering to it. As the cable has been laid only four years, it is evident that this specimen must have grown to its present height in that time, which seems to prove that the growth of coral is much more rapid than has been supposed.

It is well known that in many places springs of fresh water arise from the bottom of the sea. M. Toselli proposes to make use of them. Their water, brought through flexible tubes held at the surface by suitable buoys, would furnish ships with supplies of water they are often in need of. M. Toselli appears to have studied the question carefully, and provided for the preservation of his apparatus in the face of storms.

The rapid melting of snow in the mountain regions causes great inundations in south-eastern France and in Switzerland, and Swiss papers daily record the damages done by the floods. The greatest damage is caused by the Doubs, both in France and Switzerland. The Rhine at Basel rose on February 16 by 6·22 metres, reaching thus a level only 2·46 metres lower than during the great inundation of March 1, 1876. Prof. Forel writes to the *Gazette* of Lausanne, that the level of the Lake of Geneva rose on February 15 and 16 at the rate of three millimetres hourly, or 155 millimetres in the course of two days, and he points out that more rapid risings were noticed only three times in the course of the last twenty-nine years (in 1856, and twice in 1876), when the level rose daily 73 to 82 millim. in twenty-four hours. The amount of water accumulated in the lake was thus as large as 42,000,000 cubic metres in the course of a day. The Lake of Zurich rose at the same time 40 centimetres in twenty-four hours; but its superfices being seven times less than that of the Lake of Geneva, the figure shows a far less accumulation of water, viz. of 26,000,000 cubic metres in the course of a day.

As one of the Memoirs of the Geological Survey, Mr. Whitaker has just published a paper on the Geology of the Eastern End of Essex (Walton Naze and Harwich). Longmans and Stanford are the publishers.

We are glad to hear that an ethnographical museum was opened at Helsingfors on January 24. The nucleus of the museum was formed from collections exhibited at the recent Helsingfors Exhibition. It contains a large number of clothed figures representing the varied ethnographical types of Finland and their yet more varied costumes, interiors of peasant's homes, samples of household furniture and tools, of hunting and fishing implements, of objects used by the yet numerous conjurors, collections of stone implements, &c. The importance of the museum will be well appreciated by all acquainted with the interest afforded by the ethnography of Finland.

The French Anthropological Society has been authorised by M. Krantz to open an international exhibition in the central palace of the Trocadero. M. Quatrefages has been appointed Chairman of the Commission. Communications relating to the exhibition may be sent either to the Society in Paris or to M. Gabriel de Mortillet, at the Musée des Antiquités Nationales, St. Germain, Seine-et-Oise. The Anthropological Exhibition will be distributed into a number of sections, and several national committees might be established if necessary. Further details will soon be published for the guidance of intending exhibitors or visitors.

On February 25 the city authorities of Vienna inaugurated a novel and remarkably interesting application of pneumatic tubes for the purpose of maintaining unison and regularity in widely-separated time-pieces. The inventor is the Austrian engineer and electrician, E. A. Mayrhofer, who, after vainly trying to solve the problem by means of electricity, finally hit upon the new system. From a central bureau in the city, connected with the Imperial Observatory, these pneumatic tubes extend in all directions, laid alongside the gas mains, and branching off to the public clocks. By means of a simple apparatus in the latter the authorities in this bureau are able to exhibit the true astronomical time on the clock dials in all parts of the city, a movement of the hands occurring once a minute. At present only the city clocks have been brought in connection with the new system, but it will rapidly be extended, until it embraces the time-pieces in all the schools, public institutions, hotels, &c., and in those private residences where it may be desired.

The prospects of coffee-cultivation in Coorg seem to be somewhat gloomy, for we learn from a recent report that the plants have not only had to contend with the regular insect and fungoid diseases, but also with such an extremely dry season, that the drainage of the country became very low, and all the springs and wells nearly exhausted. Many of the coffee nurseries had to rely on hand watering from springs and rivulets, and thousands of seedling plants constantly withered and dried up. The greatest damage, however, seems to have been done by what is described as "the planter's old and implacable enemy, the *Xylotrechus quadrupes*," commonly called the borer, the ravages of which are as destructive and extensive as ever; planters are often deceived as to the presence of this insect, the appearance of the trees even when attacked, failing to convey an idea other than health. The revelation at crop time, however, convinces the sceptic of the insidious approaches and devastations of the enemy, which can be overcome and subdued only by timely and resolute extermination of every bored coffee tree. The periodical increase of the insects is attributed by residents on or near the plantation to the prevalence of dry seasons. It spreads most in open coffee fields in warm localities, and least in moist and shady places where there is high cultivation. With regard to the *Hemileia vastatrix*, or leaf disease, it seems to have considerably lessened, or, as the report says, disappeared. This is almost more than we can expect, and as much as we can hope for; nevertheless, it may be as the writer of the report says, that the disease is existing under another form, "And may reappear in those well-known orange-coloured spots, for like other fungi it undergoes certain transformations. It is singular that these orange-coloured spores are generally encircling the stomata of the lower epidermis of the leaves, and," the writer proceeds to say, "I have found them even on leaves of coffee-seedlings, not one year old. It is difficult to conceive how these spores should have come there, whether from without or within, the whole of the cellular tissue around the spots being affected as by an inernal disease. It seems equally difficult to say, whether the fungus is the cause or effect of the diseased leaf. As to remedies, these appear to be expected rather from climatic influences than from the sagacity of man, for all the propositions yet made may prove satisfactory in the laboratory, but are impracticable where any large area is to be operated upon."

THE subject of blight or disease affecting the plants in the tea plantations of India has been brought prominently under the notice of the Agri-Horticultural Society of India, a letter having been addressed to the society to the effect that the attacks of "blight and red spider having become of such a serious nature on many tea-gardens both in Assam and Cachar, but especially in the latter province, it is necessary that all possible information, with a view of mitigating the evil, should be obtained and made widely known." At a subsequent meeting of the society the line of action proposed, subject to the assistance of those interested in the matter, was to engage the services of an entomologist from England for the period of two years so that he might have time and opportunities to observe and carefully study the character of the several kinds of blight in their various localities, such observations to be published under the auspices of the society.

THE introduction of the Carob (*Ceratonia Siliqua*) into the Madras Presidency, a subject which occupied the attention of the Agri-Horticultural Society of Madras a few years since, has been again brought before the society. It is strongly recommended for cultivation in countries suffering from periodical droughts in consequence of its long roots penetrating a great depth into the earth, and because of the large quantity of mucilaginous saccharine matter contained in the pods, so that it might be largely used for feeding cattle, horses, pigs, &c. It is said, however, that although the seeds contain nitrogenous elements or flesh-making materials, they do not possess great nutritive properties, and the seeds being small and hard they are not easily masticated, and pass in their crude state undigested.

A PECULIAR request (according to the *Berliner Tageblatt*) has been made by the Society for Bird Protection to the General Postmaster in Berlin, viz., to make arrangements so that birds be not killed by the pneumatic post. The case is this: From the large air-compressing steam-engines proceed chimney-pipes to the roof, by which the required air is sucked in. The power of this suction-apparatus is so great, that both small and large birds, even pigeons, which happen to be flying over the tubes when the engine is in action, are helplessly drawn in and destroyed.

TAKING opportunity, lately, to observe with a Nicol's prism an uncommonly fine rainbow, which spanned the Oesthal in Baden Baden, M. Schiel found that with the prism in a certain position, the colours disappeared completely, and the prism was pretty dark. But on turning it through 90°, the bow appeared again in all its brilliancy. The rainbow is therefore perfectly polarised light. Several rainbows observed since have shown the same behaviour; but apparently only a very bright-coloured rainbow presents dark on the field of vision with the corresponding position of the prism.

THE additions to the Zoological Society's Gardens during the past week include a Macaque Monkey (*Macacus cynomolgus*) from India, presented by Mr. Thos. Dalby; a Galapagan Tortoise (*Testudo elephantopus*) from the Galapagos Isles, presented by Mr. W. H. Henderson; two Herring Gulls (*Larus argentatus*), European, deposited; a Common Nuthatch (*Sitta cæsia*), European, purchased; a Red Kangaroo (*Macropus rufus*), born in the Gardens.

Poggendorff's Annalen der Physik und Chemie. Ergänzung Band viii., Stück 2.—Researches on the nature of the vowel "clang," by M. Auerbach.—On the interference of reflected light (concluded), by M. Lommel.—On the tension of liquid films, by M. Sondhauss.—On a fundamental law in dioptrics, by M. Most.—On the complementary colours of gypsum in polarised light, by M. v. Kobell.

Memoria della Società degli Spettroscopisti Italiani, November, 1876.—The paper by Prof. Young, of Dartmouth College, on the displacement of the lines in the solar spectrum caused by the sun's rotation appears here. Prof. Young used the spectra of the sixth and eighth orders obtained by a grating of 8,640 lines to the inch, a collimator of 2¼ inches diameter, and 16 inches focal length attached to the 9½ inch equatorial. The observations were made chiefly on the D lines and the Ni line between them giving a result of 1·42 mile a second; this exceeds the result from ordinary observations of spots by 0·34 mile, and the author considers it a fact that the solar atmosphere really sweeps on forward over the underlying surface.—Prof. Tacchini gives a history of his journey up Mount Etna for the purpose of making spectroscopic observations of the sun. The spectroscopic and direct observations of the sun made at Palermo in October last appear here, also the drawings of the chromosphere for May, 1875.

December, 1876.—Father Secchi gives his catalogue of 444 coloured stars with notes on the spectra of the same.—Mr. Huggins contributes a preliminary note on the photography of stellar spectra, together with a drawing of the spectrum of α Lyræ.—Observations of the lunar eclipse of September 3, 1876, by A. Dorna.—Observation of the Perseids made at Palermo in August, 1876, by Prof. Tacchini and G. de Lisa.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, February 8.—"On the Hindoo Division of the Octave, with some Additions to the Theory of the Higher Orders," by R. H. M. Bosanquet, Fellow of St. John's College, Oxford. Communicated by Prof. Henry J. S. Smith, Savilian Professor of Geometry in the University of Oxford.

Attention has been recently directed to the remarkable division of the octave into 22 intervals, employed by the Hindoos. The paper commences with a slight account of the Hindoo scales as thus derived. It is then remarked that our best way to a real analysis of this music would be to study the system of 22 and compare the results with those actually obtained by Hindoo musicians. The methods, which have been employed in the writer's former paper on the subject,[1] are then extended to the higher orders, which have not been before thoroughly discussed. The system of 22 is a system of the second order, and the nature and peculiarities of such systems, and of the system of 22 in particular, are discussed.

A classification of systems of the higher orders according to their mode of forming thirds is advanced. If the system be arranged in successive series of fifths, differing by one unit in pitch, then the system is said to be of class x, if the third of any note is in the series x units below that which contains the note itself.

The system of 22 is shown to be of the second order and first class.

A system of 34, also of the second order and first class, is pointed out as being of considerable excellence, even from a modern practical point of view.

It is shown that in systems of the second order and first class, modulation through a third cannot be regarded as equivalent to modulation through any number of fifths.

The notation is extended to systems of the rth order.

The subject of the transformations of the generalised key-board is then entered upon. It is remarked, in the first instance, that any form of arrangement whatever can be constructed by rearranging a supply of keys of the ordinary patterns.

The problem of inversion is then solved, and it is shown under what circumstances, by simply inverting the succession from end to end, a key-board can be obtained in which rise corresponds to fall of pitch, and *vice versâ*.

The general transformation of the rth order is then investigated, and a rule is given by which the key-board of the rth order can be arranged with the ordinary keys.

This rule is then applied to the construction of the key-board of the second order, and a diagram is given of a portion of a key-board so arranged. Systems of the second order and first class, such as the systems of 22 and 34 above-mentioned, can be controlled with facility by means of this arrangement.

February 15.—On Crookes's force, by G. Johnstone Stoney, F.R.S., and Richard J. Moss, F.C.S.—This paper is a preliminary report of an experimental investigation of the theory of Crookes's radiometer proposed by Mr. Stoney in the *Philosophical Magazine* for March and April, 1876. The term "Crookes's force" is employed to designate the reaction which comes into play between the blackened disks of a radiometer and the walls of the exhausted chamber when a difference of temperature exists between them. The authors have sought to determine quantitatively the relation of the force to the tension of the residual gas, and the influence of variations in the distance between the reacting surfaces. For this purpose they employ an apparatus in which a blackened disk of pith can be placed at any required distance within twelve centimetres from a delicately suspended disk of thin microscope glass. The pith disk is heated by projecting on it the image of a uniformly illuminated aperture in a metallic screen. The relative magnitudes of the force are estimated by determining the distance to which the glass disk is repelled in a given time. It is sometimes difficult to distinguish between the effects of convection currents and those of Crookes's force. It is certain, however, that when the tension of the residual gas is as much as five millimetres of mercury there is a Crookes's reaction through a space of at least ten millimetres.

At distances of from twenty to eighty millimetres the very feeble force acting on the glass disk seemed to vary about inversely as the tension. It appeared to be nearly independent of the distance when the distance exceeded twenty millimetres.

At distances of five, ten, and twenty millimetres, the force on the swinging disk made some approach to varying at each tension inversely as the distance. But so far as may be judged from measures of such exceedingly feeble forces, there is a sensible deviation from this law at most of the tensions. Moreover the observations, taken as a whole, seem to suggest, in conformity with the dynamical theory, that the law changes with variations of density.

Linnean Society, February 15.—Prof. Allman, F.R.S., president, in the chair.—Messrs. W. Burns, E. L. Gardner, Prof. W. Harrington (of Michigan, University, U.S.), J. W. S. Meiklejohn, the Rev. J. Stobbs, and Sir Charles W. Strickland, Bart., were elected Fellows.—There was exhibited under the microscope by Mr. Arthur Lister the plasmodium of one of the lowly organised Myxomycetæ. This protoplasmic mass demonstrated the peculiar amœboid movements, and the occasion gave rise to an animated discussion on its contested animal or vegetable nature.—Two botanical papers were read, the first on the rootstock of *Marattia fraxinea*, Sm., by Mr. John Buchanan; the second on the Algæ collected at Rodriguez during the Venus Transit Expedition, 1874, by Prof. Dickie. The Marattia is chiefly found in the northern part of New Zealand. The Maories use it as food, but do not cultivate it systematically. They say that when it is smashed, the pieces thrown on the ground spring up freely and thus it has increased. At Wellington, where transplanted, it grows luxuriantly when placed in rich damp soil. Mr. Buchanan has now studied its mode of growth; he considers the rootstock as resembling a scaly bulb more than a fern rhizome, and likens its propagation to that of the potato, though modified. Its growth is very slow, hence, probably, its scarcity. The fresh-water Algæ of Rodriguez point in an Asiatic direction, none are African species, while some have rather a world-wide distribution.—The Secretary read a note on a new example of the Phyllodocidæ (*Anaitis rosea*), by Dr. W. C. McIntosh. This marine worm was obtained at St. Andrews. It is 1½ inch long, with relatively broadish body, blunt snout, and small eyes. On head and body it is slashed and speckled with pink, which merges into a yellow band behind.—A communication was read on deep-sea anemones (Actinaria) dredged from on board the *Challenger*, with a description of certain Pelagic surface swimming species, by Mr. H. N. Moseley, late naturalist to the above expedition. The occurrence at great depths of representatives of ordinary shallow water forms of Actinia is of profound interest. A species of Edwardsia, from 600 fathoms, has undergone but trifling modification from the littoral form. The *Cerianthus*, from 2,750 fathoms, is dwarfed, but uncommonly like its shore brethren. Thus it appears one kind is found in shallow water at the Philippines under the full glare of the tropical sun, while another species of the same genus exists at three miles depth, where solar rays never penetrate, and the water keeps at freezing point. The fact of the deep-sea-Anemones retaining vivid colouring in their dark watery abode is a point of special value as connected with certain other generalisations. The new genus *Corallinomorphus* likewise possesses interest both on account of being a near ally to certain of the simple discoid corals, and of its having the largest stinging cells (nematocysts) yet recorded.—An extract of a letter on the marsupial pouch of the Bandicoot, by Mr. R. D. Fitzgerald, was briefly adverted to by the Secretary.

Chemical Society, March 1.—Prof. Abel, F.R.S., president, in the chair. Prof. E. T. Thorpe delivered his lecture on "The theory of the Bunsen lamp." The speaker, after some preliminary remarks as to the great value of this instrument, both to the scientific chemist and also in the arts, gave a short description of the lamp and proceeded to show the principle on which it acted. The gas issuing from the jet draws in air through the holes in the side, and becomes mixed with it in the tube, the amount of air being about 2 to 2½ times the volume of the gas, and as it burns on an average 80 litres of gas per hour, as much as 250 litres of the mixed gases pass through the tube of the lamp in that space of time. After having sketched the progress of the mixture of gas and air up the tube, attention was directed to the flame itself, which is hollow, and contains a large internal space of the uninflamed gaseous mixture. As it has been found that a mixture of gas with less than 3½ times its volume of air will not burn, it is only, therefore, when it meets with an additional supply of oxygen from the surrounding air that combustion occurs. The composition of the gas in the tube and in various parts of the flame was then studied, and the probable causes of the want of luminosity in the flame stated; these are due to the dilution of the gas by the nitrogen, the oxidation of luminiferous material, and the depression of temperature produced by the diluting gases, such as nitrogen, carbonic oxide, and aqueous vapour.

---

[1] *Proc. Roy. Soc.*, No. 162, 1875, p. 390, and "An Elementary Treatise on Musical Intervals and Temperament." (Macmillan, 1876.)

Meteorological Society, February 21.—Mr H. S. Eaton, M.A., president, in the chair.—William Adams, Thomas Black, Robert W. Munro, and R. Bowie Wallcott, M.D, were elected Fellows; and Mons. U. J. Leverrier, Director of the Observatoire National, Paris, an honorary member of the society.—The President gave an inaugural address. After referring to the various theories advanced to account for changes of climate, he observed that in drawing deductions from a long series of observations of the temperature of the air, it is important to ascertain whether the conditions of the surrounding district have altered, otherwise changes in reality due to local causes may be erroneously assigned to secular variation. The climate of London has thus been modified by the consumption of fuel and the vast population. He estimated that the heat developed from the present annual consumption of 5,000,000 tons of coal on the metropolitan registration area of 118 square miles, and from all other artificial sources, would suffice to raise the temperature of a stratum of air 100 feet in depth resting on that area 2° 5 every hour. The effect of the growth of the population of London from 900,000 at the commencement of the century to 3,500,000 at the present time, and of the still greater increase in the comparative consumption of coal was manifested by the rise in the average temperature of the air at the Royal Observatory, Greenwich, which place was year by year becoming more surrounded by a network of houses and population For this reason Greenwich was not a suitable place for a Meteorological Observatory of the first order Mr. Eaton subsequently referred to some of the practical difficulties experienced in pursuing the study of dynamical meteorology.—The following papers were then read —Barometrical and thermometrical clocks for registering mean atmospheric pressure and temperature, by William F. Stanley; solar thermoradiometer, and on an improvement in minimum thermometers for terrestrial radiation, by James J Hicks

Anthropological Institute, February 27 —Mr John Evans, F.R.S, president, in the chair —Mr A H. Keihl, was elected a member.—Mr. M J. Walhouse read a paper on non-sepulchral rude stone monuments. Adverting to the extravagant Druidical and Dracontian theories formerly connected with megalithic remains, he observed that perhaps at present speculation had gone to another extreme in refusing to see in them any purposes other than sepulchral. In this paper he adduced examples, many from his own observation of cairns, cromlechs, torlithons, stone-circles, and other megaliths, which he considered could not have been connected with burials, and he advocated the non-sepulchral intention of open-sided dolmens such as Kitscoty House, and those at Rollright and Drewsteignton, comparing them with similar structures now used in India as rude temples for sacred stones and images. The paper concluded with some observations on stone-worship, especially as now practised in India. Many existing instances were described, and passages quoted from classic authors, denoting its prevalence in antiquity. Some speculations were also brought forward as to the causes of rough stones having been so frequently taken for objects of worship. Col. A. Lane Fox, Mr. Hyde Clarke, the President, and others, took part in the discussion.

Entomological Society, January 17 —Anniversary Meeting. —Sir Sidney Smith Saunders, C.M.G, vice-president, in the chair.—An abstract of the treasurer's account and the Report of the Council for 1876 were read.—The following were elected members of council, viz., Prof. Westwood, Sir Sidney S. Saunders, and Messrs. H. W. Bates, Champion, Dunning, Grut, Meldola, Stainton, Weir, Douglas, E. Saunders, Rev. A. E. Eaton, and Rev. T. A. Marshall.—The following officers were elected, viz., Prof. Westwood, president, J. Jenner Weir, treasurer, Rev. T. A. Marshall, librarian, and Messrs. F. Grut and R. Meldola, secretaries.—The president, in consequence of an accident, was prevented from attending, and the delivery of his address was unavoidably postponed till the next meeting.

February 7.—Prof. Westwood, president, in the chair.—W. Denison Roebuck, of Leeds, was balloted for and elected a subscriber.—The president nominated Messrs J. W. Douglas, J. W. Dunning, and H. T. Stainton as vice-presidents for the ensuing year.—The president delivered the address, postponed from the last meeting, on the progress of entomology during the past year. —Mr. F. Bond exhibited a specimen of the North American butterfly, *Danais Archippus*, taken in September last near Hassock's Gate, Sussex, being the third specimen taken in this country. —The president exhibited a specimen of the singular butterfly *Bhutanitis Lidderdalii*, Atkinson, from Bhotan. He also read a letter which he had received from Baron v. Osten Sacken referring to his paper on the Dipterous genus *Systropus*, published in the last part of the *Transactions* of the Society, in which he had stated that a species in Natal (*S crudelis*) had been bred from a cocoon resembling that of *Limacodes*, and pointing out that *Systropus macer*, the common species in the United States, had been bred from the cocoon of *Limacodes hyalinus*, and was a remarkable instance of community of habit among insects of the same genus in far-distant regions —The president read some remarks he had received from M. Ernest Olivier, of Moulins, respecting insects of the Dipterous genus *Bombylius*, frequenting the nests of a bee of the genus *Anthophora*, at Pompeii —Mr. McLachlan exhibited a case of a Lepidopterous larva sent by Dr Kirk, of Zanzibar, who had found it on a species of *Mimosa*. He considered it to be allied to *Psyche* and *Oiketicus*; and it was remarkable on account of its form, which bore a striking resemblance to that of a flattened *Helix* It appeared to be constructed of a substance resembling *papier maché*, with a smooth, whitish, external coating —Mr. C O Waterhouse exhibited some remarkable varieties of British Lepidoptera, viz., *Chrysophanus phlæas*, *Polyommatus Adonis*, *P. Alexis*, and *Agrotis exclamationis*.—Dr. Buchanan White forwarded an extract from the *Medical Examiner* of December 21 last, containing an account by Dr Tilbury Fox of an extraordinary case of "Prurītus," which afflicted every member of a family and household, including even the dog and cat. A specimen of the insect causing it had been submitted to Dr. Cobbold, who had pronounced it to be a species of *Trombidium*, which was believed by Dr. Fox to have originated from certain plants in the garden, and that the cat and dog which appeared to have been the first affected, were agents in conveying the parasites to the human members —The following papers were read, viz —Notes on the African *Saturniidæ* in the collection of the Royal Dublin Society, by W. F. Kirby — Descriptions of new genera and species of Phytophagous beetles belonging to the family *Cryptocephalidæ*, together with diagnoses and remarks on previously-described genera, by Joseph S. Baly —Descriptions of new species of Phytophagous beetles belonging to the family *Eumolpidæ*, including a monograph of the genus *Eumolpus*, by Joseph S. Baly.

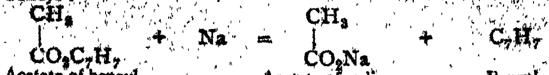
Physical Society, February 17.—Prof W. G. Adams, vice-president, in the chair —Mr. T W Philips, C.E, was elected a member of the society —Prof. Guthrie exhibited, for Mr. C. J. Woodward, an apparatus he has devised for showing to an audience the interference of transverse waves A light frame, capable of moving in a vertical plane, carries a horizontal strip of tin about two feet in length, cut in the form of the ordinary sine wave, and which supports, by means of a roller, a light wooden block carrying an ink recorder in front of a sheet of paper. This block slides in a vertical slot in a piece of wood, which can be moved horizontally, supported by a roller on another similar strip of tin fixed parallel to the first, and vertically below it. The movable frame rests on a castor attached to this block If the relative positions of the waves be now varied, and the blocks moved along them, the path traced by the ink recorder will represent the wave due to their combination —Mr. S. P. Thompson exhibited some galvanometers in the form of magic-lantern slides which he has arranged for exhibiting their indications to an audience. The instruments are, however, only capable of indicating comparatively powerful currents, and he hopes to succeed in arranging forms of greater sensitiveness. The index needle is usually formed of cardboard, and two small steel needles are attached to it parallel to its axis. It is pivoted lightly between glass plates, and influenced by the current traversing coils of wire placed beyond the circle in which it rotates. The best effects were obtained by means of two curved electro-magnets surrounding a small steel magnet, but this form is inapplicable to quantitative determinations, on account of the residual magnetism of the iron cores. A gold leaf electroscope formed on this principle was capable of detecting very small charges of statical electricity —Mr. Wilson then showed an arrangement for exhibiting convection-currents in heated water. It consists of a small glass cell with parallel sides. In the base of the wood dividing the sides is cut a slight depression, to expose a brass tube which traverses it horizontally, and is open at one end, while the other is bent at right angles and connected with a flask containing water. The brass tube, where it is exposed in the cell, is surrounded with a jelly formed of gelatine containing rose aniline, and the cell is filled with water and projected on the screen. When the tube is heated by boiling the water in the flask, the jelly is liquefied, and the liberated colouring-matter rises in the water, showing the direction of the heated current.—Prof. Guthrie exhibited an arrangement he has been using, with a view to determine the vapour-tension of water, and explained the difficulties to which such a determination is liable, and the manner in which his apparatus has so far failed. It was shown that a crystal of alum or a saturated solution of salt, when introduced into the Torricellian vacuum, depresses the mercurial column less than pure water, whereas a solution of size, gum arabic, or any colloid, depresses it to precisely the same extent. It thus appears that water in its different states of combination has different vapour densities, and their determination requires an arrangement in which the several substances can be easily introduced into the Torricellian vacuum, and very slight changes of the level of the mercurial column can be ascertained. Prof. Guthrie has been employing a U-tube thirty-three inches long, one extremity of which is bent, and terminates in a capillary opening, and a bulb is formed at the U-bend. If the substance under examination be introduced at the open end after the apparatus has been filled with mercury, inverted and the superfluous metal escaped, the mercury expelled through the capillary opening will give a measure of the amount of the depression.—Prof. McLeod suggested a modification of this form of apparatus.—Prof. Guthrie then showed the manner in which electricity is distributed on non-conductors, such as the plate of an electrophorus, by placing it for a given time beneath a point connected with a charged Leyden jar, and subsequently sprinkling a mixture of sulphur and litharge over it. It was shown that the diameter of the circle formed below the point after the superfluous powder had been removed is not purely a function of the distance between the point and the plate, but is mainly influenced by the conductivity of the material, and further, that if the point be directed obliquely towards the plate, the circle formed is very slightly eliptical, but the elipticity is in no degree proportionate to the obliquity of the point; and finally, he showed that if the non-conducting plate of an electrophorus be written upon with a metal and sprinkled with the above mixture of sulphur and litharge, the former or latter adheres according to the nature of the metal used, and he suggested that some such arrangement might be employed as a kind of electrical touchstone for discriminating between certain metals.

EDINBURGH

Royal Physical Society, February 21.—R. H. Traquair, M.D., president, in the chair.—A paper was read by Dr. Traquair, on the structure of the lower jaw in *Rhizodopsis* and *Rhizodus*. He stated that he had ascertained that the detached bone hitherto considered to be the premaxilla of *Rhizodopsis* was in reality the dentary element of the lower jaw. This bone shows one large laniary tooth at its anterior extremity, behind which the margin is set with a series of small teeth of uniform size. Complete specimens of the mandible of *Rhizodopsis* show, however, besides the large tooth in front, several others placed at intervals behind it, and internal to the range of small teeth. The question was, therefore, what had become of these other laniaries in cases where the dentary bone was found detached. An explanation of this was afforded by an investigation into the structure of the lower jaw in the closely-allied *Rhizodus*. In this gigantic form the dentary element of the mandible is conformed just as in *Rhizodopsis*, bearing one large tooth in front, the rest of the margin being occupied only by smaller ones, the remaining laniary teeth being borne by separate internal dentary pieces articulated to the inner side of the dentary proper, and of course liable to be dispersed and lost in cases where the elements of the lower jaw had become detached from each other before their entombment as fossils. Analogous accessory bones bearing the large teeth of the lower jaw had previously been known to exist in the dendrodont fishes of the Old Red Sandstone. As regards the true premaxilla of *Rhizodopsis*, it was ascertained by Dr. Traquair to be a very small bone articulated to the front of the cranial shield as in other fossil fishes of the same group. Papers were read (1) on the ornithology of Yedo, by Colin A. McVean, and (2) on the occurrence of the Black Redstart (*Ruticilla tithys*) in Stirlingshire, by J. A. Harvie Brown.

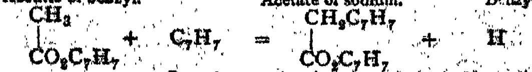
BERLIN

German Chemical Society, February 12.—A. W. Hofmann, vice-president, in the chair.—A. Wullner states that an observation lately published by F. Müller, that steam raises the temperature of saline solutions above 100°, was known before the time of Gay-Lussac, and is in no way opposed to the fact that the steam evolved from saline solutions has the temperature of the latter, as observed by the late G. Magnus and himself.—C. Hensgen continuing his researches on the action of hydrochloric acid on sulphates, has observed the transformation of blue vitriol and of sulphate of magnesia into chlorides at a red heat.—M. Conrad and W. R. Hodgkinson have found that the action of sodium on acetate of benzyle engenders benzyl-acetate of benzyl, that is hydrocinnamate (phenyl-propionate) of benzyl:—



$$\begin{array}{c}CH_3\\ |\\ CO_2C_7H_7\end{array} + Na = \begin{array}{c}CH_3\\ |\\ CO_2Na\end{array} + C_7H_7$$

Acetate of benzyl. Acetate of sodium. Benzyl.



$$\begin{array}{c}CH_3\\ |\\ CO_2C_7H_7\end{array} + C_7H_7 = \begin{array}{c}CH_2C_7H_7\\ |\\ CO_2C_7H_7\end{array} + H$$

Benzylacetate (or phenyl propionate) of benzyl.

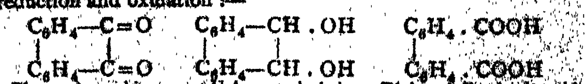
E. Chambon states that bromine transforms fuchsine into tetrabrominated rosaniline-bromhydrate $C_{10}H_{15}Br_4N_3.HBr$, a fact already known through the researches of Caro and Gräbe.—T. Iobst and O. Hesse describe several constituents of coto bark: *paracotoin* $C_{19}H_{12}O_6$, transformed by barytes into paracotoinic acid $C_{19}H_{14}O_7$, and by potash into paracumarhydrine:—

$$C_{19}H_{12}O_6 + 2H_2O = CO_2 + 2C_9H_8O_3$$

Para-cumarhydrine.

This losing water easily yields $C_9H_6O_2$ paracumarin. They also describe hydrocotoin $C_{22}H_{20}O_6$, Cotoin $C_{22}H_{18}O_6$, cotonetin $C_{20}H_{16}O_5$, oxyleucotin $C_{21}H_{20}O_7$, leucotin $C_{21}H_{20}O_6$.—H. Beckurts and R. Otto prefer sulphuric acid to alkali for transforming propionitril into propionic acid. They consider solid dichloropropionitril to be polymeric with the liquid substance. They likewise describe dichloropropionic acid and its transformation into monochloracrylic and pyroracemic acid.—C. A. Martius gives a detailed description of the production and refining of petroleum in Pennsylvania.

February 26.—A. W. Hofmann, vice-president, in the chair.—A. Christomanos published the result of a great number of analyses of Greek chrome-iron-ore leading up to the formula of R_3O_4 with varying amounts of CaO, MgO, SiO, &c. The proportion of Cr_2O_3 and FeO varies between 1 : 2, 2 : 3, 1 : 1, and 3 : 2.—From researches by K. Heumann, it appears that the greenish powder resulting from the action of nitrate of silver on ultramarine (discovered by Unger) is a mixture. The chief ingredient is yellow, but it has not been analysed.—J. H. Droeze has determined the solubility of sulphate of lime in water at various temperatures and in solutions of various salts.—T. Moddermann published speculations on atomicity.—V. Meyer denied the correctness of Ladenburg's experiments and his conclusions as to the difference of $N(C_2H_5)_3 . C_7H_7I$ and $N.(C_2H_5)_3 . C_7H_7 . C_2H_5I$.—Br. Radziszewsky communicated that the following bodies show phosphorescence under he oxidising influence of alcoholic potash: paraldehyde, metaldehyde, aldehyde-ammonia: furfurin, hydrocinnamide, hydrocuminamide, hydranisamide, anisidin; formic aldehyde. The author calls attention to the observation of Duchemin, that noctiluca miliaris acts on the skin like nettles, which have been proved to contain formic acid. He thinks that noctilucæ may contain formic aldehyde.—R. Auschütz has found that chloride of acetyl transforms bibasic acids, viz., succinic, phthalic, and diphenyl-dicarbonic acids into anhydrides, being itself transformed into acetic acid. The same chemist, conjointly with R. Schultz, has tranformed phenanthrenchinone into diphenyl-dicarbonic acid by the action of sodium amalgam by simultaneous reduction and oxidation:—



$$\begin{array}{l}C_6H_4\text{—}C=O\\ |\qquad\ \ |\\ C_6H_4\text{—}C=O\end{array}\qquad \begin{array}{l}C_6H_4\text{—}CH.OH\\ |\qquad\ \ |\\ C_6H_4\text{—}CH.OH\end{array}\qquad \begin{array}{l}C_6H_4.COOH\\ |\\ C_6H_4.COOH\end{array}$$

Phenanthren-chinone. Unknown alcohol. Diphenyl-dicarbonic acid.

E. Hartwig published preliminary remarks on phthalic aldehyde.—H. Limpricht has found that hydrochloric acid transforms sulphonic acids into the corresponding hydrocarbons:—

$$C_6H_5SO_3H + HCl = C_6H_6 (+ SO_3Cl?)$$

O. N. Witt, in a note on the history of chrysoidine, claims for himself the discovery of this colouring-matter, while he acknowledges that H. Caro has likewise prepared this substance by an independent discovery.—A. Baeyer has prepared from furfurol, $C_4H_3O.COH$, and acetic anhydride, a new acid:—

$$C_4H_3O.CH = CH.COOH,$$

a furfuryl-acrylic acid, yielding a green colouring-matter with phenol. With propionic anhydride a homologue is obtained.—

H. Schwartz has studied the bromides and chlorides of chlorinated anthracene and their action on potash.—Arno Behr, chemist to the large sugar-refinery of Messrs. Matthiessen and Wichers in Jersey city, has found in the residues of cane-sugar aconitic acid, while citric acid is one of the regular ingredients of beet root.—A. W. Hofmann after showing a circular table of chemical reactions designed by Dennis Monnier in Geneva, returned to the statement of Kern that mono-methyl-aniline, formerly described by the speaker, does not exist, and read a paper by F Hepp, who described mono-methyl-aniline obtained from sodium-aceto-methyl-aniline, with the same properties formerly described by himself. Hofmann has obtained the same body by the action of chloride of ethyl on aniline.

GENEVA

Physical and Natural History Society, December 7, 1876.—M. Théod. Turrettini presented a specimen of a diplographe, or writing machine for the blind, constructed at his workshop. The apparatus is the invention of M Ernest Recordon, and prints at once for the blind according to one of the systems in use for them, and for the seeing in ordinary characters.—M. Th. Turrettini explained the method devised by M. Raoul Pictet and himself, to obviate the opacity of the ice obtained by the machine of M Pictet. The opacity of the ice thus manufactured results from the rapidity of the freezing of the water, which does not permit the air contained in the liquid to escape during its change of state By retarding considerably this freezing the ice obtained is transparent We may thus obtain an almost complete transparency by expelling from the freezing water the air which it contains by the preliminary action on the water of a paddle-wheel agitating the liquid.—Mr Duby presented a paper relating to eighteen species and one genus of new mosses from Japan, the Philippines, and Mauritius A considerable number of mosses from Mauritius are also met with in the Sunda Islands.—M. Hermann Fol gave an accoun of observations made by him on the fecundation of eggs, especially of the sea-urchins. He has seen the zoosperm penetrate the vitellus and push a species of vesicule into the interior of the wall of the egg. Starred grooves show themselves soon after all over the vesicule The latter then detaching itself from the wall begins to move, approaches a female nucleus, and combines with it so as to form only a single nucleus At the two poles of this nucleus are formed two small masses of protoplasm, from which devolve starred grooves both in the interior and exterior of the nucleus These polar masses enlarge, deviate more and more, then the cellular division takes place In other animals the phenomenon is complicated, but may also be followed.

December 21, 1876.—Prof. Schiff gave a *résumé* of his researches on the electricity of the nerves for the purpose of examining the electric nature of the nervous agent, and determining whether the currents are produced in the nerves of living animals. He concludes that the normal nerve when the animal is in a state of immobility does not present any current. When a current manifests itself it results from the alteration of the death of the nerve such as is produced by section, or better still from nervous activity, and the contraction which accompanies it.

VIENNA

Imperial Academy of Sciences, December 7, 1876.—The following, among other papers, were read:—Contributions to a knowledge of the Bryozoa of the Bohemian Chalk formation, second part treating of the Cyclostomata, by M Novak.—Studies on the geological origin and the progressive development of the North Albanian coast land, by M. Koncicky.—New observations on Geissler tubes, by M. Rosicky.—On the earthquake of Belluno on June 29, 1873, by M. Hofer

December 14, 1876.—On the formation and integration of equations, which determine the molecular motion in gases, by M Boltzmann.—On the nature of gas molecules, by the same.—On a remarkable property of periodic series, by M Toepler.—On the methylic ether of resorcin, and on glycyrrhizin, by M. Habemann.—On grape sugar, by MM. König and Rosenfel.

January 4, 1877.—On the origin of the posterior nerve-roots in the spinal cord of Ammocoetes (*Petromyzon planeri*), by M. Freud.—New methods for solution of indeterminate quadratic equations in whole numbers, by M. Kunerth.—On the amyloid substance in heart flesh, by M. Heschl.—On aperture widening muscles, by M. Exner. Longitudinal muscle fibres in the wall of an animal tube; generally widen the tube when they contract.—Observations in November at the Meteorological Observatory, Vienna.

January 11.—On *Eunicicola Clausii*, a new parasite of annelides, by M. Kurz.—On the influence of methodical drinking of hot water on the course of *Diabetes mellitus*, by M. Sommer.—Remarks on some problems of the mechanical theory of heat, by M. Boltzmann.—On a general mode of determination of the foci of contours of surfaces of the second degree, by M. Pelz.—On the vessels of bones of the skull and the dura mater, by M. Langer.—Barometric observations in the western part of the Balkans and neighbouring regions, by M Toula.

January 18.—On drainage and irrigation works in the valley of the Save, by the General Commando in Agram.—Astronomical and geodetic determinations of the Austro-Hungarian Polar Expedition, by M Weyprecht.—On the theory of the Bessel functions, by M Gegenbauer.—On the theory of the action of cylindrical spirals with variable number of windings, by M. Wallentin.—On a peculiar formation of isocyanphenyl, by MM. Cech and Schwebel.—On the arrangement, use, and accuracy of M Roskiewicz's distance-measurer, by M Schell.—On the development-history, and the structure of the seed-envelope in Phaseolus, by M Haberlandt

I. R. Geological Institute, December 5, 1876.—The following papers were read:—M Karl v Hauer on the analysis of the acid spring lately discovered at Ranigsdorff, near Mahrisch-Trubau in Moravia The water contains a very small quantity of fixed ingredients, but the abundance of free carbonic acid is equal to the well known Giesshubel springs 10,000 parts of water contain in weight 26 parts of free carbonic acid, so that the volume of the latter exceeds by far that of the former. The springs may therefore be considered of remarkable quality.—M. J. Gamper on diluvial vertebrates. At a little distance from the Klause at the Gahus Mountain near Gloggnitz, the author found a block of limestone covered by thin strata containing remains of vertebrate bones, in some places the layer formed a real breccia of bones. Among the remains he noted especially those of bats The blocks formed a part of the inner wall of a cleft or cavern, like those often found in limestone mountains of this country M. Gamper then referred to the occurrence of clay silicate near Steinbruck, and of arseno-pyrite in Joachimsthal.—M Itache continued his communications on the eruptive rocks that he examined last summer in the mountainous regions of Upper Vintschgau, Ortler, and Veltlin, mentioning particularly the various species of tonalites from Morignone, the Gabbor rocks from Frontale and Leprese, and some little known rocks containing many garnets In the country of Soudalo and Boladore, light coloured pegmatites intersect in veins the dark coloured amphibolite and diorite rocks.—Dr Tietze on the Elburs Mountains in Persia He mentioned the relatively rare occurrence of old crystalline rocks in this mountain chain The formations which may be determined by paleontological evidence are the Devonian, the Carboniferous Limestone, the Lias, the Upper Cretaceous, showing various facies partly abounding in fossils, the Nummulite formation, and the younger Tertiary Other formations, containing no fossils, could only be judged by their position relative to those formations whose geological age was clearly to be determined Almost certain is the occurrence of Trias and Upper Jura The Lower and Middle Cretaceous are totally wanting Only a few of the named formations extend over the whole country, therefore if two sections are made at some distance from each other, they give almost invariably a different result. M. Tietze gave also a short account of the older and younger eruptive rocks, of which these mountains are partly composed. The volcanic Demavend is not only the highest but also the youngest mountain of the whole chain, whose dimensions are given by the author as 90-100 miles in length, and at least fifteen miles in breadth

January 23.—Dr E Tietze on the geological relations of the Demavend Mountain in Persia, whose height amounts to 20,000 feet. He distinguished an upper and a lower region, the former consisting of the cone heaped up by eruptions. The highest top of the cone, acting still as a solfatara, stands within the remains of an older crater-wall The lower part is composed to a height of 9,000 feet of sedimentary rocks (Jurassic limestones, Carboniferous sandstones, and old limestone). It must be noted particularly that the position of these sedimentary strata shows exactly the same relations as those of rocks in other parts of the Elburs Mountains which are not in contact with volcanoes, a proof therefore that the outburst of the Demavend volcano exerted no influence upon the older rocks in its vicinity The reporter mentioned the occurrence of streams consisting of lava-boulders on the Demavend, as they are found at present on the volcanoes of Java, then of columnar trachytes and of the lava streams keeping their original position, but steeply inclined on the slopes of this volcano. He concludes by remarking that the Demavend shows probably a double axis, such as was stated for instance on the Aetna by Sartorius and Ch. Lyell.—M. C. Paul reports on his investigations in the Karpathian Mountains made in this year. In Silesia he studied the so-called hieroglyphs of the Upper Teschen slates, whose genesis is doubtful, but which are remarkable for their constantly keeping to a strictly limited level. He also gave a more exact division of Hohenegger's Iodula sandstone and fixed the position of the Irodek sandstone which Hohenegger had adjoined to the Lower Eocene (Nummulite group) as the highest division of the Eocene. In Western Galicia the gradual change of the petrographic facies of the Lower Karpathian sandstone (Neocomien) was studied. This formation consists in the northern zone of dislocation, chiefly of sandy and clayey strata, in the southern, which is called the penninic cliff-zone it shows a more limy composition. In Przemysl he visited the locality rendered important by Niedwieczky's discovery of ammonites. It was evident that the Neocomian ammonites were contained in a zone of those rocks called usually Ropiauka beds, which had been from other reasons already denoted as Neocomien. In Eastern Galicia the Karpathian sandstones could be divided into their proper groups and marked on the map, conformable to the results obtained by the reporter in the adjacent Bucovina. The sediments of the Karpathian sandstone divide here into the lower period (Ropiauca beds, Neocomian), the middle period (for the most part massy sandstones, probably middle Cretaceous), and the upper period, most certainly Eocene (to which belong sandstones containing Nummulites, the well-known fish-slates of Delatze, the Smilus slates, Schipoter beds, and the Magura sandstones of Czeruahora).

PARIS

Academy of Sciences, February 26.—M. Peligot in the chair.—M. Le Verrier reminded the Academy of the importance of watching on March 21, 22, and 23 for the possible transit of an intra-Mercurial planet across the sun. He also presented tome xiii. of *Annales de l'Observatoire de Paris*. This contains the theory of Uranus and Neptune, and M. Cornu's memoir on determination of the velocity of light between the Observatory and Montlhéry (by Fizeau's method improved). He finds this velocity 300,400 kilometres per second of mean time; the deduced solar parallax is 8″·88, 8″·88, or 8″·80, according as the number is combined with the equation of light given by Delambre (493″·2), with Bradley's constant of aberration (20″·25), or with that of Struve (20″·445).—M. Debray was elected member for the section of chemistry in place of the late M. Balard (the other candidates being M. Cloez and M. Friedel).—Experiments on the origin and the nature of typhoid fever, by M. Guérin. He had in view the supposed direct influence of water-closets in producing the fever, and experimented on rabbits, injecting fecal matter, urine, blood, &c., from typhoid patients. He concludes (1) that such fecal matter contains, after issuing from the system, a toxical principle capable of causing death in a class of animals, in time varying from a few hours to a few days; (2) that the same holds for urine, blood, mesenteric liquid, and the detritus of mesenteric ganglions and of ulcerated intestinal mucus of typhoid subjects; (3) that these matters, after some months, are found to retain in large measure their original toxical principles; (4) that the fecal matters of healthy subjects or of those affected by other diseases have not the toxical principles which appear in excrementitial products of typhoid subjects.—On the effects of a jet of air in water, and on the suspension of water in air, by M. De Romilly. Among other experiments: Into a bell-jar, the mouth of which is closed with net, water is sucked up by means of a tube, with stopcock, entering the jar above. On closing the cock and raising the jar the liquid is retained, there being a meniscus at each mesh and a general meniscus. On inclining the jar the water flows out, but the smaller the mesh you may incline further without escape of liquid. Using metallic net, one may place a lighted gas jet under the suspended liquid, which will boil (gently) without falling down. (In this case the jar should be connected with another larger, the mouth of which rests in water.)—On the functions of leaves in the phenomena of gaseous exchanges between plants and the atmosphere; *rôle* of stomates, by M. Merget. He shows that the leaf functions of absorption and exhalation are arrested when a layer of varnish is formed on the face bearing the stomates. Thus the leaf may be subjected to mercurial emanations without absorbing a trace of the metal, which can, of course, be easily detected by photographic processes. On the other hand, if an ammoniacal liquid be injected into the leaf, the liberation of the dissolved gas by the face that has stomates is proved by the odour of this face, it white appearance when a rod dipped in hydrochloric acid is brought near, and its printing of paper sensitised with nitrate of mercury.—On ophthalmia, by M. Brame. He specifies twelve different categories and treatment.—New experiments to try for combating the phylloxera of the roots, by M. Rommier. He proposes salts or oxides of mercury, lead, copper, zinc, and others, dissolved in alkaline hyposulphites (potash or lime). Such compounds would not be acted on by the acids of the soil, like previous insecticides.—Determination of the lines of curvature of a class of surfaces, and particularly of the tetrahedral surfaces of Lamé, by M. Darboux.—Integrals of curves of which the developers by the plane and the developed by the plane are equal to each other, by M. Aoust.—Fourth note on the theory of the radiometer, by Mr. Crookes.—On the action of water on chlorides of iodine, by M. Schützenberger. If chlorides of iodine are not decomposed into hydrochloric acid, iodic acid, and free iodine, it is because the direction of the reaction is modified by the existence of a compound of hydrochloric acid and of protochloride of iodine stable in presence of water.—Formation of quinones by means of chlorochromic acid, by M. Etard.—On a saccharine matter extracted from leaves of walnut, by MM. Tanret and Villiers. The composition of the body is the same as that of *inosite*, but it has some special properties, and the authors name it (provisionally) *nucite*.—On the salts of the Algerian Chotts, by M. le Chatelier. They contain chloride of sodium and sulphate of soda; probably also carbonate of soda mixed with gypsum.—On three recent falls of meteoric stones in Indiana, Missouri, and Kentucky, by Mr. L. Smith.—Experiments on acute poisoning with sulphate of copper, by MM. Feltz and Ritter. These were made on frogs, pigeons, rabbits, and dogs. Sulphate of copper cannot be regarded as a harmless agent, though its introduction into the system does not, in the great majority of cases, cause death. No one would consent to swallow, in food or drink, the quantity that would prove fatal.—On the congestive and hæmorrhagic alterations of the brain and its meninges in birds, by M. Larcher.

THE TREASURY REPORT ON METEOROLOGY.

WE gave in our last number the report of the Treasury Committee on the administration of the Government meteorological grant, and we shall now offer a few emarks on it and on the evidence upon which it has been ounded, as contained in the Blue-book before us.[1] The xpenditure is devoted to the meteorology of the ocean, hat is, to the part of it traversed by our ships and to that f the British Isles.

As regards the former, though much valuable work, specially in the practical point of view, has been done, his work belongs distinctly to a government department f the Admiralty. It does not seem desirable that charts or the direction of seamen should be made out according o different methods by two institutions, supported by ational money. It is then proposed by the committee hat the charting work, together with the marine superinendent of the Meteorological Office, who has done his uty so well, should be transferred to the Hydrographic Department of the Admiralty, while the scientific part hould be done in connection with investigations, including bservations both over land and sea. This appears a most reasonable decision.

Though the second part of the business of the Meteorogical Office is limited to a small surface, yet it is one with which we are more immediately concerned, and surounded as we are by the sea, this part really involves all he modifications which surfaces of land and water may roduce on the actions of meteorological causes. It seems o be supposed that observations on the ocean must resent meteorological variations in a much simpler form, ecause the atmosphere rests on a surface which is at nce more level, and at a more constant temperature than hat of the land; but it seems not to have been remarked hat the conditions under which the observations are made re much more complex. If we could imagine a search nto the laws of continental meteorology founded on the bservations made by some passengers in railway trains cross France, Germany, and Russia, the difficulty of iecing together observations of very various degrees of merit for the deduction of even accurate means would be at nce evident; that of searching for laws would become still more so. It is no doubt desirable that the meteorological ariations over water should be studied apart, but for this nd an observatory placed on some small island in midcean would be a more satisfactory way of obtaining the nd in view. Whether this would aid in the search for he causes of phenomena met with under very different onditions in our latitudes is by no means certain.

The department of the Meteorological Office occupied with the meteorology of the British Isles, includes that f storm warnings; indeed this is, at present, the great ractical work. There are numerous stations at which eye" observations are made daily, and these are teleraphed to the central office in London. There are also even observatories having instruments which register continuously the variations of the meteorological elements. The storm warnings are founded on the telegraphed observations; the registered observations have a different object. They can no doubt be employed after warnings have been issued to verify the observations and to satisfy any doubt that may have existed as to errors committed, but their chief object, in the first instance, is purely scientific.

It has long been seen that storm warnings are not founded upon laws that can be distinctly stated. Though observations made over a considerable tract of country are made use of, and a certain knowledge exists of relations between atmospheric pressure and winds, yet the warnings depend to some extent upon a practical experience which, like that of the shepherd and sailor, cannot easily be communicated to others.

The seven observatories were established to obtain good materials with which a scientific study might be founded and from which laws might be deduced giving increased probabilities of accurate prediction of the weather tomorrow from our knowledge of what it is to-day. This is not, however, the only use of the observatories. If all the scientific precautions have been taken with respect to them, they will in that case be to the meteorology of the country what carefully measured base lines are to its exact survey; each will give a point to which the observations made around it may be referred and corrected.

The great question before the Committee was how best to aid in making meteorology a science—a science from which practical results may be deduced. Millions of meteorological observations have been made and published; the seven observatories are producing continuous registers of the variations of barometric pressure, temperature, wind direction and force, &c. What is to be done with all these? Are we to go on piling Pelion on Ossa with the idea that heaps of observations will enable us to reach the mysteries they enclose? And can the Government be satisfied that they have done enough when they present the public with volumes of observation in something of the way in which Hamlet offered his friend the pipe—"Govern these ventages with your fingers and thumb, give it breath with your mouth, and it will discourse most eloquent music"?

The question then is how to get at the mysteries; or how to find a musician with breath enough to blow and skill enough to draw harmonious sounds from this giant pipe. We can only glance at parts of the testimony of the most distinguished witnesses.

When we remember that after a century of research by men of the greatest eminence—mathematicians, physicists, meteorologists—we cannot tell why the air presses heavier at ten o'clock than at four o'clock; we see that meteorological investigation includes some of the most difficult scientific problems. With this fact in view, some of the questions put to the witnesses would seem almost *comiques*, did we not know that their object was to draw out something of value in the reply. Thus, with reference to finding a "man of genius to try and get something out of the observations which have been made" (1,012), the question (1,017) is put to Sir G. B. Airy: "But you would hardly think it a safe thing to select, for instance, a young man from Cambridge, and say to him: 'Now you must take up this subject'?" When we remember, also, that the Astronomer-Royal has directed a meteorological observatory nearly forty years, and that he now says meteorology is not a science (940), it is naught, and in short that he has not been able to make anything out of it, we can understand with what profound conviction he replied, "I do not think that would be a safe thing."

---

[1] "Report of the Treasury Committee Appointed to Inquire into the Contions and Mode of Administration of the Annual Grant in aid of Meteorogical Observations; together with Minutes of Evidence, Appendix, and dex." (London, 1877.)

Sir William Thomson was also examined on this question, and he thinks (1720) "the best way would be to get some thoroughly able young man, well acquainted with mathematics and of good judgment to take up the whole subject of the harmonic analysis of the observations." No doubt the harmonic analysis has some advantages as representing mean values approximately by a series of simple oscillations occupying the whole, a half, a third, &c., of the time-period considered, which can be compared when the conditions vary; but it is only a first step, one which may be misused if it is supposed that each oscillation must represent the different periodic actions of the same or of different causes. Kaemtz employed this method forty years ago on every possible meteorological variation, but we cannot say that any important result was obtained by its means.

What has to be done was indicated by the Astronomer-Royal in answer to question 1,015); men (one man cannot undertake the work in all its directions) must be "seized upon" who have displayed "talent for things of that sort," who by long study have become saturated with the facts of the science and who have shown the capacity to devise new methods and to employ them with success. Such men, as Sir George Airy says, in answer to another question (991), should be asked to devote themselves to examining the observations already made, and to "turning them over in all conceivable ways." Such men, he says (1,015), are to be taken "on opportunity," that is to say, if they present themselves we should lay hold of them. But this is true for every occupation demanding special qualifications. It would seem sometimes as if the difficulties were exaggerated, and sometimes under estimated. If we had a Newton among us, he could do little till the meteorological apple has fallen, and the tree will require, we think, a good deal of shaking first. That the specialty of turning a thing "in all conceivable ways" is not very common, may be deduced from the evidence before the committee; but many look on meteorological investigation as a kind of lottery, where just because so many blanks have been drawn, every one has a better chance of getting a prize; and some very clever people think that the affair may be done by a machine.

There is also the very urgent reason for "turning over" the observations made at the seven observatories, that it is not possible to determine their value, nor how far they can be usefully employed for strict scientific investigation till this is done. Mr. Buchan, one of the few working meteorologists examined, says (1,530), that the eye-observations "secure an exactness and accuracy which photographic self-recording instruments do not possess." This, if true, is a very serious matter, and we shall have to return to it at another time.

The subject of observatories, the most important in connection with the progress of meteorology as a science, was also brought forward by the Committee. The question was put to the Astronomer-Royal (1,045): "Might I ask what led your office to undertake the meteorological part of its work in 1840?—Because nobody else did." This answer must evidently be taken with reference to certain conditions. Had the Government been encouraged at the time to support a magnetical and meteorological observatory, paying a competent man to direct it, we can scarcely doubt that they would have done so. Sir G. Airy's reply means, we believe, that nobody was ready to undertake the duty for nothing but himself. We think it is much to be regretted that the director of the National Observatory, overcharged as he is with the duties connected directly with his office, should have been allowed to undertake scientific work, demanding so much care and devotion of time, which was really not at all in his specialty, however excellent the motives might have been which induced him to do so.

This is now well understood in other countries. In Paris there is now a magnetical and meteorological observatory with a distinct head; another observatory devoted to solar physics is rising; and similar arrangements have been made in Germany and Austria. It is the very essence of "penny wise, pound foolish" which can seek from one man to direct with success three or four observatories at the same time, when each of them will task the energies of the cleverest men in the different departments to make something good out of them.

The question is further put (1,050)—"In the former part of your evidence you spoke as if meteorology at present was scarcely in a scientific position at all, as too uncertain to be called a science at present?—It is not in a scientific condition at all, I think."

"1,051.—I want to connect that answer with the fact that in 1840 you undertook in this Government Department these particular inquiries; at that time you must have formed some idea that these studies were worth pursuing for national objects, and in a national establishment?—Observing the movement that was going on in other places, it was very desirable that Greenwich should be one of the stations in concert with them, but still I was so diffident about the success of it, that after three years, I think at the next meeting of the committee, or I forget by what name it was called, where the representatives of different nations attended, I earnestly urged them to cease. I did not see that there was any use in going on. I recommended them to do something like what I have spoken of to-day, to stop where they were, and try what they could extract from those observations that they had collected, before they proceeded further with them."

It has always been a tendency with the heads of great national scientific institutions to annex other scientific work than that for which the institutions were founded. We remember that the late Prof. Nichol described at the meeting of the British Association at Glasgow in 1840, the numerous works he was about to carry forward in different departments of astronomy; to all he added a magnetical and also a meteorological observatory, with special reference to important meteorological problems, which he proposed to take up. Photoheliography and spectroscopy were not then in existence, or doubtless they also would have been included. The Astronomer-Royal then said (we do not remember the exact words, but they were to this effect): "Let me, as an old observer, recommend Professor Nichol, as a young observer, to undertake less and he will do more."

We have much pleasure in finding that we agree so generally with Sir G. Airy's views. We do not think, however, that it was desirable to place a meteorological observatory in Greenwich Park. We have already said why we do not think it was necessary, or even advantageous to the sciences, that both magnetism and meteorology should be placed under the same direction as the National Astronomical Observatory. Indeed the Astronomer-Royal has allowed (in his evidence) for meteorology, what is well known to scientific men all over the world for magnetism, that his well-intentioned devotion to these subjects has not been repaid by the results he has obtained.

Sir G. Airy thinks the existence of the Kew Observatory unnecessary (1,028); that they can furnish observations "at Greenwich as good or better, but quite as good certainly" (995). We quite agree that Kew and Greenwich are not both necessary, but it will be seen that we would greatly prefer to see magnetism and meteorology relegated elsewhere (we do not admire the position of Kew). With reference to the comparative value of the observations made at the two observatories, it has always been to us a matter of surprise that with two observatories within a few miles of each other, no comprehensive, strictly accurate, and scientific comparisons of the observations, magnetical and meteorological, made in them, should have been made and published. We cannot tell how far they agree or disagree. One might at least have been used as an aid to the other; if there are differences, such a comparison would have led to a search for their causes, and errors might thus have been corrected. It would be a very disagreeable matter if, when compared, instruments at the two observatories should be found not to go together as well as Admiral Fitzroy's weather-glass and an aneroid barometer.

A great national observatory for the prosecution of a branch of science of so much practical importance as meteorology should not be merely observational, but also experimental. Let us take one of the simplest cases, one brought forward before the Committee: How should we place a thermometer? Sir G. Airy says (984). "The mere observation of getting the temperature of the air is one of the most difficult things I know. If you are on the north side of a building within some distance you get it too low; if you are on the south side you get it too high, and if you are close to the ground you get something different." This is all perfectly exact; and we may add, if you keep the thermometer in one place probably the sun will shine on the ground near it differently at different hours of the day and in different months of the year, so that there is a varying source of error in the same place. The Astronomer-Royal is also asked if he can estimate the probable difference between a thermometer at four feet and forty feet above the ground (987), but he cannot; and at what height a thermometer should be placed, but he replies only that four feet is the usual height.

We mention these questions to show that nearly everything has as yet to be placed on a scientific footing. We do not think four feet is a good height, and agree with the Astronomer-Royal that thermometers have been placed too near the ground, where they have been affected by many local differences which would have been to a great extent avoided at a greater height. Of course observations may be made at any height from the soil when special questions are in view. Similar difficulties exist for other instruments, and it is certain that we are making masses of observations which might have been much more valuable to science had experiments of the class indicated been made in the first instance. In such an observatory, also, there is a whole series of physical experiments which could and should be performed, independently of those which should more properly be placed in the hands of specialists.

In the Report of the Committee, we find the following (Art. 8):—"As regards the first, although it may be desirable at some future time to create a permanent meteorological establishment on some such footing as that of the Astronomical Observatory at Greenwich, with an officer of scientific eminence at its head, we think that matters are scarcely ripe for such a step at present." We have been in some cases satisfied with the report, but here, if we understand the meaning of the word "ripe," we must differ. We believe that matters have been ripe any time the last forty years; but we hope to return to this subject on another occasion.

The Report of the Committee is all that could probably be expected with the evidence before it. There are at present two purely scientific works that should be carried forward. Something should be done with the observations of the seven observatories, and much should be done to encourage research in connection with meteorological questions generally. It should not be imagined that an investigation with reference to some very small variation can have no practical value, that is to say, that the practical results which may flow from it can be measured by the amount of the variation. Nor should it be supposed that any question which touches on atmospheric variations should be neglected, in this respect, because the relation may appear remote. The movements of the sun's envelopes, the spots, the protuberances; the moon's possible action on solar emanations may all appear unconnected with our calms or our storms, and may yet all have a relation to both.

To conclude, we object to a cumulation of duties on one head, by which things are not only not well done, but through which others are prevented from doing them well. We think centralisation hurtful to science, and we regret that 1,000*l.* a-year has not been granted to Scotland, by which a healthy rivalry would have been gained.

We have given most place to Sir G. Airy's testimony because his is really the most important, but we cannot help inquiring why so few directors of observatories and meteorologists were examined. Dr. Lloyd, who has directed a magnetical and meteorological observatory for many years; Prof. Balfour Stewart, once secretary to the Meteorological Committee and director of the Kew Observatory; Mr. J. A. Broun, who has directed observatories in Scotland and in India; the Rev. Mr. Main, director of the Radcliffe Observatory; Prof. Piazzi Smyth, director of the Edinburgh Observatory; all of whom have been occupied with meteorological investigation, are all wanting, and they are all men who might have said something worth hearing on what should be done.

MR. TROTTER ON UNIVERSITY REFORM

On Some Questions of University Reform. By Coutts Trotter, M.A., Senior Fellow and Tutor of Trinity College, Cambridge. (Cambridge, Deighton.)

DURING the short life of the Oxford and Cambridge Bills of last year, it was my lot to hear from many of my London friends many dismal, sometimes almost contemptuous, prophecies concerning the future of natural science at the old universities. For myself, in looking forward towards possible and probable changes, I always lay to heart the hackneyed consolation of the unsuccessful Liberal Orator, "Time is on our side." Whatever happens, science cannot lose much and may gain largely. How great a progress might with the least possible shock to conservative principles be effected by the help of men in whose minds a broad sympathetic love of learning is associated with a delicate appreciation of the present university feelings and habits, may be learnt by any one who will take the trouble to read Mr. Trotter's brief pamphlet.

There are men who in their so-called radical ways of thinking, exalt theoretical statements above practical suggestions, and thus are led to insist that all university reform is useless which is not based on the two abstract principles :—1. That the interests of education are essentially opposed to those of learning : 2. That the interests of the colleges are essentially opposed to those of the university. Such men argue with great vehemence that it is hopeless to expect learning to flourish in a place like Cambridge, for instance, where education, so far from being neglected, as Mr. Lowe seems to think, is pushed with yearly increasing energy (they speak of it as being "rampant," and assert that the students, who have been long over-examined, are now in danger of being over-taught), and where a poor university, like an almost penniless king whose only subjects are a few wealthy barons, contends in vain with colleges which not only are at the present moment far richer and stronger than it, but must always tend to be so, since the feeling which binds a student to his university is akin to the mild emotion of patriotism, while his affection for his college is more like the family love of home.

To this class of reformers Mr. Trotter does not belong. How far he would agree with these abstract principles cannot be learnt from his pamphlet. He, perhaps, is one of those who think that abstract principles are like the timbers of a ship, which, through the very making of the vessel, come to the surface only after shipwreck. At any rate, he adopts what to many will seem the wise course of confining himself to the practical consideration of how, with the least possible dissipation of energy, education may be converted into learning, and how the university, which ought to be the seat of the latter, may be fortified without injuring that "college life" which is the natural nstrument of the former, and which, to all who know t, has charms too great to be neglected by any wise eformer.

On these matters, all his remarks, coming as they do from one who, having a true love of learning, has for several years been prominently engaged in college and university business, seem to me worthy of very serious attention. I can readily imagine that his views will be condemned by two opposing parties. Many academic conservatives will call them "revolutionary." Many academic and other radicals will stigmatise them as a compromise. They do indeed favour that dreadfully commonplace "middle way"; but they possess this notable characteristic—they are tentative and progressive. They may not at first convert the university into a palace of learning; but if adopted, may, without fear of strain, be expanded in proportion to the demands of knowledge and the wealth of the united corporations.

In the first of the three divisions of his pamphlet, Mr. Trotter deals with the relations of education and knowledge; and his leading idea is the multiplication of what, in general terms, may be called professorships, the duties of which shall be so light as to afford leisure for research, and the promotion to which shall be at least largely dependent on fruitfulness in advancing learning. He would make learning and education, what the pious founders thought they had provided for their being, co-partners in the wealth of the colleges; and would sweeten and lighten teaching with the spirit of research. In this he will doubtless fail to please those who press for the endowment of research "untrammelled by teaching duties;" but is not, after all, the difference between him and them one of detail only, and not of "abstract principle?" Putting aside certain tasks of continued observation, all investigators, or at least all with comparatively few exceptions, would be assisted rather than hampered in their inquiries by having from time to time to give expositions of their particular studies to an audience of some kind or other. And that is all which is really included under the duties of professor. How much or how little teaching ought to be demanded of this or that man must depend on the particular circumstances of each case; and the few instances where absolute dumbness is an essential to successful research, might without difficulty be provided for by special arrangements.

These professorships Mr. Trotter would divide into three classes.—(1) Ordinary Professorships, such as now exist; (2) Lectureships, somewhat corresponding to the present College Lectureships; and (3), what, in the absence of any more suitable word, he proposes to call Extraordinary Professorships. The first class he proposes to limit in number and exalt in dignity so that each professor should be considered as at least the nominal head of the particular study to which he is devoted. Although he does not expressly state it, Mr. Trotter evidently intends that the men holding these offices should be eminently men of research; and hence while their incomes would be ample, their official duties would be light. The extraordinary professors would form a more numerous class and would be appointed either for fruitfulness in research or for great teaching talent, or (and it is hoped frequently) for both. The emoluments and status of an extraordinary professorship ought to be such that a man might look to it as a post for life and not merely as a stepping-stone to something else. The third class of lectureships would be still more numerous, and serve in part at least as feeders to the other professorships. Though, for them, as for the other two classes, research would be a qualification at least on a level with didactic ability, the teaching duties of a lecturer would naturally be heavier than those of a professor. It may be urged, as Mr. Trotter himself feels, that extraordinary professor is a very awkward title. Professor adjunct, or assistant professor is distinctly objectionable. It seems to me that there is much to be said in favour of calling the new professors by the simple title of professor, and of inventing for the higher and more select posts some such style as professor director, or professor rector; indeed, the duties of a member of this class would probably in many cases consist largely in a general guidance and supervision of the studies carried on in his own particular science.

His plans also provide assistants both for teaching and research, demonstrators, &c., and include the establishment of what he proposes to call "senior scholarships," *i.e.*, posts to be filled by able young men at the close of their student career for the purpose of enabling them to devote themselves free from all trammels, for two, three, or more of their best years, to learning research. This is, indeed, at present, perhaps the most crying want of the university, a want most imperfectly met or not met at all by fellowships as now administered.

The scheme by which Mr. Trotter proposes to unite the university and the colleges in the function of appointing and regulating this professoriate requires development; but it has the great merit of strengthening the hands of the various "boards of studies," and if adopted would soon grow into a natural and healthy form of government under which the hiring, by candidates for university posts, of special trains for the conveyance of their outlying voters, would become a grim and a grotesque reminiscence of the past. It must be remembered, however, that no artificial scheme will secure purity of election, unless the electors be thoroughly leavened with the leaven of loyalty to learning; and that such loyalty will only be found where research, rather than teaching, is regarded as the great aim of university life, where Leah is woo'd chiefly in the hope that Rachel may be won.

All these proposed changes, to say nothing of university laboratories, museums, &c., require money; and in the second part of his pamphlet Mr. Trotter discusses the methods by which the wealth of the colleges may be rendered available for university purposes. Here two plans present themselves. There is, first, what may be called the "social" plan. In this the colleges are supposed to undertake the care and protection of certain university posts or institutions, this college, for instance, supplying the funds, in the shape of fellowships or otherwise, for this professorship, or taking the charge of that laboratory. It may be regretted that Mr. Trotter has not entered more fully into the discussion of this plan, which is sure to find ardent supporters in the colleges It offers the college a *quid pro quo*, and promises to strengthen rather than weaken "college life." The difficulties of the plan lie in the question of election. If the university elects, the college may have to receive into its bosom a man whom it detests, if the college elects, it may not unlikely choose the very man the university would seek to avoid. Such a scheme cannot be made to work satisfactorily even with the help of elaborate checks and counter-checks, unless the actions of both colleges and university are directed by thorough loyalty to learning.

The second plan is that of "taxation," or as a small but prominent party prefers to call it, "confiscation," by which the colleges are called upon to contribute, in proportion to their wealth, to the common university funds. And on this point Mr. Trotter's suggestion that the contributions "should be variable within limits, and fixed from time to time, in accordance with the wants of the university, by some competent authority representing the colleges," is worthy of consideration as an improvement on the older scheme of a fixed contribution in the form of a definite percentage tax on the collegiate divisible revenues. At the same time it is difficult to overlook the possible occurrence of bitter and frequent discussions as to what, at any given time, are to be considered the actual needs of the university.

The money which the colleges are in the one way or another to be called upon to devote to the university must come from the pockets of the scholars, or the fellows, or the heads of houses; and the third part of the pamphlet is devoted to a consideration of these three classes.

Concerning the fellows, Mr. Trotter, with a boldness which will undoubtedly prevent many Conservatives from recognising at first how moderate a compromise his whole plan of reform really is, writes as follows:—"On the whole, I am disposed, mainly for the reasons put forward by Mr. Sidgwick in the *Contemporary Review* (April, 1876), to advocate the abolition, or at any rate the restriction within very narrow limits, of the class of fellowships *held purely as prizes*." Such a proposal will be opposed tooth and nail by many both within and outside the university who have never attempted to answer Mr. Sidgwick's arguments; and Mr. Trotter himself states that he imagines "public opinion" is not at present prepared to support so extreme a measure.

In the matter of the scholars Mr. Trotter proposes no marked innovation, though he seems to think changes of some kind are desirable. To his general approval of present practices he will find few demurrers either within or outside the university; and yet the evil influences which the system of scholarships is secretly exercising on both education and learning are well worth consideration; *mutatis mutandis*, many of the arguments against prize fellowships might be well applied to prize scholarships.

The heads of houses form the last topic on which Mr. Trotter dwells, and those who know university life, whatever their opinions, must award to him the praise of having brought forward into open and plain-speaking discussion a subject on which, for many reasons, it is difficult for any fellow of a college to say his mind. That he boldly advocates the abolition of heads of houses is perhaps less important than that the question should be thoroughly considered. At the same time his arguments seem irresistible; he says all that can be said in favour of maintaining these ancient offices, but concludes that all the advantages they offer might be secured by other arrangements which would bring to the university at the least an annual income of 15,000*l.*, and yet eventually be felt by no college as a burden—by some, possibly, as a relief.

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.]

Science at Oxford

THE anonymous "Oxford Man" who so effectively reformed his Alma Mater on paper in the last number of NATURE can hardly be complimented on his successful and unfilial misrepresentations. It is not true that "of all the 360 fellowships in the various colleges only five are held by persons (exclusive of professors) who have been elected to them in consideration of their attainments in physical science." At the present moment no less than six fellowships are being held by *biologists*, viz., at Exeter, two; at Magdalen, two; at Pembroke, one; and at Ch. Ch., one; and two fellowships at Merton, one at Brasenose, one at C. C. C., and two at Ch. Ch., are tenable for physics or chemistry solely. It is true that one Merton fellowship and the one at Corpus is at the moment vacant, but this does not affect the question. Thus there are *twelve* instead of five fellowships in the hands of natural science honour men, and considering the few who graduate in the science school as compared with the vast crowds who in the aggregate go out in other schools, the number is by no means despicable. There is, moreover, the equivalent of a fellowship held by the Millard Lecturer in physics, who receives from Trinity an annual grant of 200*l.* This list of prizes takes no account of those fellowships in which "the application of mathematics to physics has been allowed to count in establishing a students' claim to such fellowship."

It is difficult to make out why the statistics of 1875 should have been selected by "an Oxford Man," to whom one would imagine the calendar for 1877 should be by no means inaccessible, and the conclusions to which consideration of these statistics has led him irresistibly suggest to those who know Oxford as it is, that "an Oxford Man's" survey is retrospective.

That the public schools pay so little heed to physical science is matter for regret, which is however tempered by the assurance that a change has been inaugurated in places, and the conviction grows daily stronger that the claims of natural truth are forcing a recognition in these centres of preliminary culture. At Eton, at Rugby, and at Clifton, science is no longer a bye-word and a play, but with masters to teach and willing boys to learn, biology and physics and chemistry are fast becoming realities where, not very long ago, they were but phantom names.

It is folly to hint of "introducing any branch of physical science into any one of the compulsory examinations." Such a course would effectually crush the growing taste for natural knowledge; it is only by leaving it an optional or alternative subject that the present prejudice against the study of science can be satisfactorily subdued.

Only ignorance of the Oxford of to-day could have led to the expression "even the heads of houses are with few exceptions men who have been schoolmasters, or who hope to be so." The Master of University, and the Dean of Christ Church can alone claim to have served in the capacity which has been asserted of the majority. The conclusion of the sentence quoted is ridiculous when applied to the senior members of the collegiate bodies.

The concluding paragraph of "an Oxford Man's" article is perhaps most glaringly indicative of sublime ignorance of the Oxford of to-day. Those whose interest, it is assumed, "it is to suppress a class of studies of which they are themselves ignorant," include many names honoured even in metropolitan centres of scientific culture; and it would better become all "Oxford men" who, *in absentia*, are prone to think of the University as they knew it, to assure themselves that things have remained *in statu quo*, than to censure in ignorance that a little careful inquiry would completely dispel. CHARLES H. WADE

Magd. Coll., Oxford, March 12

Just Intonation

OTHER occupations have prevented my replying sooner to Col. A. R. Clarke's amusing charge (vol. xv. p. 353), that it is I (instead of he himself) who "confound vibration numbers with their ratios." Three examples are included in his first letter: "The vibration numbers of the diatonic scale being represented by—

$$1,\ \frac{9}{8},\ \frac{5}{4},\ \frac{4}{3},\ \frac{3}{2},\ \frac{5}{3},\ \frac{15}{8},\ 2."$$

The figures are correct in this instance, but instead of being "vibration numbers," they represent only the *ratios* of vibration. Then follows: "if we build the scale upon the dominant $\frac{3}{2}$, the vibration numbers will be—

$$1,\ \frac{9}{8},\ \frac{5}{4},\ \frac{45}{32},\ \frac{3}{2},\ \frac{27}{16},\ \frac{15}{8},\ 2,$$

and if we built upon the sub-dominant $\frac{4}{3}$, the vibration numbers will be—

$$1,\ \frac{10}{9},\ \frac{5}{4},\ \frac{4}{3},\ \frac{3}{2},\ \frac{5}{3},\ \frac{16}{9},\ 2."$$

Such ratios as these could not pass unchallenged in NATURE, therefore I drew the anonymous writer's attention to the second and third scales, only pointing to the first intervals in each, and as "oversights." It was reasonable to expect that he would submit the scales to some competent musical friend, who would correct them throughout. Instead of doing so, the Colonel announced himself, and had the courage to write, "the errors and oversights with which Mr. Chappell charges me are imaginary." Under the plea of "making the matter clearer," he changed the ratios (January 18), but still he could not set them right. Col. Clarke's third letter convinces me that he does not permit his figures to be called in question by any person. Perhaps, then, one illustration of the Colonel's system of making, or of transferring, ratios may interest the reader. I select his $\frac{45}{32}$, because its source may perhaps be pointed out. Mr. Colin Brown introduced that ratio as from F to B natural in the scale of F. The Colonel saw that F, G, A, and B *natural* were four consecutive long keys, and so also were G, A, B, and C, therefore the ratio of the one ought to do for the other. It was excellent geometry, because all the keys are of the same width; only, whether they were tones or semitones cannot have entered into the Colonel's calculation.

It may be assumed that Mr. Colin Brown did not construct any harmonic instrument of six octaves above F, in order to hear such a thorough dissonance among the quarter-tones as 45 vibrations *sounding in cycles against* 32, but *that* he had a sheet of paper before him, and added the intervals $\frac{9}{8}$ to $\frac{5}{4}$. The $\frac{9}{8}$ was for the major tone from F to G, and the $\frac{5}{4}$ for the major Third from G to B. This $\frac{9}{8}$ from F to G, might have assisted the Colonel to correct his sub-dominant scale.

Allow me to add a note which may be in time for Mr. George Grove's glossary. I now recollect that the so-called "Comma of Pythagoras" is claimed by Boethius, and, as his treatise was once a college text-book, it was in all probability from it that the moderns first applied the name "comma" to that most minute of intervals. It is a favourite plaything with mathematicians, but, being inaudible as a sound, whether as a difference, a ratio, or any other way, it may well be spared from books upon mundane music. WM. CHAPPELL

Strafford Lodge, Oatlands Park, Surrey

Typical Division of Stars.—Borrelly's Comet

EXCUSE me asking you to allow me to rectify a statement in NATURE, vol. xv. p. 344, col. 2. It is stated there that M. Konkoly has followed M. Vogel's typical division of stars. I beg to observe that this typical division has been proposed by myself since my first publication in 1866 (*Memorie* of the Società Italiana, ser. iii. tom. i. p. 1) and *passim* in my first publications.

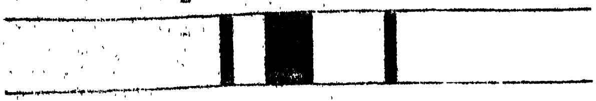
Again you say that M. Vogel discovered, in 1871, the bright lines of β Lyræ. I beg you also to note that these lines were announced by myself in my first publication of the same year, 1866, and even printed in the special catalogue of spectral stars, published in Paris in 1867, and widely circulated (p. 21). I have also announced that these lines were invisible in after years.

I do not wonder at these omissions, since unfortunately the Italian language is very little understood out of our country.

P. R. SECCHI

Rome, February 24

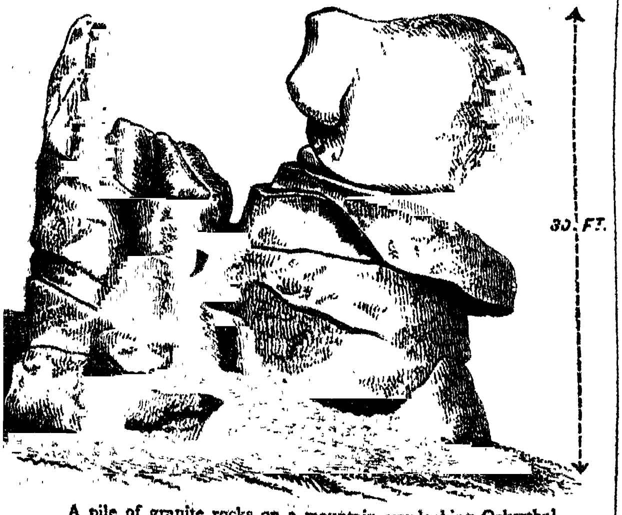
P.S.—On the 15th of this month I obtained a sight of the spectrum of Borelly's Comet. It was composed of a bright line very large in the green, another *more* refrangible in the blue, and another *less* refrangible in the yellow (?) but this was narrow and faint. Their figure was approximately as follows:—



I could not determine them better. The lines, especially the central one, were pretty brilliant.

"Stone Rivers"

THE interesting account of the mode of formation of "Stone Rivers," given in a late number by Sir C. Wyville Thomson, recalls to my mind some apparent moraines which I observed, and somewhat similarly explained, some years ago in the Hartz Mountains. In a paper read before the Geological Society of Dublin in 1872,[1] I thus speak of them: "The first thing that one notices on entering this valley [the 'Ockerthal'] from the north is that the bed of the stream is crowded with granite pebbles and boulders, which become of greater size as we proceed up the valley. The boulders are soon so large—many of them some tons in weight—and are situated so far up the slopes on each side, that the first idea is, we have here the morass of a former great glacier. I looked diligently for ice marks, but could see none; and I soon found that the causes which have the effect of scattering huge blocks of rock on the slopes and on the bed of the river are now at work and are slowly, but surely, altering the contour of the adjoining granitic mountains. . . . . All over the sides and upon the summits of these mountains are scattered the most fantastic piles of immense boulders. Some of them are over thirty feet in height and form conspicuous objects in the landscape; others, again, are deep in the forest, away from pathways, and are not to be seen until one climbs quite up to them. . . . . It is quite clear that the contiguous surfaces of the blocks in these piles are undergoing a slow decomposition, that the joints are becoming gradually looser, and in consequence the cohesion of the component pieces less and less. Sooner or later the upper portions must either slip off or topple over, and roll down the mountain side. And this is not mere theory, for I hear that every now and then a boulder does fall and comes crushing down the hill until quietly deposited near the bottom. It would appear that while the surrounding rock has been decomposed and has fallen down in the manner indicated, these heaps have the longer resisted. But they are yet to follow in their turn; when the atmospheric agencies have sufficiently done their work, gravity will come in and lower the whole."



A pile of granite rocks on a mountain overlooking Ockerthal.

Instances of the turning over of the edges of slaty strata from the weight of the superincumbent mould and vegetation are common in the Hartz. I find in an old note-book the following entry:—"I was interested at seeing the upper slates on the left wall [of a quarry near Goslar] bent so much over that their dip has become 75° to the north [the regular cleavage dip of the district is about 40° *south*]. Whether this is due to the weight of the ground above, to a landslip, or to the action of a glacier, I am not quite sure. I incline, however, to the first theory, for, although the slope of the hill is not high, the constant weight of the superincumbent earth and rubbish, bearing downwards for ages, would, it seems to me, be enough to cause such a result."

Scientific Club PHIN. S. ABRAHAM

The Measurement of the Height of Clouds

AMONG the various parallactic methods for determining cloud heights, one of which Mr. Malloch has put in practice (NATURE, vol. xv., p. 313), the use of the cloud shadow as a second station seems worthy of notice, as it requires very simple apparatus and observations.

On any partially cloudy day at the sea-side, an observer with a sextant may, from a cliff, easily determine cloud heights by the following elements:—A. Altitude of a given point of cloud above the horizon, allowing for dip. B. Depression of the shadow of the same point on the surface of the sea. C. Sun's altitude. D. Lineal elevation of observer above sea-level. The measurements should be taken when the cloud, the sun, and the observer all lie in a perpendicular plane; *i.e.*, when the cloud shadow is seen on the sheen of light reflected from the wavelets; otherwise azimuth observations, and less simple calculations, must be applied. Full moonlight might also be used at night.

On practically trying this method in September, 1875, the time of day was selected when the sun was in the direction to or from which the wind was blowing; thus the cloud shadows slowly sailed along the sheen on the sea, and could be followed by successive timed observations for half-an-hour or more, so that their velocity, and any variation in their height, could be ascertained.

The results are of course most accurate when both clouds and sun are at considerable altitudes, and I believe that this method will give results quite as accurate as the photographic process. The rounded forms are the greatest trouble, and measurements of the centres of little isolated masses of cloud are the best. The height of the observer above the sea is of course easily obtained by the angular width of a base measured on the beach.

The same method might be employed with shadows on land, by using a theodolite and a map; and though it is only applicable to one or two classes of clouds, yet its simplicity may induce some of your sea-side readers to make such observations.

Bromley, Kent W. M. FLINDERS PETRIE

The "Hog-Wallows" of California

MY friend, Mr. Thomas Belt, F.G.S., has kindly sent me the following extract from a paper by Prof. Joseph Le Conte, in the *American Journal of Science* for 1874 (p. 366), in which an explanation is given of the above-named formation (NATURE, vol. xv. p. 274) and of similar mounds farther north. It will be seen that Prof. Le Conte refers them wholly to "surface-erosion," but it is not clear whether he means "pluvial" or "aerial" erosion, or the two combined. More explanation seems required to account for the *removal* of the eroded matter over a surface thirty miles wide without producing any continuous ravines or other water channels:—

"*Prairie Mounds.*—The irregularly ramifying grassy glades or prairies already described as existing at the southern extremity of Puget Sound are studded over as thickly as possible with *mounds* about three to four feet high and thirty or forty feet in diameter at base." . . .

"The whole country between the Dalles and the upper bridge of Des Chutes River, a distance of about thirty miles, is literally covered with these mounds." . . . "The true key to their formation is given here, as it was not at Mound Prairie, by the great variety of forms, sizes, and degrees of regularity which they assume. They vary in *size* from scarcely detectable pimples to mounds five feet high and forty feet in diameter at base, and *in form* from circular through elliptic and long-elliptic to ordinary hill-side erosion-furrows and ridges." . . .

---

[1] "Notes on the Geology of the Hartz," by P. S. Abraham, M.A., B.Sc., &c. Plates VIII. to XI. Journ. R. Geol. Soc. of Ireland, vol. xiii. Pt. 3, p. 92, 1873.

"No one, I think, can ride over those thirty miles and observe closely without being convinced that these mounds are wholly the result of surface-erosion, acting under peculiar conditions. The conditions are a *treeless country* and a *drift soil* consisting of two layers, a fine and more movable one above and a coarser and less movable one below." . . . "The necessary condition, I believe, is the greater movableness of the surface soil compared with the sub-soil." . . . "Surface erosion cuts through the finer superficial layer into the pebble layer beneath, leaving, however, portions of the superficial layer as mounds."

"Similar less conspicuous mounds, under the name of 'Hog-wallows,' are well known to exist over wide areas in middle and southern California."

The words in italics are so in the original.

ALFRED R. WALLACE

SCIENCE AT CAMBRIDGE, MASS.

THERE is marked activity in all scientific pursuits in and about Harvard University. The Agassiz Museum has at last had its management fully turned over to the University, the transfer being effected by permission from the State Legislature. At present the estimated worth of the property is $322,000; the land and buildings being valued at $100,000, and the collections at $60,000; the rest being trust funds. By the transfer, Harvard will have the use of the collections for educational purposes, and the Peabody Museum of Archæology will erect an edifice connected in plan with the Agassiz Museum. The Peabody trust provides for a Professorship of Anthropology, as well as for collections and a building. The Agassiz Museum is arranged so as to display types of the whole animal kingdom in their natural classification. Great facilities are already furnished to students and specialists, and these facilities will now be further increased. The force employed in the Museum is sufficient not only for the care of the specimens, but also to aid in new research.

There is a steady increase in the number of Harvard students in the scientific courses—physics, chemistry, natural history, botany, anatomy, and physiology. Textbooks are little used in these courses; students are required to handle the things themselves, in the laboratories. "Summer schools" are conducted from June to September, in which teachers from the public schools become pupils. Chemistry has been taught in these summer schools for three years, geology and botany for two years, and zoology will be undertaken this year under Assistant-Professor Walter Faxon. Prof. Shaler's Summer School of Geology is the most widely-known of these enterprises. This year it will be conducted with headquarters successively in the Connecticut Valley, the Berkshire Hills of Massachusetts, and the Helderberg or the Catskill Mountains of New York. The class will be limited to fifty members. After the school closes, a trip will be made by those who can join in it to Cleveland, Nashville, Louisville, and the Mammoth Cave. Besides the Summer Schools, there is also organised a series of four courses of lectures to teachers, which include laboratory work. These are given on Saturdays from January to May. They embrace geology, physics, botany, and zoology, and have the services of Professors Shaler, Trowbridge, Goodale, and McCrady, and some assistant-professors of special repute. There are about forty members to a class.

The Boston Society of Natural History sustains a similar series of course-lectures to teachers during the winter months. The instruction is practical, as far as it can be made so by the illustrative specimens in the Society's collection. Prof. Shaler is also organising a system to furnish teachers with selected specimens and appropriate text-books and descriptions. It is expected that this new system will be the means of inducing teachers in the public schools to make further collections for their own use and to instruct their scholars. The Harvard Natural History Society is very actively engaged in promoting scientific education, especially among beginners in such studies. Prizes are offered for the best essays of the students upon their actual observations in natural history and botany. A free course of six scientific lectures is furnished by this Society, the lecturers being eminent specialists in the University. Two scientific associations at Cambridge are also doing active work—the Nuttall Ornithological and the Cambridge Entomological Clubs. The latter is the larger of the two, and contains many members of eminence. It publishes a periodical, the *Psyche*. The Nuttall Club publishes a quarterly magazine, the *Bulletin*, edited by Prof. J. A. Allen. This list of scientific enterprises in and around Cambridge, Mass., is by no means exhaustive, but it will give a fair notion of the activity with which they are promoted at the present time. It is hoped that the present year will be marked by even greater effort than its predecessors.

NATURAL HISTORY AND GEOLOGICAL RESULTS OF THE ARCTIC EXPEDITION

THE public will, we are sure, be glad to hear that though the Admiralty have declined to undertake or assist in the publication of the results of the late British Arctic Expedition, beyond matters purely hydrographical, the natural history and geological collections brought back by the expedition are being rapidly arranged and named. The whole of the numerous collection of fossils from the Silurian (Wenlock), Devonian, Carboniferous Limestone, and Miocene rocks of the coasts of the circumpolar sea have been examined by Mr. Etheridge, the palæontologist of the Geological Survey, and found to contain several new and interesting forms, which will be described in his forthcoming paper, at the Geological Society, on the Arctic fossils brought back by Capt. Feilden, R.A., and which will accompany a paper by that officer on the rocks and general geological facts observed by him in the Arctic area.

We especially rejoice to find that Capt. Feilden has brought back a large series of notes and portions of rocks glacially scratched and scored, scratched boulders and pebbles, which will throw much light upon the manner in which this country was glaciated during the Drift period. It will be seen that stones on a headland coast can receive the greatest possible amount of glaciation by the mere impinging of floe-bergs, driven by violent gales and currents, on the breaking up of the pack. On the much-vexed question of the parallel roads of Glen Roy, light also may possibly be thrown, for terraces fringe nearly every valley flanking the Arctic coast, formed by fresh water, dammed by pack ice. These rest on marine beds of boulder clay, with sea shells, which rise to heights of more than 500 feet above the present sea-level, and prove the recent elevation of the land, which movement is still going on; the marine beds outside the ice foot fringing the coast of to-day will doubtless ere long be elevated above the water-level, and be covered with the latest fluviatile terrace behind the pack.

To those accustomed to the magnificent results brought to England by perfectly equipped expeditions like that of the *Challenger*, proceeding leisurely through seas teeming with the luxuriance of tropical life, the collections brought back by the Arctic Expedition may appear small; but we feel sure when the specimens are fully catalogued, and the difficulty realised of carrying heavy specimens of rocks and fossils when up to the arms in snow, and of securing insects with fingers numbed by a temperature of 50° below freezing, it will be felt that the naturalists of this expedition have made excellent use of their opportunities. We may mention that the extensive series of Miocene plants associated with the thirty-feet coal-bed of Lady Franklin's inlet will be described by Prof. O. Heer, the insects (recent) by Mr. McLachlan, and the fishes by Dr. Günther, of the British Museum.

THE PHYSIOLOGICAL ACTION OF LIGHT

Method of Experimenting.—One of the chief difficulties in arriving at the exact relation between [illegible] variation and the luminous and colour intensity of light, was the continually diminishing sensibility to the stimulus, owing to the abnormal conditions of the eye when removed from the head. When the experiment begins, the eye is remarkably sensitive to light, and a large variation of current is obtained; but the amount of this current is gradually falling, in consequence of the gradual change in the parts of the eye, owing to their loss of vitality and sensibility. In fact, the parts are dying—the blood is not circulating, and molecular and chemical changes are slowly occurring. In the case of the frog however, it is a fact that the retina retains its sensibility from three to four hours, and sometimes longer. After a lapse of two hours the frog's eye frequently remains in a tolerably stable condition, in which it does not lose sensibility rapidly. This condition may last for four or five hours. In order to get rid of the difficulty of [illegible] death of the parts, various methods were tried in earlier experiments in the attempt to remove the eye as quickly as possible, and to make the observations rapidly. In the case of the warm-blooded animals this did not lead to good results, because the sensibility to light disappeared in a very few minutes. On several occasions the posterior aspect of the eye was exposed in the living anæsthetised warm-blooded animal, and on bringing one electrode into contact with the severed optic nerve while the other touched the cornea, the observations were tolerably constant. This method was troublesome and difficult.

Diagram showing arrangement of apparatus in the experiment on eye o frog A, Eye showing the electrode, E, in contact with it. B, Skin removed, and subcutaneous tissue in contact with other electrode, E K, Key. G, Galvanometer Arrows indicate direction of current. Cornea, positive Back, negative.

These experiments are now made in a different way. By placing a frog, rabbit, or pigeon under the influence of chinoline, the animal remains motionless. A small portion of the surface of the cranium is then removed so as to expose a portion of the brain. One of the electrodes is brought into contact with the surface of the cornea, and the other with the surface of the brain. The blood is still circulating. A current is obtained; and all the effects I have just mentioned may be observed with ease. The animal remains in this condition, retaining its sensibility to the action of light, for as long a period, in the case of the frog, as forty-eight hours. These observations led to the discovery made recently, that there is no necessity for even exposing the surface of the brain. That is to say, the action of light can be traced, if needful, through the whole body. If, for example, we take a frog, place it in position, slightly abrade the skin on the surface of the head or back, or any part of the body, then adjust the electrodes, one in front of the cornea and the other upon the abraded skin, we obtain an electrical current which is affected by light in the usual way. But if the electrode in contact with the cornea be shifted to some other part of the body, a current may be obtained; but this current is not sensitive to light. In order to produce the specific action of light upon the eye, the retina must be included in the circuit. This discovery enabled us to perform many experiments without injuring the animal, except to the extent of abrading or removing a small portion of skin. It at once opened up the way for making observations upon warm-blooded animals (one of the chief difficulties in our earlier investigations). For example: give a rabbit or a guinea-pig a small dose of chinoline, and the animal remains prostrate and quiet. Then cut off a little of the hair from the surface of the head at the back of the neck, and abrade the skin so as to have a moist surface; bring the electrodes into position, placing one in contact with the abraded surface, and the other in contact with the surface of the cornea, and you will at once obtain the effect.

Action of Light in Warm-blooded same as in Cold-blooded Animals.—By the use of chinoline we were able to make experiments of the kind just described for a considerable time, without the necessity of maintaining artificial respiration. The result of those investigations upon warm-blooded animals has been to show that in these, as in the cold-blooded, light produces first an *increase* in the electric current on impact; continued light usually causes the electrical current to diminish; and on the removal of light, there is a second rise, as described in the case of the frog. In our earlier investigations, we always observed in the case of warm-blooded animals (when the eye had either been quite removed from the body or was receiving an inadequate supply of blood), that the action of light caused a negative variation, that is, a *diminution* in the electrical current. By improved methods, however, which have the effect of placing the eye in conditions more normal, we find that light causes a *positive* variation, that is, an increase; thus agreeing with what had hitherto been observed in the eye of the frog. This is a point worthy of notice. Du Bois-Reymond showed, even in the case of sensory nerves, that physiological action caused a *negative* variation. But it appears that in the case of the retina the action of the normal stimulus is to cause a positive, not a negative variation.

Experiment with the Living Lobster.—The action of light can be readily shown in this animal. Fix it loosely in a cloth, and lay it on the table in a slightly oblique position. With a small trephine remove a circular portion of the carapace, about three millimètres in diameter, and expose the moist tegumentary surface. Bring one electrode into contact with this surface, while the other touches the cornea. The usual effects of light may then be noted; but in the case of the lobster, the variation caused by the impact is greater than what we have noticed in any other animal, often amounting to one-tenth of the total amount of current. Another interesting experiment, comparable with that of the two eyes just described, may be made on the lobster by placing an electrode in contact with each cornea. The result frequently is apparently no current, but in reality the currents neutralise each other. Light falling on the one eye causes the

at the Royal

say to the left, while if it fall on the other eye, the needle swerves to the right. When the eye of the lobster, removed from the body, was divided longitudinally into segments, each segment was found sensitive to light. The effect of light was then to increase the primary current, but no inductive action was observed on withdrawal. This observation is interesting as a confirmation of the views of physiologists regarding the mode of action of a compound eye.

Diagram showing arrangement of apparatus in experiment on living lobster A, corneal surface, having electrode, E, in contact with it. B, portion of carapace removed so as to expose moist surface for electrode, E. K, key. G, galvanometer. Arrows indicate direction of current.

Mode of Experiment on Eye of Fish.—An experiment upon the eye of a fish may be made in a very simple way, by a method adopted in Prof. Stricker's laboratory in Vienna. Take a fish and give it a very small dose of woorara. It soon becomes almost motionless, and sinks in some cases to the bottom of the vessel. The animal would soon die in consequence of paralysis of the movement of the gills necessary for respiration. But, if we take the animal out of the water, put it upon a glass plate, introduce a little bit of cork under each gill, and then by means of an india-rubber tube placed in the mouth, allow a little water to flow over the gills, the fish will live out of water for many hours. By this method may be made the experiment upon the eye of a fish with like results.

Observation on Human Eye.—Having succeeded in detecting the action of light on the retina of the living warm-blooded animal without any operative procedures, it appeared possible to apply a similar method to the eye of man. For this purpose, a small trough of clay or paraffin was constructed round the margin of the orbit, so as to contain a quantity of dilute salt solution, when the body was placed horizontally and the head properly secured. Into this solution the terminal of a non-polarisable electrode was introduced, and in order to complete the circuit the other electrode was connected with a large gutta-percha trough containing salt solution, into which one of the hands was inserted. By a laborious process of education it is possible to diminish largely the electrical variation due to the involuntary movements of the eye-ball, and by fixing the eye on one point with concentrated attention, another observer, watching the galvanometer, and altering the intensity of the light, can detect an electrical variation similar to what is seen in other animals. This method, however, is too exhausting and uncertain to permit of quantitative observations being made.

of Variation in Direction of

One phenomenon particularly attracted the attention of physiologists, and especially of those who first saw the experiments, viz., that sometimes, in the case of the eye of the frog, light produced an increase in the electrical current, and in other cases a diminution. This we could not at first account for. But we have been able to make out that the positive and negative variation, or the increase or diminution of the natural current on the action of light, depends upon the direction of the primary current, when the cornea and brain are in circuit. If the cornea be positive and the brain be negative, then light produces an *increase* of the electrical current. If, on the other hand, the cornea be negative and the brain positive, light then produces a *diminution* in the electrical current. It is thus conclusively shown that the current superadded, or if we may use the language, induced by the action of light, is always in the same direction; only in the one case it is added to, and in the other subtracted from, the primary current.

The Use of Equal and Opposite Currents.—Many experiments were performed in which equal and opposite currents were transmitted through the galvanometer at the same time. By the use of resistance coils, it was not difficult to balance the current from the eye; but, owing to the inconstancy of even a Daniell's cell in such experiments as these, it was impossible to avoid fluctuations which might possibly have been mistaken for those due to the action of light. This difficulty was got over by what was formerly called *the double eye experiment*, in which two similar eyes are placed in reversed positions on the electrodes, so that the current from the one neutralises that of the other. When this is accomplished, it is easy by means of a blackened box, having a shutter at each side, to allow light to fall on either the one eye or the other, and it is then shown that the galvanometer needle moves either to the right or left, according to the eye affected. Instead of removing the eyes from the head and balancing them as just described, it is a much better method to apply the two electrodes directly to the corneas in their natural position. By a little manipulation, it is possible to obtain two positions that seemingly give no electrical current. In these circumstances, light, allowed to fall on the one eye or the other, produces the effects above detailed.

Action of Polarised Light and Colours of Spectrum.—The next point investigated was the action of polarised light and the various complementary colours. Early experiments, by passing light through solutions having various absorptive powers and by the direct coloured rays of the spectrum, &c., lead always to the same conclusion—namely, that the most luminous rays produce the greatest effect. For studying the action of polarised light, the simple contrivance of a black box, having a hole on one side of it, placed over the eye, may be employed. Opposite the hole two cylindrical tubes of brass, each carrying a Nicol's prism, were placed, and between the two prisms a thin plate of quartz is introduced, producing the various colours of polarised light on rotating one of the prisms. The general results were exactly the same as with the colours of the spectrum. In all cases, the impact of the yellow rays produced the greatest effect. It has also been ascertained by this method that the effect of the *impact* of light is much more regular than the effect of its removal. The results of one series of observations are given in the two following tables:—

Action on Frog's Eye of Colours of Polarised Light.

	Initial Effect.	Final Effect
Purple	rise of 3	rise of 14
Light blue ...

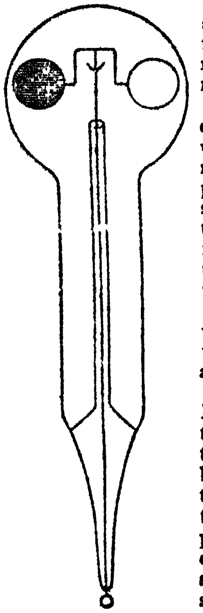
(*To be continued*)

SIR WILLIAM GROVE ON THE RADIOMETER[1]

SIR WILLIAM GROVE described some experiments he had recently made with a modification of Crookes's radiometer. After a few prefatory trials, such as coating one-half of the bulb with tinfoil and electrising it, which gave no notable results, he devised a method, shown in the accompanying sketch, by which he could electrise the whole of the internal system. Four aluminium vanes, each blackened on one side, had metallic arms and a metal point at their crossing that rested in a metal cup. The latter was united to a platinum wire that passed through a glass tube and was fused into it, the platinum wire protruding. Lastly, the glass tube was fused inside the apparatus and hermetically sealed, the end of the platinum wire being exposed. The vacuum in this apparatus was considered by Mr. Crookes[2] to be as perfect as in his radiometers generally, but Sir William Grove doubted that it was so The following were the results :—



1. With the faint light of a lucifer match or of one or two candles, the vanes invariably turned the opposite way to the normal, the polished surface being repelled. With a dark heat, as from an iron shovel heated short of redness, they went the normal way. These effects continued for several days, but not permanently; the apparatus seemed to have leaked and to have become sluggish and irregular.

2. On electrising the protruding platinum wire with a rubbed rod of glass or sealing-wax, the vanes rotated sometimes one way and sometimes the other.

3. On connecting the negative pole of a Ruhmkorf's coil the results were uncertain, but the positive pole caused the vanes to rotate steadily, and its effect was even better than that from light or heat. In the dark the effect was very beautiful, as the dark vanes moved through a phosphorescent glow. The total results were considered by Sir William Grove to be somewhat negative, but they tended to show that all the effects were due to residual air. He suggested in explanation of the last experiment, that more electricity would escape from the rough than from the polished faces of the vanes, as the former presented a vast number of points. Consequently the rough faces would produce more disturbance of the gas in front of them, and would themselves be more affected by the reaction than the plane faces. The polished surfaces being repelled by luminous heat is, however, very difficult of explanation.

In his second notice Sir William Grove described some further experiments he had made with Crookes's radiometers since the last meeting of the club. He did not now entertain much doubt that these movements are due to the effect of residual air. Mr. Crookes had kindly made a second instrument for him, and the one that he described at the last meeting, of which the vanes were metallic and in metallic connection with a platinum wire that protruded outside the apparatus, had been re-exhausted. Both now act normally, the black faces of the vanes being repelled by light and by heat. When the protruding wire is now electrised by a Ruhmkorf's coil the effects that were previously observed are altogether absent, there is not the slightest luminosity round the vanes, and the current does not pass. But although the current is now incapable of traversing the small space of one-tenth of an inch that separates the vanes from the glass, induction acts across it just as well as before. This is shown by the readiness with which the vanes follow the movements of a piece of rubbed glass or sealing-wax held near the apparatus. It is therefore evident that the effects of attenuation of air upon discharge and upon induction are not the same. When attenuation has commenced and is increasing, the discharge passes more and more rapidly, until it becomes a glow, or according to the old theory of electricity, polarisation becomes more and more readily subverted; but a further attenuation stops the discharge entirely. On the other hand, induction continues, and appears to be in no way lessened by extreme attenuation. These results cannot be accounted for by the old theory that discharge is the consequence of subverted induction.

It farther appears that a radiometer is a most delicate electroscope. By tilting it until the vanes touch the glass, the interior of the glass may be electrised, and it will then remain for days in that condition. He had performed this operation eight days ago, and the movements of the instrument by light or heat have been thereby wholly checked. Every endeavour has been made to discharge or neutralise the electricity on the glass surface, as, for example, by covering the exterior of the globe with tinfoil and connecting this with the platinum wire, nevertheless the glass remains charged, showing what a perfect insulator a good vacuum is.[1]

The above is a copy of the abstracts in the club book. They are now further published, as some partial notices of them have appeared in foreign journals. W. R. G.

[1] I may state that the electricity did ultimately become dissipated, but not until several weeks had elapsed.—W. R G.

THE NORWEGIAN NORTH SEA EXPEDITION, 1876[2]

II.

Researches relating to the Salt-water Fisheries.

BY the side of the more strictly scientific researches it was also our intention during the expedition, if opportunity offered, to give close attention to all the circumstances that might stand in any connection with or throw any light upon our most important salt-water fisheries. As I already during a series of years had been engaged in the study of our fisheries, the prosecution of these researches was committed to me.

For this reason there was added to our other equipment various fishing apparatus, as hooks and lines for deep-sea fishing, and several sorts of drag-nets with various sizes of mesh. The use of such implements could, as a matter of course, only be reckoned upon in good weather and with a pretty smooth sea, which we, however, had promised ourselves might occur at least now and then during our three months' excursion at the best season of the year. But the state of the weather was unfortunately so utterly unfavourable during our whole expedition that the employment of the apparatus we have referred to was not to be thought of. For the same reason the apparatus for measuring the velocity of the currents, exceedingly important in the first place for the physico-meteorological researches, but also for those with which we are now concerned, could not be brought into use. During the few fine days we had in the course of our expedition we were too near the coast for these researches to have any special interest.

Although the state of the weather thus laid insurmountable obstacles in the way of the researches referred to, I have, however, during our expedition, been able to establish certain facts which, in my opinion, are of no inconsiderable importance in this direction, and will be of great use in guiding us in the continued practical scientific researches concerning our fisheries. It is of these facts that I now proceed to give some details.

It is ascertained by our soundings that off our coast there are several fish-banks of whose existence there was no previous knowledge, and on which a profitable fishery with bank vessels may certainly be carried on during the summer months.

The so-called "Storegg" (great edge) off Romsdal's Amt has been from old times famous for its immeasurable richness in fish, and there has been an obscure tradition that it was not the only point where such fishing could be carried on on a large scale, but that there were to be found similar rich fish banks at many other points far out in the open sea, "were man only fortunate enough to fall upon them." The mystic account of the "Havbro" (sea pier or jetty) has now been for the most part explained by the surveys set on foot during our expedition. The "Storegg" is nothing else than a piece of the edge of the extended barrier, which in the west forms the boundary line beyond which lie the cold polar sea-deeps. That so clear a knowledge of this edge within a very limited extent has been already obtained, without the least idea being formed as to its proper connection, naturally arises from the polar sea-deeps here running in closer to the coast than at any other point. A new piece of the continuation of this edge had already been found by soundings made from the steamer *Hansteen*, and we have now been able to establish its existence at several other points, and that both farther south and farther north it retires more and more from the coast to a distance of from twenty to thirty Norwegian (140 to 210 English) miles.

---

[2] By Prof G. D. Sars From Christiania *Dagbladet* of January 27. Continued from p 414.

Although it may not be constant everywhere, it appears, however, to be the rule that at the bottom, at the farthest boundary of the barrier, before it slopes towards the great depths lying beyond it, it rises somewhat, and assumes simultaneously a hard stony character, as is the case, as is well known, at the Storegg. At the first sounding, when we went out from Husoe, we struck this edge at about twenty Norwegian (140 English) miles' distance from the coast (stations 16[1] and 17[2]). The bottom, which before had everywhere appeared to be soft, suddenly, at a depth of 221 fathoms, became hard and stony, and retained this character even after it had sloped about fifty fathoms down towards the deep sea lying beyond. That there was here a pretty abrupt descent is clear from the circumstance that we already at the next station reached far down into the cold area with a depth of 412 fathoms, and a bottom temperature of ÷ 1°·3 C. Farther north, about the latitude of Trondhjem, we found at a depth of 190 fathoms, and likewise on the boundary line between the warm and cold area, a very similar edge with rocky bottom, which falls off with a pretty steep slope towards the west (Station 89[3]). Also on the opposite side of the tract of sea we traversed, we had occasion to observe a similar state of things. Off the Færoe Islands, and at a considerable distance from them, we were fortunate enough, though the weather was exceedingly unfavourable, to find the outer edge or opposite point of the extensive Færoe bank (Station 38[4]), whereby its extent and configuration could be to some extent determined, and the state of things here appears to be very similar to the Storegg.

By the carefully-planned soundings which were undertaken from Ramsen Fiord westwards, there could be established at a comparatively inconsiderable distance from the coast, the existence of a hitherto quite unknown, well-defined, steep bank of considerable extent, with a hard bottom, and a depth of only 62–93 fathoms (Stations 63,[5] 64,[6] 65[7]). Beyond this there was a very gentle and even descent towards the great deeps, but we did not here meet with any true edge as at the Storegg. It may be added that in the outer part of Sogne Fiord (Sognfjœen), we found a pretty extensive plateau, with a hard stony bottom, and a slope both inwards and outwards (depth from 206 to 211 fathoms).

That all the points mentioned above are excellent fishing-grounds I have not a moment's doubt. Everywhere, where at a considerable distance from the coast, such banks with hard or stony bottom have been found, there have always on closer examination been found large quantities of fish, and although an attempt made by us by attaching to the lead a short line with hooks and bait was unsuccessful, there cannot be any negative conclusion drawn from this method of research, which was unfortunately, by reason of circumstances, very unsuitable for the purpose.

The kinds of fish which are found on the sea-banks are, as is well known, principally ling, torsk (*Brosmus vulgaris*), halibut, and cod, the so-called bank cod. I have already, in my reports to the department, clearly set it forth as my opinion that the so-called bank cod is not a different variety from the well-known winter cod, or *skreid*, which in winter and all through the spring, visits our coast for the purpose of spawning. The earlier hypotheses concerning the migrations of the winter cod (*skreid*) from great distances in the sea, I have, after a close study of the nature of this fish, been obliged entirely to abandon, and the experience obtained during our expedition confirms me in this. It is my conviction that the winter cod, which is to be found along our coasts during winter, and which is the object of some of our most important fisheries, is during the rest of the year distributed only over that tract of sea whose bottom forms the barrier against the polar sea-deeps lying beyond it, and that the outer boundary of this barrier (the so-called Havbro), with its well-developed animal life and favourable bottom, forms a suitable habitat for innumerable multitudes of this fish.

Very dissimilar are the circumstances with reference to the second of the varieties of fish most important for our fisheries—the herring. Here my earlier researches have led me just to the opposite conclusion. While the cod is evidently a genuine bottom fish, and as such dependent on the nature of the bottom and partly on the depth, the herring, on the contrary, in consequence of its whole nature, is a genuine pelagian fish, and its occurrence is therefore exceedingly independent of the depth or the nature of the bottom, but, on the contrary, dependent on the physical and biological conditions in the upper stratum of the sea. As these are very changeable, this species of fish may have been furnished with means to enable it speedily to seek out the most favourable tract of sea. The herring has also, as contrasted with the cod, obtained its elegantly-compressed, wedge-like form, whereby with the speed of an arrow it can shoot along through the water, and in a comparatively short time traverse long distances. Although I do not adopt the old ideas, according to which the spring herring comes as it were from the ice-covered sea about the North Pole, I am, however, inclined to believe that, not only when it visits the coast to spawn, but also during the rest of the year, it undertakes irregular migrations in the open sea. The distribution of the herring in the sea is dependent on the distribution of the small animals which form its food. These small animals are all pelagian, mainly small crustacea of the order Copepoda, which keep more or less near the surface of the sea, and are commonly known by our fishermen under the name of "aat." Only when the herring during winter resorts to the coast to deposit its spawn are its movements for the time independent of the occurrence of "aat." The whole other part of the year, on the contrary, the shoals range through the open sea, inasmuch as they prefer to betake themselves to that region of the sea where, at various seasons, there is the greatest abundance of "aat." The great mass of the herring shoals can thus very naturally, towards the approach of winter, or at the time when the development of the organs of generation drives them to resort to the coast in order to spawn, be found sometimes at a less, sometimes at a greater distance from their spawning places according as the sea in one direction or another has the greatest abundance in "aat." On this again mainly depends, I am convinced, the fluctuations in our spring herring fisheries. For as the spawning migration begins long before the roe or milt are ready to be deposited, the mass of herring, if at that point of time it finds itself close to the coast, will reach it so early that it will be obliged to remain there for a considerable time, during which it will naturally come to seek closer in towards the coast in the fiords and bays. In the contrary case, when the mass of herring at this point of time finds itself at a considerable distance from its spawning places, so long time will have passed before it reaches them that the spawning process will go on immediately after their arrival at the coast. The herring will then remain only a short time along the coast, and the spawning will then for the most part be carried on on the outermost banks, less accessible to the fishermen, in other words, the spring herring fishery will be very short or exceedingly unsuccessful.

This is, in short, the theory which I already, several years ago, in consequence of researches made by me along our coasts, was led to advance as in my view the only probable scientific explanation of the remarkable irregularities which in course of time are observable in our spring herring fisheries. I have, however, unfortunately this time only very few facts to support my theory with, and I cannot, therefore, be surprised if it has been received with mistrust, as merely a hypothesis. There are, indeed, a few reports from seamen of their having observed large herring shoals far out in the open sea, immediately before the beginning of the spring herring fishing, as there have been observed by others at various seasons of the year great masses of "aat" at different points in the sea, and we have information concerning this last phenomenon, partly also from trustworthy scientific men (Kroeyer), and that just from that region of the sea, which here most interests us; but these statements were, however, too few to form complete evidence that the open sea is in fact a suitable dwelling-place for the enormous masses of herring which at certain seasons of the year move towards the coast.

[1] Station 16, lat. 62° 23′ 9″, long. 2° 17′ E. from Greenwich.
[2] Station 17, lat. 62° 33′; long. 2° 4′ E. from Greenwich.
[3] Station 89, lat. 64° 1′; long. 6° 7′ 5″ E. from Greenwich.
[4] Station 38, lat. 62° 57′; long. 3° 47′ W. from Greenwich.
[5] Station 63, 64° 41′ 3″ N. L., 9° E. from Greenwich.
[6] Station 64, 64° 42′ N. L., 8° 50′ E. from Greenwich.
[7] Station 65, 64° 42′ 5″ N. L., 8° 39′ E. from Greenwich.

During our expedition I therefore considered it a very important object to examine closely the distribution of the "aat" in the tract of sea over which we sailed. For this purpose the sea was examined almost daily, often several times a day, by the help of a surface-net. The results of these examinations completely confirmed my previous view on this point. During the whole passage from Norway to the Færoe Islands, the sea was found everywhere filled with enormous masses of the so-called "red aat" (almost exclusively *Calanus finmarchicus*) which, as is well known, forms the food best liked by the herring, and, what deserves to be remarked, the quantity of this "aat" appears to increase with the distance from the coast, being greatest at a distance of about twenty Norwegian (140 English) miles. Besides the "red aat" we also observed farther out to sea, great quantities of another pretty blue sort of "aat" (*Pontella Patersonii*), which appears to belong more to the Atlantic Ocean, and which, to distinguish it from the other, might be called the "mackerel aat," as it probably forms the principal food of the mackerel at those seasons of the year when this fish is not in the neighbourhood of the coast. This "aat" also shows itself sometimes, particularly during great takes of herring in summer, among the "red aat" close to the coast. When we went northwards from the Færoe Islands toward Iceland, it was remarkable that the "aat" almost entirely disappeared from the sea. At the same time the sea had assumed a very different colour. While during the whole passage from Norway to the Færoe Islands it had been a deep blue, it was now a light, dirty, greyish-green. This peculiar circumstance, for which I cannot yet account, but in which a peculiar relation of the ocean currents certainly plays a considerable part, appears to stand in close connection with the occurrence of "aat," and will be the subject of careful researches during our next expedition. I had a very convenient opportunity of observing this phenomenon from my cabin, the light of which was almost on a level with the sea. When, by the pitching of the vessel, the glass was washed over, the whole cabin was clearly illuminated with a very beautiful, intense dark blue light, and I have often, when, after my work was ended, I was taking a little rest in my cabin, been greatly delighted with this phenomenon, which so strikingly reminded me of my stay in the south the preceding winter, and my ever-memorable visit to the blue grotto at Capri. Now, on the contrary, the illumination was quite different, namely, light greenish. This colour remained constant so long as we were in the navigable water near Iceland, and the sea was everywhere, as has been stated, almost completely free from "aat." The previously-observed state of things recurred first when we, on our return voyage, approached the coast of Norway. The water resumed its beautiful blue colour, and the sea swarmed with "aat." I cannot help supposing that the conditions observed during our expedition is not always the same, as several recent accounts state that the sea about Iceland is specially rich in "aat." It appears as if the constant westerly storm, which we had to put up with during our expedition, in combination with the strong up-going current, had had a disturbing action, and forced the mass of "aat" farther in towards the Norwegian coast. If this should in fact be the case, a supposition which in the mean time with the little experience we have yet had on the point can scarcely be supported with full evidence, there may be seen in this (if the above-mentioned theory of mine with reference to the migrations of the herring be accepted) a good omen of the improvement of the spring herring fishery in the near future. That the herring is where the herring food (the "aat") is, I consider a settled point. Although we unfortunately had no opportunity of directly establishing the presence of herring by the help of our nets, there were not wanting the best signs of it at the points where the "aat" was most numerous. Not a few whales (both *sildekval*, *Physalus antiquorum*, and *staurhyrning*, *Orca gladiator*) were observed at such places, as well as large numbers of birds (chiefly kittiwakes), and, at a considerable distance from the coast at stations 75[1] and 76[2], there were large brown spots in the sea, like extensive sea-weed fields, but which on a closer examination were found to be enormous masses of "aat" closely packed together, on which the fulmar petrels (*procellaria glacialis*), our constant companions during our excursion, feasted to their heart's delight. That these enormous "aat" masses could not be packed together here by pure accident is evident, and that the current alone should be able to do this here far out in the open sea I cannot believe. I am rather of opinion that the herring shoals have driven this "aat," together in the same way as may often be observed in the case of coal-fish, and that there, under these brown spots on the sea, there were enormous shoals of herring (*sildebjerge*).

I am much disappointed that circumstances did not permit us to use our nets here. We might have been able in this way readily to establish the occurrence of the herring far out at sea. It is to be hoped in the mean time that in our next expedition we shall be more fortunate in the weather, and we shall then put this herring question in the first rank, the rather as we shall be then farther north or nearer the waters, which, in my opinion, are the proper home of spring herrings (*vaarsilden*) and the great herrings (*storsildens*).

OUR ASTRONOMICAL COLUMN

THE SUSPECTED INTRA-MERCURIAL PLANET.—M. Leverrier, in a circular addressed to astronomers, has again directed attention to the importance of close and frequent observations of the sun's disc, on March 21, 22, and 23, but especially on the intermediate date, with the view to detect the small planet, which he assumes to have been already observed in transit on six occasions, and which there would appear to be just a possibility, may be again projected upon the face of the sun at this time. In his reasoning upon this subject, M. Leverrier adopts for the place of the node, the value he had deduced from the well-known observations of Dr. Lescarbault on March 26, 1859, but the uncertainty attaching to the result renders it impossible to pronounce definitively on the occurrence of a transit in the present month.

The six observations to which reference is made above are those of Fritsch, at Quedlinburg, October 10, 1802; Stark, at Augsburg, October 9, 1819; Decuppis, at Rome, October 2, 1839; Sidebotham, at Manchester, March 12, 1849; Lescarbault, at Orgères, March 26, 1859; Lummis, at Manchester, March 20, 1862.

Attributing these observations to the passage of a single planet across the sun's disc, he found a formula for the heliocentric longitude at any time, in which an indeterminate entered, allowing of several solutions of the problem of finding the period of revolution, and hence the mean distance of the body from the sun. Two of the solutions appear to possess equal precision in the representation of the observations; in the first, the time of revolution is found to be 33·02 days, and the mean distance from the sun 0·201, that of the earth being taken as unity: in the second solution the length of the revolution is 27·96 days, and the mean distance 0·180. Whichever period we adopt, we find from M. Leverrier's formula that the suspected planet should be in conjunction with the sun on March 22, astronomical reckoning, for the meridian of Greenwich, though to decide definitively as to the passage or otherwise of a planet across the sun's disc at this time, it will be necessary to examine it not only throughout the whole of the corresponding revolution of the earth upon her axis, but owing to uncertainty in the data for prediction, during the twenty-four hours preceding and following, or as already stated, on March 21, 22, and 23.

It is difficult to understand how six observers, without, as M. Leverrier remarks, any relation with each other, nor any knowledge of the periods under discussion, can have fallen by chance upon six exact epochs of a phenomenon explicable by the motion of a single planet. Though suspicion has attached in the minds of some astronomers to one or two of the observations to which we have referred, the fact pointed out by the illustrious French astronomer does appear very strongly confirmative of their reality. At any rate, the existence or otherwise of such a body may be decided by systematic examination of the sun's disc, near the calculated epochs of conjunction, within the assumed transit-limits; but it so happens that after the present month there is very little probability of a transit taking place either at the spring or autumn node for several years, and hence the greater necessity for continuous observation of the sun at the period named.

Extensive preparation has been made on the recommendation of M. Leverrier; the Astronomer-Royal availing himself of the telegraph, has notified observers at Madras, Melbourne, Sydney, and at Wellington and Canterbury, New Zealand, and we believe intends to organise a careful watch upon the sun's disc at the Royal Observatory, Greenwich. We know that a similar scrutiny will be carried into effect in American longitudes, so that it is not probable that a planet can present itself upon the sun on this occasion without being detected. Photography will be brought into requisition at more than one station. Where it is not available in the event of a planetary body being detected, it will be necessary to determine the differences of right ascension and declination from the sun's limbs at frequent intervals as long as the object is projected upon the disc; from such observations carefully made the position of the orbit will be very approximately determined, and we should be enabled to follow up the new member of the solar system.

THE NEW OBSERVATORY AT KIEL.—Prof. Peters has issued a brief description of the new observatory just erected a little to the north of Kiel, the present head-quarters of the *Astronomische Nachrichten*. The unfavourable position of the observatory at Altona, so long directed by Prof. Schumacher, and the desire to bring the establishment into nearer relation to the university at Kiel, led to successful negotiations about twelve years since for a suitable site near the town. The buildings were commenced in 1871 and are now completed. There is a free horizon and a considerably better climate than at Altona, and no interruption from surrounding buildings.

The instruments in the new observatory include Reichenbach's meridian circle, formerly at Altona, which was so far improved by Repsold, as described in the *Astronomische Nachrichten*, that it may be considered a new instrument. The Repsold equatorial, also at Altona, is mounted in one of the smaller towers, and in another, a parallactically-mounted comet-seeker, to which is attached a 4-feet refractor, its optical axis being parallel to that of the comet-seeker. Prof. Peters explains that the refractor being provided with a high power, may be useful in deciding whether any nebulosity caught up in the seeker is a comet, or a star-cluster.

About two months since, an equatoreally mounted refractor by Steinheil of Munich, with an object-glass eight Paris inches in diameter, was added, of the performance of which Prof. Peters promises details at a future date. The meridian circle is at present employed in the observation of all stars to the ninth magnitude, within 10° from the pole, the same class of work, indeed, in which Schwerd and Carrington so long occupied themselves.

The position of the new observatory at Kiel is in longitude 0h. 40m. 35·5 E. of Greenwich, and latitude 54° 20′ 29·7″.

Besides its connection with the Kiel University, the observatory is also in relation to the Danish Marine, and contains facilities for testing the rates of chronometers at different temperatures, and a time-ball, apparently very similar to the one at our Royal Observatory, which is dropped at noon, mean time at Kiel.

65 OPHIUCHI (FL.).—Of this star Baily says, "Observed by Flamsteed on May 6, 1691, at 14h. 10m. 58s., and regularly reduced by him. . . . But no such star is now to be found. It is neither Piazzi xvii. 308, nor xvi. 251, as conjectured by that astronomer. Prof. Airy has been kind enough to look for this star, at my request, but has not been able to discover it." The place of this star, given in the British Catalogue, brought up to 1850, is—

R.A. ... ... 17h. 51m. 37·6s. Precession + 3·506s.
N.P.D. .. 107° 59′ 18″ „ + 0″·732

There is no star in this position in Argelander's southern zone nor in the zones observed at Washington; neither is there an star in these zones with which it can easily be identified, o admitting any probable error of observation. Did Flamstee observe an object of the class which we are accustomed to ter "new stars?" The Chinese annals record the appearance of a extraordinary star in the year 386, which remained stationar from April to July in the same "sidereal-division" that 6 Ophiuchi would fall, and then disappeared. It may be wort while to watch any small stars near its position.

BIOLOGICAL NOTES

FLORA OF NEW GUINEA.—Letters from Sydney of Januar 12 state that the Italian traveller, D'Albertis, had returne there from his last trip to New Guinea, and was engaged i preparing an account of his voyage up the Fly River. Hi fine collection of dried plants is in the hands of Baron vo Mueller at Melbourne, who is describing many of the new plant in his "Papuan Flora." Among them is a grand *Hibiscu* which Baron von Mueller has named *Hibiscus albertisii*, i nearest affinity is with *Hibiscus tupiliflorus* of Hooker, of Gua daloupe and Dominica, in the West Indies. There is also a ne *Mucuna*, which he has named *Mucuna bennetti*. D'Alberti describes this as one of the most beautiful of all the flowers see in New Guinea; it is abundant on the banks of the Fly Rive and the pendulous masses of large red blossoms cover the loftie trees from the base to the summit and form one of the mos gorgeous sights it is possible to conceive. There was also a yello flowering species of the same genus which was rare, and onl met with in the interior of New Guinea, in lat. 6° south, on th banks of the Fly River. The flowers of this species were onl seen on the tops of the trees, forming a dense mass of blossom There was likewise another species of *Mucuna* met with, bearin blue flowers. All these and a number of other novelties wi duly appear in Baron von Mueller's forthcoming part of hi "Papuan Flora."

SALMO ARCTURUS.—We are informed that the Salmono brought home by the Arctic Expedition from Grinnell Land is new species of Charr, described by Dr. Gunther under the nam of *Salmo arcturus*. It resembles in some points the Loch Kill Charr from Inverness-shire.

PROF. OVSIANNIKOFF ON THE FUNCTIONS OF THE CEREBELLUM.—In the seventh volume of the *Memoirs* of the S Petersburg Society of Naturalists Prof. Ovsiannikoff commun cates the results of experiments he has made in collaboratio with M. Weliky on the physiological functions of the cerebellum Preventing, by the tying of the carotid artery, the effusion blood which usually accompanies the cutting out of the cere bellum, Prof. Ovsiannikoff proved by a series of experimen that the last operation does not at all paralyse the co-ordinatio of motion. A rabbit remained alive during two weeks after a the upper half of the cerebellum was cut out, and did not sho any traces of such paralysis, nor did it lose its faculty of co-ord nating its movements after all the cerebellum was cut out, unt an effusion of blood produced this result. A long series varied experiments made by M. Ovsiannikoff on rabbits, pigeon fishes, and frogs, confirms this result, as well as some wel known pathological cases reported by Brown-Sequard, Mar Combetta, and others.

FAUNA OF LAKE GOKCHA.—The seventh volume of th *Memoirs* of the St. Petersburg Society of Naturalists contai interesting information, by Prof. Kessler, on Lake Gokcha, lyi in the Erivan government (Caucasus), at a height of 6,419 fee It is surrounded with mountains from 9,000 to 12,000 feet hig and occupies about 660 square miles. Altogether its averag depth is from 150 to 250 feet, reaching only in one instance

361 feet. The lake has only a small and shallow outflow, the river Zanga, running into the Araks. The fauna of the lake and of its shores is varied. *Spongillæ*, not determined as yet, are very numerous Among the *Vermes* the most common is the *Nephelis vulgaris*, the *Crustacea* are represented by a variety of microscopical forms and by a species of *Gammarus*, this species being probably all but the only representative of that kind, as the dredging was not pursued to depths greater than 150 feet The snails are remarkably numerous, and all belong to species common in European lakes (*Limnæus stagnalis*, *L ovatus*, *L auricularius*, and *Planorbis carinatus*), they differ only by their unusually fine and brittle shells. The common frog (a local variety) and the *Bufo viridis* are numerous The number of fishes is immense, but they belong to only five species, of which three are new These three, which occupy an intermediate position between the *Salmo fario* and the *S trutta* and *S lacustris*, will be described by Prof. Kessler under the names of *Salmo ischan*, *S gegarkuni*, and *S bolschak* The fourth species of fishes is very nearly allied to the *Capoeta fundulus*, Pall, a species most characteristic of Central Asian waters The fifth is akin to the *Barbus cyri*, De Filippi, it inhabits mostly the short and cold rivers running from the mountains

ANTS —Mr McCook has recently brought before the Academy of Natural Sciences of Philadelphia, an account of his investigations on *Formica rufa* He finds that ants descending the tree paths, with abdomens swollen with honey dew, are arrested at the foot of the trees by workers from the ant hill The descending ant places its mouth in contact with that of the food seeker, the two being reared on hind legs Frequently two or three of its fellows are thus fed in succession by one ant, mostly complacently, but sometimes only on compulsion Mr McCook made many experiments, which lead to the conclusion that there is complete amity between the ants of a large field, embracing some 1,600 hills, and many millions of creatures Insects from hills widely separated always fraternised completely A number of ants from various hills were placed in an artificial nest, and harmoniously built galleries and jointly cared for the cocoons

NEW FORMS OF HALIPHYSEMA —The second half of the second volume of *Biologische Studien*, by Dr L Haeckel, has just reached us It contains an account of a wonderful family of minute forms belonging to the genera Haliphysema and Gastrophysema, and some supplementary remarks on the Gastræa theory Six plates illustrative of the new forms accompany this part The genus Haliphysema was established by Bowerbank for *H tumanowiczii* and *H ramulosum* The species described as *H. echinoides* seems almost certainly to be that described in 1870, by Perceval Wright, as *Wallichii*, but the two new species described as *H primordiale* and *H globigerina*, the latter with a mosaic of Globigerina shells laid over it, are most extraordinary and interesting forms The presence of a pore area in the tiny form figured in the previous note seems to points to its not having any close affinity to this new family of Haeckel

NOTES

PROF. SIR C WYVILLE THOMSON, F R S, has been appointed Rede Lecturer at Cambridge for the ensuing year. Sir Wyville Thomson will deliver a lecture in the Easter term

A BOTANICAL Congress assembles at Amsterdam on the 12th of April.

THE Iron and Steel Institute meets in London on March 20 and following days On Wednesday, the 21st, at the rooms of the Institution of Civil Engineers, Dr. Siemens, F R S, will deliver his inaugural address, and the Bessemer Medal will be presented to Dr. Percy. A number of important practical papers are set down for reading.

CAPT. ALLEN YOUNG has presented to the Museum of the Royal College of Surgeons a collection of the skulls of Esquimaux obtained by himself and the surgeon of his vessel, Mr. Horner, during the last cruise of the *Pandora*. The honour of knighthood has been conferred upon Capt Young.

SIR JOHN LUBBOCK'S Ancient Monuments Preservation Bill was, we are glad to say, read a second time in the House of Commons on Wednesday week We hope none of its important provisions will be impaired in the select committee to which it has been referred, but that it will be passed essentially as it stands

THE *American Chemist* for December, 1876, contains an interesting Inaugural Address to the American Chemical Society on "Science in America," by Dr. J W Draper The Address on a similar subject by Vice President C A Young, at the last meeting of the American Association for the Advancement of Science, has been printed separately In both addresses the important work done by Americans in various departments of science is justly insisted upon, and the future of science in America spoken of in hopeful terms Men of science in England, we are sure, will heartily endorse all that Professors Draper and Young claim on behalf of their countrymen as original workers in science, and there is every reason to believe that there is a bright future for science in America

As soon as the news that Mr Edward, the Scottish Naturalist, had resigned the curatorship of the Banff Museum spread over the country, he was pressed to accept various situations, among others one in Aberdeen and another in Durham, the latter in the University of that city He has been obliged to decline all these offers owing to the state of his health He had been solicited by the Meteorological Society of London to become one of their observers. This request he had owing to the same cause declined The work is, however, congenial, and does not demand a change of residence, and we believe he has yielded to a second very pressing application

THE Sedgwick Prize, founded in honour of the late Prof. Sedgwick, for an essay on a geological subject, has been adjudged to Alfred John Jukes Browne, B A, of St John's College, Cambridge The subject of the essay is "The Post-tertiary deposits of Cambridgeshire, and their relation to deposits of the same period in the rest of East Anglia." The subject for the Sedgwick Prize to be awarded in 1880 is the best essay on "The Fossils and Palæontological Affinities of the Neocomean Beds of Upware, Wicken, and Brickhill The prize is open to the competition of all graduates of the University of Cambridge who have resided sixty days during the twelvemonth preceding the day the essays must be sent in, that is, before October 1, 1880.

A PRELIMINARY meeting has been held in Paris by some influential followers of the Positive Philosophy for the purpose of establishing a course of lectures according to the system of Auguste Comte, as modified by Littré Important resolutions were passed as to the teaching of the several sciences which, according to the theoretical view adopted by Comte, constitute the encyclopedic education At the next meeting resolutions will be proposed for meeting the expenses of the institution and regulating its administration

AN arrangement has been made with the Cassel publisher, Theodor Fischer, whereby the hitherto very expensive publication *Palæontographica*, will be published in yearly volumes at not more than forty-five shillings each

THE Balloon Commission of the French Government, styling itself "Commission pour les Communications par Voie Aérienne," has become a standing institution, and includes within its province carrier pigeons as well as æronauts and balloons.

IN the *Journal of the Society of Arts* for March 9 will be found an important and interesting lecture by Prof. A. B. W. Kennedy, C.E., on "The Growth and Present Position of the Science of Machines."

THE unification of the meridian has been advocated at Rome before the Italian Society of Geography, by M. Boutillier de Beaumont, the president of the Geneva Geographical Society. He proposes to adopt the Behring meridian which has been chosen by the American meteorological service for the universal daily observations. M. Boutillier de Beaumont proposes also to adopt the division into hours of fifteen degrees for angular divisions as well as for temporal minutes.

MANY of us will have read with interest Capt. Wiggins' account of his endeavours to establish sea-communication with the great rivers of North Siberia, as given in the last number of the *Geographical Magazine*. Capt. Wiggins has now just started on his return to the Yenisei, overland, to bring back his ship which he stowed away in October last at Kureika, on that river. He is accompanied by Mr. Seebohm, F.Z.S., a distinguished member of the British Ornithologists' Union, who has embraced this opportunity of visiting the nesting-haunts of some of our rarest and least-known European birds, and otherwise exploring an almost unknown country.

A "SOCIÉTÉ des Voyages d'Études autour du Monde" has been constituted at Paris by the liberality of M. Bischofsheim and others. Its object is to organise a regular service of voyages round the world for the instruction of those who are able to afford the expense. The first departure is to take place from Marseilles in the end of May next. The voyage will occupy less than a full year. Opportunities will be given to cross South America from Monte Video to Valparaiso, and to visit the United States and India. The commander of the steamer will be M. Biard, a lieutenant in the National Navy and the promoter of the Society. Passengers may be registered up to April 10 next. A library, instruments for experiments, and a staff of competent teachers will be on board.

AMONG the papers in the January number of the *Bulletin* of the French Geographical Society are the following:—On a journey into the Sahara and to Rhadames, by M. Largeau; Across the Pampas, by M. Désiré Charnay; on the French Expedition to the Ogové, by M. Savorgnan de Brazza; a letter from Dr. Halub on his travels in South Africa

WE regret to notice that the Marquis de Compiègne, the French West African explorer, has died of a wound received in a duel at Cairo.

A GEOGRAPHICAL Society was established at Marseilles in the beginning of March. The president of the new Society is M. Rambaud, a merchant who is acting as representative of the Sultan of Zanzibar. Not less than 200 members subscribing *1l.* were registered, and donations have been collected to the amount of 800*l.* A public library has been opened, a course of public lectures on geography established, and the Society is arranging a Museum of Raw Materials from every country.

THE *Daily Telegraph* announces the receipt of important letters from Mr. Stanley, under date Ujiji, August 7 and 13. Mr. Stanley has made a complete survey of Lake Tanganyika, apparently settled the questions of outlet and level, and made important discoveries at the north end of the lake. He also describes his discoveries at and about the Nyanzas, though it does not appear that he has succeeded in circumnavigating Albert Nyanza. Mr. Stanley intended to cross the country to Nyangwe, where he would determine his final course.

AT the meeting of the Royal Geographical Society on Monday the business consisted of the reading of papers "On the Distribution of Salt in the Ocean," by Mr. J. Y. Buchanan; "A Journey through Formosa," by Mr. H. J. Allen; and "A Trip into the Interior of Formosa," by Mr. T. L. Bullock. The first paper summarised experiments which had been made during the cruise of the *Challenger* on the specific gravity and saline strength of the ocean water at various depths. 1,800 samples had been obtained, and by the testing of them Mr. Buchanan had ascertained, first, that the specific gravity of sea-water was greater than that of fresh; and, second, that the variations in its specific gravity pretty exactly indicated the amount of salt held in solution. It had been found that the water was freshest at the equator and at the poles, and most impregnated with salt in the intermediate regions. The papers on Formosa were descriptive of the journeys through the island taken by the respective readers, and entered into details of the character of the inhabitants—Chinese, semi-barbarians, and aborigines.

ON March 26 Sir George Nares will read a paper on the "Geographical Results of the Arctic Expedition," at the Royal Geographical Society.

WE have received from a correspondent a very detailed account (illustrated by drawings) of the Kimberley diamond mine in South Africa. The conclusion as to the mode of origin of the diamonds to which his study of the district appears to have led our correspondent is as follows:—That they were formed in volcanic vents which have been opened in the midst of sedimentary rocks (sandstone and shale, with thin coaly seams), which vents probably existed at a considerable depth under the sea. As to the material which by its decomposition may have yielded the pure carbon in a condition ready for crystallisation, our correspondent suggests that it was probably some hydrocarbon derived from the coal by distillation.

WE notice the following details on the Jurassic flora of Eastern Siberia in a memoir by Dr. Oswald Heer, published in the *Memoirs* of the St. Petersburg Academy of Sciences. This formation occupies about 200 miles along the shores of the Amoor, between the villages Oldoy and Vaganova, and border, probably, the south-western foot of the Stanovoy ridge. In the Irkutsk government it occupies a large space in the south-eastern corner of this province, where the district around the village Ust-Baley (on the Angara, forty miles to the north of Irkutsk) will be now, after the appearance of Oswald Heer's description, one of the most typical representatives of the Jurassic flora, by its beautifully preserved plants, insects, and fishes. All Siberian Jurassic plants belong to the period of the Brown Jura, and their nearest relations are the Jurassic deposits of Scarborough and of Cape Bogeman, in Spitzbergen. They mostly belong to new species; the most common of previously-known species being only the *Asplenium* (*Pecopteris*) *Whithiense*, and the *Gingko Huttoni*. Three still existing kinds, *Asplenium*, *Thyrsopteris*, and *Dicksonia*, have their representatives among the East Siberian Jura. The most interesting group, by the variety of its forms, is the group of the Coniferæ (more than thirty species), and especially the group of the Salisburiæ. Altogether, the Siberian Jurassic flora occupies the first rank by the variety of species it affords (eighty-three species), the richest yet known flora, that of Yorkshire, numbering only seventy-three species.

A CORRESPONDENT writing from Knoxville, Tennessee, U.S., states that on two occasions he has witnessed true towering in wild ducks, one a call duck the other a summer duck. He adds to the list of towering birds already named the Virginia quail (*Ortyx virginianus*), and wild pigeon (*Ectopistes migratoria*).

A PRACTICAL Society of Natural History has been recently established in Paris under the title of Société Parisienne. Its special aim is to procure young people the means to study nature by lectures and excursions.

FROM researches on the nature of the vowel "clang," in Prof. Helmholtz's physical laboratory, M. Auerbach (*Pogg. Ann.*) comes to the following conclusions, which appear to throw new light on some unsolved problems:—1. All clangs, especially the vowels of the human voice and speech, are to be defined as the consequence of the joint action of two moments, a relative and an absolute. 2. The relative moment is the mode of distribution of the whole intensity among the individual partial tones as determined by their ordinal number. The absolute is the dependence of the whole intensity on the absolute pitch of the partial tones, and the modification of the distribution, on change of the fundamental tone, therewith connected. 3. The difference of the vowels in the former relation is a result of the power of changing the form of the mouth-cavity. The differences of the absolute pitches characterising the various vowels, and of their influence, are a result of the power of changing the volume and size of the mouth-cavity. 4. The first partial tone is always the strongest in clang; it deserves, therefore, the name of fundamental tone. 5. The intensity of the partial tones as such decreases in general as their ordinal number increases; exceptions indicate the nearness of the boundary of the consonant region. 6. The intensity of the partial tones decreases more slowly the nearer the vowel clang is, therefore more quickly the duller this is. 7. The characteristic pitch is higher the clearer, and deeper the duller, the vowel clang. 8. The variations of the intensity, in consequence of the influence of the characteristic pitch, are greater the fuller the vowel is. Very slight variations indicate the nearness of the consonant region. 9. All the vowels admit of being sung within the whole range of the human voice; but the dull speak in very high, the clear in very deep, positions. 10. A little attention only is needed to perceive in a vowel clang the over-tones (often comparatively very strong) without artificial aids. They then sound very similar to the pure tuning-fork tones.

CONTINUING his researches on fluorescence, M. Lommel (*Pogg. Ann.*) arrives at the following conclusions:—1. There are two kinds of fluorescence. In one each excitant homogeneous ray falling within the limits of the fluorescence-spectrum excites not only rays of greater and equal, but also rays of shorter wave length; the latter so far as they belong to the region in question. In the second kind, each homogeneous ray excites only rays of greater or equal wave length. 2. There are substances which have only the first kind of fluorescence; each excitant ray excites the whole fluorescence spectrum. Hence they are not subject to Stokes's law. Such are naphthalin, red chlorophyll, and eosin. 3. There are substances which have only the second kind of fluorescence, and which therefore, throughout their fluorescence spectrum, obey Stokes's law. Such are most of the fluorescent substances hitherto examined. 4. There are substances which have both kinds of fluorescence, so that the first kind is proper to a certain portion of their fluorescence spectrum, and the second kind proper to their remaining parts. Hence these obey Stokes's law only in part. Such are chamaelin red, blue, and green.

THERE are several ways of decomposing water with only one electrode. One is this: let some water in a glass be brought in contact with a Wollaston electrode (*i.e.*, a fine platinum wire inclosed in glass and touching the water only by its extreme section), and connect the wire with the conductor of an electric machine in action. Fine bubbles of oxygen are liberated at the point. What becomes of the hydrogen? M. Lippmann replies (*Journal de Physique*) that so long as the water continues charged the hydrogen remains in excess. On discharging the water it escapes at the platinum point, this being then the electrode of exit. But may it not be that the hydrogen is set at liberty within the liquid or at its surface while the corresponding oxygen is liberated (there being, according to this view, two electrodes, one the platinum point, the other diffuse and of large surface)? The objection, M. Lippman says, cannot be refuted by direct experiment, but the impossibility of the hypothesis appears on considering the quantities of chemical and electrical work called forth during the experiment. He gives two demonstrations of this.

WE have received the first two numbers of a new Italian monthly periodical, *l'Elettricista*, the object of which is to give an account of the progress of the science of electricity. This publication is one of many signs that the countrymen of Galileo have made up their minds again to take an active part in scientific investigation, and especially not to forget that branch which owes so much to Volta. The papers do not lay claim to originality, but the first number especially is interesting, and if kept up on the same standard the periodical can do a great service in spreading modern ideas in Italy. We note especially the paper on absolute electrical units, by Naccari, and on some phenomena presented by electrified powders, by A. Ricco. The second number contains chiefly abstracts from foreign periodicals. Padre Secchi draws some conclusions from imaginary results, which he believes were obtained by Mr. Chrystal in his verification of Ohm's law.

IN a paper read the other day by M. Fulke, before the Wissenschaftlicher Club of Vienna, on German emigration to the United States, it was estimated that from 1820 to the present, nearly 10,000,000 must have emigrated, or a fourth of the entire population of the United States. M. Fulke lamented the extent of the movement, also the facility with which the Germans in America seemed to lay aside their customs and usages, and even their native tongue. In conclusion, he drew a parallel between the Germans in the United States, and the Germans in the whole of Austria. Here, too, the German element was about a fourth of the whole population, but what a contrast to the other case!

THE additions to the Zoological Society's Gardens during the past week include a Bonnet Monkey (*Macacus radiatus*) from India, presented by Mrs. Payton; a Rose Hill Parrakeet (*Platycercus eximius*) from Australia, presented by Mr. J. J. Chapman; a Rufous-vented Guan (*Penelope cristata*) from Central America, presented by Mr. Daniel Miron; two Hooded Crows (*Corvus cornix*), European, presented by Mr. F. Cresswell; a Macaque Monkey (*Macacus cynomolgus*) from India, deposited; a Two-Wattled Cassowary (*Casuarius bicarunculatus*) from the Aroo Islands, a Hooded Crane (*Grus monachus*) from Japan, a Hodgson's Barbet (*Megalæma hodgsoni*), two Striated Jay Thrushes (*Grammatoptila striata*), three Black-headed Sibias (*Sibia capistrata*), three Brown-eared Bulbuls (*Hemixos flavala*), two Rufous-bellied Bulbuls (*Hypsipetes Mclellandi*), a Red-headed Laughing Thrush (*Trochalopteron erythrocephalum*) from the Himalayas, purchased.

SCIENTIFIC SERIALS

FROM the *Naturforscher* (January, 1877) we note the following papers:—On radiation in space, by H. Buff.—On cave-insects, by L. Bedel and E. Simon.—On the germination of the fruits of mosses, by P. Magnus.—On the action of a di-electric body upon an electric one, by R. Felici.—On the preparation of pure alcohol yeast, by Moritz Traube.—On the limit between chalk and tertiary deposits in the Rocky Mountains (U.S.), by M. Delafontaine.—New researches on Bacteria, by E. v. M.—On the specific power of glycose (grape sugar) of turning the plane of polarisation, by B. Tollens.—On the exhalation of carbon acid and the growth of plants, by L. Rischawi.—Researches on assimilation in plants, by A. Stutzer.—On the assimilation of water and lime salts by the leaves of plants, by J. Bohm.—On the phenomena of heat accompanying muscular action, by J. Nawalichin.—On the molecular volumes of sulphates and selenates, by Otto Pettersson.—Electro-dynamic theory of matter, by F. Zoellner.—Elements of the orbit of the double-star 24 η Cassiopeiæ, by Ludwig Graber.—On the action of an electric discharge upon solid isolators, by W. Holtz.—On the external sexual differences upon our fresh-water fish, by V. Fatio.

THE *Memoirs of the St. Petersburg Society of Naturalists*, vol. vii., contains a series of valuable physiological contributions, the most important of which are :—On the comparative anatomy and metamorphology of the nervous system of the Hymenoptera, by E. K. Brandt.—On the influence of condensed air, oxygen, and carbonic acid on the nervous irritability of animals, by M. Tarkhanoff.—On changes in the eye produced by the section of the *nervus trigeminus* by M. Chistoserdoff.—On the psychomotor centres and on the bifurcation of electric currents in the cerebellum and corpora quadrigemina, by MM. Weliky and Shepovaloff.—On the influence of salicylic acid on the circulation of the blood, by MM. Dubler and Chistoserdoff.—The action of chinine and atropine on the hearts of frogs and rabbits, by Mdlle. Pantéléeff, and on the nucleus of the red globules of the blood, by A. F. Brandt.

SOCIETIES AND ACADEMIES

LONDON

Royal Astronomical Society, March 9.—Prof. Cayley, F.R.S., vice-president, in the chair.—The minutes of the previous meeting were read by Mr. Glaisher, F.R.S., the recently-elected secretary.—Two communications of immediate importance were made by the Astronomer-Royal. The first of these referred to the supposed intra-mercurial planet, and he expressed a wish that it should be published as widely as possible without delay in order that amateur astronomers might lose no opportunity of scrutinising the sun's disk during the latter half of the present month, but especially on the 22nd instant, from sunrise till sunset. He had been requested by M. Leverrier to make known that his computation of the elements of the supposed planet, from such reported observations as were available, pointed to March 22 as the day on which it might be expected to transit the sun's disk. He recommended that the disk should be continuously watched for several days before and after that date. The second communication of the Astronomer-Royal referred to the opportunity which will occur next autumn of determining the solar parallax by observations of Mars in opposition. He read an extract from a paper of his own published some years ago in the *Monthly Notices*, showing the great importance he attached to this method as compared with others, and pointing out that fifteen years from the present time must elapse before another nearly equal opportunity will occur of applying it. He dwelt with much emphasis on the ease and simplicity of the observations required and on their singularly inexpensive character. Lord Lindsay had offered to lend his heliometer, and Mr. Gill had offered his services gratuitously for an expedition to St. Helena or Ascension for the purpose, so that the money required would not exceed 500*l*. The Government would be asked to supply this sum, but if they refused, other means should be taken to raise the money, and if a subscription list became necessary, he would gladly contribute 20*l*. himself. Another Fellow, a member of the Council, then suggested that a part of the Carrington bequest might be available, and failing that, offered to contribute 100*l*. towards the expedition if it had to be carried out by private means.—Mr. Gill was called upon to explain the peculiar merits of this method of determining the solar parallax. It depended upon the difference of R.A. between Mars and certain stars measured early and late on the same day, which measures could be made by the heliometer with extreme accuracy.—Papers were presented by Prof. Zenger, C. Todd, A. T. Arcimis, S. W. Burnham, Dr. Robinson, A. de Gasparis, E. J. Stone, A. Marth, J. Tebbutt, Capt. Tupman, Prof. S. Newcomb, Capt. Abney, Sir G. B. Airy, T. W. Backhouse, Rev. S. J. Perry, Dr. Ball, Dr. Royston Piggott, Mr. Penrose, Mr. Knott, Mr. Nelson, and Mr. Kobel, some of which were read. Four new Fellows were elected.

Linnean Society, March 1.—Prof. Allmann, F.R.S., president, in the chair.—Messrs. R. Gillies, H. Goss, Dr. A. Gunther, and M. Moggridge were elected Fellows, and Dr. M. C. Cooke an Associate of the Society. The embryo of *Dyospyros embryopteris*, Pers., upon the fruit and seed of which species Gærtner founded his genus *Embryopteris*, was exhibited by Mr. W. P. Hiern. He explained how the immature fruit was gathered in India for the sake of the tannin contained, and hence the probability of Gærtner's having been misled as to the true structure of the seed and imperfect embryo, which Mr. Hiern now correctly describes.—Dr. Maxwell Masters brought before the meeting a series of specimens illustrative of what is commonly known as "Burrs" or "Witch-knots." The examples exhibited were collected by Mr. Webster, gardener to the Duke of Richmond and Gordon. Some of these productions were illustrations of dimorphism or bud-variation, probably reappearance of latent ancestral characteristics or disjunction of parental forms usually amalgamated. Others doubtless owed their origin to some injury to the terminal bud, subsequent hypertrophy of the branches, and excessive development of adventitious buds. Injury apparently was frequently the result of insect puncture, as in the case of the birch, the "burrs" on which had been lately discovered by Miss E. Omerod to be produced by a species of *Phytopus*, at other times it was the result of parasitic fungi or of injury consequent on frost, the wounds caused by birds, the action of wind, &c.—A most important communication on the flora of Marocco (*Spicilegium Floræ Maroccanæ*) was read by Mr. John Ball, F.R.S. (Pres. Alpine Club). By a sketch map he pointed out the peculiar physical features of the territory penetrated at several points by Dr. Hooker, Mr. G. Maw, and himself in 1871, and he mentioned how that Marocco, though within but a few days' sail of London, was in many respects a *terra incognita* to Europeans. Whilst the Sultan and population of Marocco generally are averse to the admission of Christians and strangers into their country, the hill tribes, derived from the warlike Berbers, are decidedly hostile and indeed dangerous to travel among. The flora, then, of this interesting region, is necessarily very imperfectly known. Mr. Ball gave a lucid historical account of what little had been done by earlier botanists, Zanoni 1675, Spotswood 1673, and Broussonnet 1790-9. The collections of the latter having been distributed to several European botanists, and here and there incidentally noticed by them ; Cavanilles of Madrid temporarily secured to Spain a fair share of honour by his publications in the scarce periodical *Ann. d. Ciencias Nat.* M. Cosson has lately been working Broussonnet's material deposited in the Montpellier Museum. Schousboe, Danish Consul at Mogador, commenced 1801, but left unfinished a flora of Marocco. Jackson (1809) in his account of the Empire of Marocco, has noticed the curious Cactoid Euphorbias. P. Barker Webb in a short visit (1827) to Tangier and Tetuan, discovered a new genus of Cruciferæ. Between 1840-1870 several Frenchmen touched at various points, and the "Pugillus Plantarum" of M. Boissier, contains merely a germ of future work.—The Rev. Mr. Lowe contributed to the Linnean Society, 1850, a list of plants observed by him at Mogador. But notwithstanding the preceding labours, a mere tithe of the flora has yet been worked out, and almost nothing satisfactorily. Mr. Ball, in 1851, attempted to reach the higher summits of the Lesser Atlas, but the disturbed condition of the district obliged him to desist. M. Balansa was likewise repulsed in 1867 (though fortunate in collecting numbers of new and remarkable species) ; but Mr. Maw was more successful in 1869. Messrs. Hooker, Maw, and Ball's routes in 1871 were then pointed out, and detailed but technical description of the plants collected, given. In giving a summary of results in a tabular form, Mr. Ball showed that the proportion of Compositæ, leguminosæ, and Liliaceæ, is unusually large, whilst Gramineæ, and Ranunculaceæ is exceptionally small. Of Rosaceæ there are 16, of Saxifrageæ 5, of Primulaceæ 7, of Gentianeæ 8, and of Cyperaceæ only 28 species, thus showing the peculiarity that but a small proportion of these natural orders are present, which otherwise are so characteristic of the mountainous countries of the north temperate zone. It seems as if five temperate floras were represented as follows :—1, Mediterranean in general ; 2, Peninsula ; 3, Desert ; 4, African mountain flora ; 5, Macaronesian—to which may be added 6, Cosmopolite or widely-spread European species. The total number of phanerogamous plants now described are 1618 species, and among these many novelties.—Mr. J. G. Baker then read a paper on the Liliaceæ, Iridiaceæ, Hypoxidaceæ, and Hæmodoraceæ of the late Dr. Welwitsch's Angolan Herbarium, which, through the courtesy of the executors, he has been enabled to work out. Not only are there a large proportion of the species new to science, but many genera are new though pertaining to Central African types already known. The excellent condition of the specimens, the care taken in selection of various stages and characters of the plants, and descriptions taken on the spot by Dr. Welwitsch have rendered Mr. Baker's study very complete and satisfactory.—A technical descriptive paper by Mr. Charles Knight on the Lichens of New Zealand, was taken as read. —The Secretary also read a short notice of a new form of Ophiuridæ from the Philippines, by Mr. Edgar A. Smith. The distinctive characters of the specimen the author regards as subgeneric, and names it (*Ophiomastix*) *Acantharachna mirabilis*.

Zoological Society, March 6.—Dr. E. Hamilton, vice-president, in the chair.—Mr. E. W. H. Holdsworth exhibited and made remarks on a specimen of *Geocichla layardi*, from Ceylon. —Prof. Owen, C.B., communicated some notes made by Mr. G. F. Bennett, while exploring the burrows of the *Ornithorhynchus paradoxus*, in Queensland, with comments on them.—A communication was read from Lieut.-Col. R. H. Beddome, containing the descriptions of three new snakes of the family Uropeltidæ, from Southern India.—M. A. G. Butler read the descriptions of some new species of Heterocerous Lepidoptera in the collection of the British Museum, from Madagascar and Borneo. Amongst the latter was the type of a new genus, proposed to be called *Mimeuplæa*.—Mr. G. French Angas read a paper in which he gave descriptions of a new species of *Bulimus* from Western Australia, and a *Paludinella* from Lake Eyre, South Australia; these he proposed to call respectively *Bulimus ponsonbyi*, and *Paludinella gilesi*.—A second paper by Mr. Angus contained the descriptions of one genus and twenty-five species of marine shells from New South Wales.—Mr. Angus also read a further list of additional species of marine mollusca to be included in the fauna of Port Jackson and the adjacent coasts of New South Wales, with remarks on their exact localities, &c., thus bringing up the number of species now ascertained to inhabit Port Jackson and the adjoining shores to a gross total of 693.—Mr. Phineas S. Abraham, M.A., B.Sc., read a paper containing a revision of the Anthobranchiate Nudibranchiate Mollusca. The paper comprised a general and historical introduction to this group of Nudibranchs, *i.e.*, those which bear the branchiæ upon the dorsal surface, more or less surrounding the arms, and allusion was made to all the principal work which had been done upon these animals. The second part consisted of definitions of the larger divisions and of the genera, with the enumeration, synonyma, references to and habitat of, as far as possible, every species hitherto published. In the last general list, viz., that by H. and A. Adams, but 163 forms were mentioned; this list included 457. The third part contained descriptions of forty-one hitherto undescribed species belonging to the genera *Doris*, *Chromodoris*, *Hexabranchus*, *Acanthodoris* and *Doridopsis*.—A communication was read from the Count Salvadori, containing notes on some birds mentioned by Dr. Cabanis and Mr. Reichenow, as collected in Papuasia and in the Moluccas during the voyage of the *Gazelle*.

Geological Society, February 21.—Prof. P. Martin Duncan, F.R.S., president, in the chair.—Samuel Arthur Adamson, William Mason Cole, Thomas Floyd, William Stukeley Gresley, Edward Pritchard, Joseph Pryor, and John Gwillim Thomas were elected Fellows of the Society. The following communications were read:—On possible displacements of the earth's axis of figure produced by elevations and depressions of her surface, by the Rev. J. F. Twisden, M.A., Professor of Mathematics in the Staff College. Communicated by John Evans, F.R.S. The object of this paper is to discuss the question of the possibility of a displacement of the earth's axis of figure under the conditions indicated in a question (suggesting the possibility of a displacement of the axis of figure from the axis of rotation, amounting to 15° or 20°) put to mathematicians in a passage of the Anniversary Address delivered to the Society by its president, Mr. J. Evans, on February 18, 1876. The treatment of the question is kinematical; the forces by which the elevations and depressions might be effected do not come under discussion. In determining numerically the amount of the deviation from the formulas investigated, approximate numbers seem to be sufficiently exact for every useful purpose. The conclusions arrived at are as follows:—(1) The displacement of the earth's axis of figure from the axis of rotation that would be effected by the elevations and depressions suggested in the question above referred to would be less than 10′ of angle. (2) A displacement of as much as 20° could be effected by the elevations and depressions of the kind suggested only if their heights and depths exceeded by many times the height of the highest mountains. (3) Under no circumstances could a displacement of 20° be effected by a transfer of matter of less amount than about a sixth part of the whole equatorial bulge. (4) Even if a transfer of this quantity of matter were to take place, it need not produce any effect, or only a small effect, on the position of the axis of figure, *e.g.*, if it took place in a way resembling that suggested in the question, it would produce a displacement amounting to but a small part of 20°. (5) If, however, we suppose a deviation of the axis of figure from the axis of rotation amounting to as much as 20° to have been by any means brought about, the effect would be to cause a sort of tidal motion in the ocean, the greatest height of which would tend to be about twice the depth of the ocean. The author suggests as probable that the effect of this tendency would be to cause the ocean to sweep over the continents in much the same way that a rising tide sweeps over a low bank on a level shore. (6) The notion that a large deviation of the earth's axis of figure from its axis of revolution may be effected by elevations and accompanying depressions is at first sight an inviting way of bringing polar lands into lower latitudes, and thereby accounting for the more genial climate that is believed to have once prevailed in such countries as Greenland. The investigation by which the above results have been obtained seems to show that the desired explanation is not to be sought in the direction indicated by Mr. Evans's question. Whether there is any other agency by which a gradual displacement of the pole geographically could be effected is a question of far wider scope than that discussed in the present paper, and one which the author does not profess to determine.[1] —Note on a specimen of *Diploxylon*, from the coal-formation of Nova Scotia, by J. W. Dawson, F.R.S. The author described the occurrence in Coal-measure sandstone at the South Joggins of an erect stump of a Sigillarian tree 12 feet in length. It originated in a coaly seam 6 inches thick, and terminated below in spreading roots; below the coal-seam was an underclay 3 feet 4 inches thick, separating it from an underlying seam of coarse coal. The stem, which tapered from about 2¼ feet in diameter near the base to 1¼ foot at the broken end, was a sandstone cast, and exhibited an internal axis about 2 inches in diameter, consisting of a central pith cylinder, replaced by sandstone, about ⅜ inch in diameter, and of two concentric coats of scalariform tissue, the inner one $\frac{1}{16}$ inch in thickness, the outer constituting the remainder of the axis. The scalariform tissue of the latter was radially arranged, with the individual cells quadrangular in cross section. A few small radiating spaces partially filled with pyrites obscurely represented the medullary rays, which were but feebly developed; the radiating bundles, passing to the leaves, ran nearly horizontally, but their structure was very imperfectly preserved. The cross section, when weathered, showed about twenty concentric rings; but these under the microscope appeared rather to be bands of compressed tissue than true lines of growth. The thick inner bark was replaced by sandstone, and the outer bark represented by structureless coal. On a small portion of one of the roots the author traced the remains of stigmarioid markings. From the above characters the author identified this tree with *Diploxylon* of Corda, and stated that it was the first well-characterised example of this type of Sigillarians hitherto found in Nova Scotia. The author compared the structure of this stem with that of other Sigillarians, and remarked that it seemed to come within the limits of the genus *Sigillaria*, but to belong to a low type of that genus approaching *Lepidodendron* in structure; those of the type of *S. elegans*, Br., and *S. spinulosa*, Renault, being higher in organisation, and leading towards the still more elevated type described by him in 1870. He further discussed the supposed alliance of these trees with Gymnosperms, and the probability of the fruits known as *Trigonocarpa* being those of *Sigillaria*, and expressed the opinion that the known facts tend to show that there may be included in the genus *Sigillaria*, as originally founded, species widely differing in organisation, and of both Gymnospermous and Acrogenous rank.

Royal Microscopical Society, March 7.—H. C. Sorby, F.R.S., president, in the chair.—A letter received from Mr. Frederick Ebsworth, Australia, descriptive of a supposed new method of using the micrometer, which the author had found very useful in measuring the fineness of wool, was read by the Secretary.—A communication from the Rev. W. H. Dallinger, entitled "Additional Notes on the identity of *Navicula crassinervis*, *N. rhomboides*, and *Frustulea saxonica*" was read by the Secretary, and some further observations on the subject were made by Mr. Ingpen, Mr. Slack, and Mr. Chas. Brooke.

---

[1] The first draught of the paper, of which the above is an account, was drawn up last August, and was shortly after sent to Mr. Evans. It was written independently of the wider view of the subject taken by Sir W. Thomson in his Address delivered at the last Meeting of the British Association, and by Mr. G. Darwin in his paper, of which an abstract has been published in No. 175 of the *Proceedings* of the Royal Society.

CAMBRIDGE

Philosophical Society, February 26.—A communication was made to the society by Mr. Creighton on the order in which the secreting and the conducting parts of an acinous gland appear in the individual development and in the succession of animals.

PARIS

Academy of Sciences, March 5.—M. Peligot in the chair.—The following papers were read:—On the temperatures of combustion, by M. Berthelot. M. Bunsen's hypothesis, that the specific heat of the components and that of the products are constant quantities, independent of temperature and pressure, does not always apply; *e.g.*, to gases formed with condensation. Still his measurements allow of calculating without any hypothesis on specific heats, two limits between which the temperature of combustion is necessarily comprised. That of carbonic oxide by oxygen at constant volume is between 4,000 and 2,600; by air, between 2,200 and 1,750. That of hydrogen by oxygen, between 3,800 and 2,400; by air, between 2,100 and 1,700.—Physical and mechanical action of incandescent gases after combustion of powder; application of these facts to certain characters of meteorites and bolides, by M. Daubrée.—Agreement of the laws of mechanics with the liberty of man in his action on matter, by M. de Saint-Venant.—Observations of solar protuberances during the second semester of 1876; rotations lxix. to lxxv., by P. Secchi. Very few protuberances; average 5·4 (and even this exaggerated, including small jets), average height 40·8 seconds. Few protuberances over 68 seconds, general maximum between 40° and 50° latitude. The most notable point is the frequency of thin, very high and straight hydrogenic threads, sometimes one minute high; this indicates great calm. Metallic protuberances rare, and always preceding or accompanying spots. In December there was an important instance of a spot with apparent rotation; two nuclei in same penumbra, then separated by a bridge, which ere long was broken. The movement was in the direction of the hands of a watch, and the spot near the equator gained on that further north.—Observations of the spectrum of Borrelly's comet, by P. Secchi. Three bright bands, a broad one in the green, a narrower in the blue, a third still more narrow and less refrangible, but difficult to define.—Report, in name of the Academy, on measures to be taken against Phylloxera, in regions uninvaded or threatened. The Commission advise interdiction of exportation and importation from phylloxerised regions, thorough destruction by fire of any vines attacked, and vigorous disinfection of ground and stocks in neighbourhood.—Dr. Bastian, in a letter, proposed to come to Paris and make his experiments before the Commission on spontaneous generation.—On the asymptotic lines of a surface of the fourth degree, by M. Rouché.—Demonstration, by the principle of correspondence, of a theorem on the contact of surfaces of an implex with an algebraic surface, by M. Fouret.—On the extension of the theorem of Fermat generalised, and of the *Canon Arithmeticus*, by M. Lucas.—On the mechanical theory of heat, by M. Levy.—Method of extracting platinum from chloroplatinates, by M. Duvillier. He utilises the property which salts of platinum have of being reduced in boiling by alkaline formiates in the presence of alkalies.—On the isomerism of rotatory power in the camphols, by M. de Montgolfier.—On a vat of aniline black, and on the transformation of aniline black into a fluorescent rose colouring matter, by M. Goppelsroeder.—Researches on the acidity of the gastric juice of man, and observations on stomachic digestion, made with a gastric fistula, by M. Richet.—Action of hydrosulphite of soda on the hematosin of blood, by M. Cazeneuve. The change of colour might prove useful in legal medicine.—Experimental study on the *rôle* of the blood in transmission of vaccinal immunity, by M. Raymond. He inoculated children with blood from newly-vaccinated children. Neither was vaccination thus produced nor was there ulterior immunity. But, resorting to transfusion of blood from a vaccinated heifer to another heifer, he obtained immunity, in the latter, without any eruption.—On the maintenance of constant temperatures, by M. D'Arsonval. In his system are two concentric cylindro-conical vessels; the interior, open above, being the cavity of the stove; the water bath is in the concentric space, and its dilatation acts on a caoutchouc membrane governing the passage of gas into the Schloesing regulator.—On "grisoumetres," or firedamp measuring apparatus, by M. Coquillon. Their principle is, that hydrogen or any of its compounds in the gaseous state is completely burnt in presence of oxygen and a palladium wire white hot.—On the unity of the forces in geology, by M. Hermite. Gravity may serve as the common measure of the forces which maintain the equilibrium of continents.—Chemical examination of turnerite, by M. Pisani.—Observation of a parhelion on February 5, by M. Soucaze.—On the treatment of cancerous affections by acetic acid and the acetates, by M. Curie.—Results of microseismic observations, by M. Bertelli.

VIENNA

Imperial Academy of Sciences, February 1.—On Peltier's experiment, by M. v. Waltenhofen.—On space-curves of the fourth order with a double point, by M. Weyr.—On the theory of electrodynamics, by M. Lippich.—On the theory of algebraic equations, by M. Igel.—New method of deduction of Taylor's series, by M. Zimels.—Report on the excavation of a bone deposit at Zeiselberg, by M. Wurmbrand.

February 8.—On collateral innervation, by M. Stricker.—Contributions to knowledge of hydrate of chloral, by M. Cech.—Researches on vaporisation, by M. Baumgartner.—On the condition of heat equilibrium of a system of bodies with reference to the force of gravity.—On the diffusion of vapours through liquid films, by M. Exner.—Observations during 1876 at the Central Institution for Meteorology and Terrestrial Magnetism.

ROME

R. Accademia dei Lincei, February 4.—Palæontological notes on the fossils of Genoa marls, by M. Issel.—Thirty years' experiments of Messrs. Lawes and Gilbert at Rothamsted, by M. Ronna.—On some palæozoic fossils of the Maritime Alps and the Ligurian Apennines, studied by Michelotti.—The tertiary formation of Reggio in Calabria, by M. Seguenza.—Monograph of tertiary nuculidæ found in the southern provinces of Italy, by M. Seguenza.—On the quaternary sea, by M. Moro.—On the existence of realgar and orpiment in the hills of Santa Severa in the province of Rome, by M. Sella.—On the modular equations of Prof. H. J. Stephen Smith, by M. Cremona.—On a new difficulty proposed against Melloni's theory, by M. Volpicelli.—Effect produced by the mass of Monte Mario on the vertical of the observatory on that hill, by M. Kella.—Experimental researches on electric discharges, by M. Righi.—On a class of finite and continuous functions which have only one derivative, by M. Dini.—On the degeneration of cut nerves, by M. Colasanti.—On the coloration proper of the retina and modifications of it, by M. Boll.—On the constitution of chlorammonium and aldehydes of ammonium, by M. Schiff.

BRITISH MANUFACTURING INDUSTRIES

British Manufacturing Industries. Edited by G. Phillips Bevan, F.G.S. "Hosiery and Lace," by the late W. Felkin, Nottingham; "Carpets," by Christopher Dresser, Ph. D.; "Dyeing and Bleaching," by T. Sims (second edition); "Pottery," by L. Arnoux, of Minton's Factory; "Glass and Silicates," by Prof. Barff, M.A.; "Furniture and Woodwork," by J. H. Pollen, M.A. (second edition). (London: Stanford, 1877.)

Industrial Classes and Industrial Statistics. By G. Phillips Bevan, F.G.S. Vol. 1, "Mining, Metals, Chemicals, Ceramics, Glass, and Paper." Vol. 2, "Textiles and Clothing, Food, Sundry Industries." (London: Stanford, 1876-7.)

THE first edition of the first two volumes has been already noticed in these columns. The speedy issue of a second edition bears out the favourable opinion previously expressed with regard to them, and of this series of short comprehensive essays on British manufactures generally. There can be no doubt that any one wishing to take a general view of any of the subjects on which they treat will gain a good idea of their principles from a perusal of these volumes.

The latter two volumes, dealing as they do with the condition of the British industrial classes considered as *workers*, form an appropriate pendant to the "British Manufacturing Industries," in which the nature of the *work* which they perform has been already spoken of. Though, as Mr. Bevan says, the British workman "has from a political point of view . . . been frequently written and talked about—too much so, indeed, for his own good or for the good of the country—his social condition as dependent upon, or connected with, his special branch of labour," is comparatively seldom inquired into. This topic forms the subject of the present work.

In treating the subject one or more chapters are devoted to each of the divisions named above. A description of the character of the work in each department is given, together with the conditions whether healthy or otherwise, under which it is performed. This is supplemented by statistics as to the numbers employed in the various industries, the quantity of material manufactured, its value, the wages of the workman or workwoman, the effects of various industries on the rate of mortality, and some account of working class legislation and federation. The distribution of the various industries over the country is graphically shown by two maps in each volume.

The statistics are very full and complete, and being compiled mostly from official sources, may be taken as accurate and reliable. With regard to the introduction of this profusion of figures the author remarks that he has done so "in the hope of showing, how intimately allied is the development of our manufactures with the state of wages and the general condition of the working classes." There can be no doubt that Mr. Bevan's volumes clearly show that our English operatives are in better condition generally now than at any previous period, and this is so whatever be the standpoint from which they are regarded.

In reading the descriptions of the various handicrafts and under what conditions they are executed, one sees that there is much yet to be done in some branches to render the work still easier of execution and less unhealthy. Science has done much for the coal-miner; but more remains to be done in order that he may be better protected from sudden outbursts of fire-damp or choke-damp. It is evident from the quotation of Dr. Angus Smith's analyses of the air from metal mines, that some further legislative enactment is required to compel the more thorough ventilation of such mines. Blast-furnace workmen, it is true, do not work under very unhealthy or dangerous conditions; but there are one or two points in which there is room for improvement. For example, the "chargers" more particularly, are now and again rendered insensible by breathing escaping carbonic oxide, sometimes with fatal results; while once in a while, from the fall of the material in the furnace after "scaffolding," explosions occur in the "hearth" resulting in the forcible expulsion of the front or side of the furnace and of the molten metal, which occasionally envelops the workmen, who in some instances have been literally roasted to death. Possibly at some future period the dangers to health and life arising from these causes may be diminished or entirely obviated by the application of scientific principles.

The injurious effects and diseases resulting from the vapour of ordinary phosphorus and "phosphoric fumes" in match-making are fully pointed out (and the remedy in the use of red phosphorus), also those of oxide of zinc, sparks of metal and dust, poisonous gases, powdered glass and emery, and poisonous colours, in brass, needle, chemical, glass and emery paper, and paper-hanging manufactures. In the second volume the "sizing" of cotton goods, "singeing" of fabrics generally, "heckling" of flax, preparation of tobacco, use of "Scheele's green" and similar preparations in flower-making, and the closeness and general want of ventilation in workrooms, in dress-making, &c., are shown to result prejudicially to the health of the worker. Affections of the eyes from close work, as in watch and lace making, are not lost sight of. Neither are deformities resulting from working in constrained and unnatural positions.

In this connection it may perhaps reasonably be doubted—as the result of actual experience—whether "the effects of chlorine are transient and less serious" than follow from the inhalation of sulphuretted hydrogen. Weldon's chlorine-process is noted as an improvement on the old process, while Deacon's—which may fairly rank with it—is left unnoticed. On the same page a small matter needs correction; "mangan*i*te" and "permanga*ni*te" should, of course, be mangan*a*te and permanga*na*te. Mr. Bevan might be puzzled, perhaps, to show how tobacco acts as food, under which head he classes it.

A list is given of the legislative Acts hitherto passed affecting industries, which shows that the amelioration of the condition of the worker to its present improved state has not been an easy task. The trade societies are classed as trades unions, friendly societies, and co-operative societies; of the first the opinion is given that they are "at most a doubtful blessing," while the latter are considered as both useful and excellent.

The abundant statistics given cannot fail to be of great service in many ways. The volumes altogether are very readable, and throughout the statements are usually reliable. Should a second edition be required it might possibly be improved by the addition of a "table of contents."

W. H. W.

THE GERM THEORY

The Germ Theory Applied to the Explanation of the Phenomena of Disease. "The Specific Fevers." By T. Maclagan, M.D. (London: Macmillan and Co., 1876.)

IN his preface the author states that "one object which he has in view is to rescue the germ theory of disease from a false and misleading position, and to give to it its true and legitimate standing as a pathological question." The subject discussed is whether the propagation of germs in the system can produce specific fevers. He believes it can, and assumes that all contagia are living organisms, probably albuminous, reproducing their kind, living for a considerable period, speedily perishing when freely exposed to the atmosphere, and so minute as to elude the highest powers of the microscope.

If, however, the particles in sheep-pox, small-pox, and vaccine, be the infecting matter, they are easily seen by the microscope, and ought therefore to be found in the blood, but such is not the case.

Dr. Maclagan holds that "all microzymes are not contagia, but all contagia may be microzymes." The fact that the contagia fluids are most potent when fresh, and that their virulence diminishes as bacteria increase in them is explained by saying that disease-germs are more minute organisms than bacteria, and are the food on which bacteria live. According to this view, bacteria not only do not constitute infection, but destroy it.

Dr. Maclagan says "that the chief action of an organism on its environment is the consumption of nitrogen and water. A disease-germ is a parasite, and requires a special *nidus* as well as nitrogen and water; the parasite finds a *something* in its *nidus*—the second factor—the parasite being the first. Without this second factor no bad result follows the reception of the contagium." Different periods of incubation are accounted for by the varying amount of the second factor and the number of germs imbibed; incubation itself by germ-growth and reproduction; and the onset of the symptoms by the germs becoming mature.

The consumption of nitrogen by the contagium particles causes wasting of the tissues, *i.e.*, the organisms eat the albumen intended to nourish the body. They also drink largely of water from the liquor sanguinis, which, being rich in soda, explains why soda-salts are often absent from the excretions during fever. The same retention of soda-salts, however, often happens in acute pneumonia, which has no relation to infectious disease.

Increased elimination of urea is explained thus:—"The increased consumption of liquor sanguinis by the contagium particles leads to increased formation of retrogressive albumen and of urea." It seems by this that contagium particles have livers and kidneys, and excrete urea. Diminished excretion of urea is held as "due to consumption by the contagium particles of the water requisite to enable the kidneys to perform their excretory function." What then, we ask, becomes of the water consumed by the contagium particles? Do their kidneys excrete urea in excess with limited water, while those of the patient are unable to do so? or do the contagium particles not consume water when the urea is increased as well as when it is diminished? In fever the quantity of water drank by the patients is very great, but that, according to Dr. Maclagan, is because the quantity of contagium particles is also very great. We find, however, the same symptoms in symptomatic fevers, with no contagium particles present, and we have great difficulty in believing that ultra-microscopic organisms in a person's blood could consume several tumblerfuls of water in twenty-four hours.

The heat of specific fevers is partly ascribed to the propagation of the contagium causing increased consumption of tissue. But increase of living matter causes the disappearance of heat, not its production. Again, the author states that the fecundation of the organisms may be accompanied by an elevation of temperature analogous to that which occurs under similar circumstances in other organisms.

As regards treatment, at page 163 the following occurs: "If we were to bleed, to purge, to give antimony to, or even *simply to withhold food and water* from, all the cases of typhus and enteric fever which occur, there can be no doubt that we should find the mortality from those diseases greatly increased." Dr. Maclagan is right here, for by *simply withholding food and water*, there can be no doubt that he would greatly increase the mortality by starving his patients to death. He, however, believes that fever patients should be supplied with nitrogen and water to compensate for what the organisms consume.

The cessation of the fever and its specificity are attributed—the first, to the organisms, as parasites, requiring a special nidus which contains a suitable pabulum, and when the latter is exhausted the fever ceases; the second, to a local lesion in the *nidus*, which is the part where fecundation of the organism takes place. In small pox this *nidus* and lesion is in the skin, in typhoid in the bowels, and so on. It is well-known, however, that many medicines act on special parts of the body, and yet we do not think of calling them parasites which require a special *nidus*. The author gives many other plausible, and some very unusual explanations of febrile phenomena by means of the germ theory, all of which, we believe, are far more clearly and rationally explicable on the physico-chemical theory. The writing of this book must have cost Dr. Maclagan much trouble. We have read it very carefully, and commend the author's honesty in stating his views, but question if the work will go far in realising the object for which it was ostensibly written.

OUR BOOK SHELF

A Manual of Cinchona Cultivation in India. By George King, M.B., F.L.S., Superintendent of the Royal Botanical Garden, Calcutta, and of Cinchona Cultivation in Bengal. (Calcutta, 1876.)

THIS manual is another contribution to the numerous books, papers, and articles that have appeared of late years on the subject of cinchona. Varied as these contributions have been, and valuable each one in itself, this manual brings together much that is useful, not only on the scientific aspect of the subject, but also on the harvesting of the bark crop in India, as well as on the commercial value of the Indian cinchona plantations. The manual will probably find its largest circulation amongst owners of land who have embarked in the cultivation of cinchona as a commercial enterprise, or those who intend doing so, Chapter iv. being devoted entirely to cultivation: and this part of the subject is treated of very fully; the author giving the various details of suitability of climate, temperature, rainfall, elevation, soil, drainage, &c., together with the more practical operations of preparing the ground, sowing seeds, propagation, planting, and other matters of a similar character, which, from the nature of Dr. King's position as superintendent of the Government cinchona plantations, must be trustworthy, if not from his own practical experience, certainly from the fact of his being able to command the opinions of the best men in this important branch. The same may be said of Chapter v., on the "mode of harvesting the bark crop." Turning to Chapter vii. on the "local manufacture of a cinchona febrifuge," we come to what is interesting and important to the whole community, namely, some of the practical results of the cinchona introduction into India, in the production of a cheap but efficient febrifuge. This preparation, which Mr. Broughton, the Government quinologist calls amorphous quinine, consists of the total alkaloids of cinchona bark, in the form of a non-crystalline powder, mixed to some extent with the resin and red colouring matter so abundant in red bark. "This alkaloid," we are told, "has been accepted by the medical profession in the Madras Presidency, as a remedy in malarious fevers, scarcely, if at all, inferior to quinine." About 600 lbs. of this substance was produced in the Neilgherry factory up the end of the year 1872-73, but the process of manufacture was found too costly, and the factory was accordingly closed. A more simple process was commenced in Sikkim, by Mr. Wood, who arrived in India in 1873, and by this process at the present time, about a ton per week of dry red bark is being worked up. The bark, hitherto so utilised, has been chiefly derived from thinnings and prunings, undertaken from time to time in the interests of the trees. By the end of the current financial year (1875-76) about 32,000 ounces of alkaloid will have been turned out. Next year a much larger quantity will be yielded. It has been calculated that of this efficient febrifuge there can soon be yielded from three to four tons annually, at a cost of rather less than one rupee per ounce.

Some interesting appendices are attached to the Manual—one shows the stock of trees in the Neilgherry cinchona plantation, another the stock in the Sikkim plantations, another the meteorology of the same plantations, and the last one gives the opinions of medical men holding important positions in India, on the efficacy of the cinchona febrifuge. With the manual are also issued three extra pages, descriptive of the process at present used for manufacturing the above substance, by Mr. C. H. Wood, the Government quinologist. J. R. J.

Die Euganeen. Bau und Geschichte eines Vulkanes. Von Dr. Ed. Reyer. (Wien, 1877.)

THIS is Dr. Reyer's first publication, and we gladly acknowledge it to be a very promising one. The subject, a minute geological treatise of the Euganean Mountains near Padua, illustrated by a well-drawn map, hardly calls for a lengthy notice on our part, but the little work is attractively written, and testifies to the complete mastery the author possesses over his subject. He minutely describes the structure of these mountains, then dwells upon the consequences he draws from this regarding their geological history, and raises before the eyes of the reader an interesting picture of times long past, and of forms long extinct. Dr. Reyer's language has the advantage of being clear and to the point, and free from all unnecessary ornament. We have pleasure in recommending the book to our readers, and hope that it may soon be followed by another production from Dr. Reyer's pen.

Die Erde und ihre Völker: ein geographisches Hausbuch. Von Friedrich von Hellwald. Erster Band. Zweite Auflage. (Stuttgart: Spemann, 1877.)

THIS work has met with deserved popularity in Germany. Dr. Hellwald is known as one of the most accomplished living geographers, and is well fitted to undertake the compilation of a work like the present. It will, we believe, be completed in two volumes, the volume before us dealing with America and Africa. The author follows to some extent the method of Reclus in his *magnum opus*, though, of course, on a smaller scale. He takes the great divisions of the land and water one after another, and in a thoroughly interesting and clear style, summarises all that is known of them on the basis of the latest discoveries, and under a variety of well-selected heads. The work, so far as we have tested it, is up to the latest date, and we know of no more trustworthy, interesting, and handy compendium of geographical information. Some of the illustrations might bear improvement, especially in the case of North America, where, we think, a freer use might have been made of the magnificent illustrations in the U.S. Survey publications. On the whole, however, the work is a valuable "family book," as it is meant to be, and we should think would prove of considerable service to teachers of geography. We have no doubt that many would welcome an English edition of the work.

LETTERS TO THE EDITOR

Science Fellowships at Oxford

YOUR correspondent, Mr. Charles Wade, is an undergraduate of Magdalen College, and makes the very natural mistake of supposing that fellowships once assigned to natural science are, like the class of college prizes with which he is more familiar, namely, the scholarships, regarded by the colleges giving them as in a certain sense appropriated for future vacancies, to the subject which has once been connected with them. This is not the case, and accordingly your readers will find that Mr. Wade's enumeration of twelve fellowships, as assigned to natural science at Oxford, is erroneous, whilst the statement of "an Oxford Man" that only five fellowships are at this moment held as rewards for proficiency in natural science, is correct. From Mr. Wade's list must be removed the three Lee's readerships at Christ Church, which are not of the nature of ordinary fellowships, but are special foundations and enumerated by "an Oxford Man" with the professorships. Of the nine remaining on Mr. Wade's list, one at Merton does not exist, nor does that at Corpus, nor that at Pembroke, whilst that at Brasenose was not offered purely and simply for physical science. Hence there are but five fellowships at Oxford now held for natural science, or six if we count that at Brasenose.

Since I have no reason to ingratiate myself either with those who defend or those who attack the abuses of Oxford, I shall not imitate Mr. Wade, but sign myself SOCIUS

Spectra of Metalloids

IN a recent number of NATURE (vol. xv., p. 401) I gave a short abstract of a paper by Messrs. Angström and Thalén, on which I should like to make a few remarks. It is known that Plücker first drew attention to the fact that one body may have different spectra, and he seemed inclined to attribute these spectra to different allotropic states of the element. Later on, however, attempts were made to give another explanation of the phenomenon. It is against these attempts that Angstrom and Thalen chiefly protest in their paper. They use, however, the word element, in a different sense from that in which it is generally used. An elementary body, they say, can only have one spectrum. We are aware that bodies, as iodine and sulphur, can give two spectra, but then the band spectrum is due to an allotropic state, which, from a spectroscopic point of view, behaves like a compound body. It would seem from this and other remarks, that, from a spectroscopic point of view at least, they consider an element to be not only a body which cannot be decomposed into two different bodies, but a body which cannot be resolved into any simpler molecular state. I have no objection against this if it is always clearly understood that our authors include allotropic states under the denomination of compounds. For instance, they lay great stress on the fact that a spectrum of fluted bands is always characteristic of a compound body. According to their definition of a compound this is perfectly correct, for no doubt the band spectrum belongs to a more complicated molecular state, but they cannot bring this argument forward as tending to show that Swan's spectrum of the candle belongs to a hydrocarbon, or that the fluted spectrum of nitrogen belongs to an oxide of nitrogen. The fact simply means that the molecule which gives these band spectra is to the molecule which gives the line spectra as the molecule which gives the absorption bands of iodine is to the molecule which gives the lines of iodine.

There is no doubt that we must be exceedingly careful, especially working with Geissler's tubes, not to ascribe to an element a spectrum which really belongs to a combination of that element with some other body present. The question what spectra an element really has must be settled in each individual case by careful experiments. Let us examine the two examples chosen by Messrs. Angström and Thalen. The first is carbon. Watts has already shown that the spectrum marked by him originally No. 2, really belongs to an oxide of carbon. The only spectrum under discussion is therefore Swan's spectrum of the candle. On this point Attfield's experiments are entirely conclusive They have been amply confirmed by Watts and others I take one case out of many. The flame of dry cyanogen gas shows the same spectrum brilliantly. The onus of the proof that a hydrocarbon can here be present lies entirely with those who make that assertion. Messrs. Thalen and Angstrom in the present paper assert that this spectrum is due to acetylene In the year 1871 Prof. Angstrom published a paper, in which he tried to show that Wullner's second spectrum of hydrogen really belongs to acetylene. Other experimenters have confirmed this fact. In order to escape admitting that carbon has two spectra, Messrs. Angstrom and Thalen are forced therefore to assume that acetylene has two spectra.

The chief object of this letter is to say a few words on the spectrum of nitrogen. In the year 1872 I published a paper in which I gave an experiment tending to show that the band spectrum of nitrogen really belongs to an oxide of nitrogen. The experiment was this: Clean pieces of sodium were heated in a tube containing nitrogen; the band spectrum then disappeared, and another spectrum came out, which I then thought to be identical with the lines of nitrogen. The experiments were repeated by Stearne and Wullner; they also found that the bands disappeared, but the lines of nitrogen did not come out. I convinced myself that what I had seen was not the line spectrum of nitrogen, but the disappearance of the bands alone seemed to me to be an object of further investigation Mr. Salet at last gave a full and correct explanation of the experiment Nitrogen is absorbed by sodium under the influence of the electric spark, and the lines I had seen were the lines of sodium. As Mr. Salet has shown, my measurements agree better with the lines of sodium than with the lines of nitrogen. The bands of nitrogen remained if care was taken that the spark did not touch the sodium. If I have refrained hitherto from acknowledging the justice of Mr. Salet's conclusions, it is only due to the fact that I felt a natural curiosity to repeat his experiments; I have not yet been able to do so, but I have no doubt what the result would be. Mr. Salet's paper was only published after Prof. Angstrom's death, and I cannot help thinking that the professor would have considered his experiments conclusive against the assumption that the bands of nitrogen are due to an oxide of nitrogen. The only argument which Messrs. Angstrom and Thalen bring forward to support their theory is that in a tube containing rarefied air which showed the bands of nitrogen when the spark passed, nitric oxide was formed. But surely nitrous acid fumes are produced by sparks showing the line spectrum of nitrogen. Ozone is formed by sparks giving the lines of oxygen, yet we do not conclude that the line spectra of nitrogen and oxygen are due to nitrous acid and ozone.

If anyone still believes that an element can only have one spectrum at the temperature of the electric spark, I propose to him the following problem:—Let him take the three gases, carbonic acid, acetylene, and oxygen. If he investigates their spectra carefully he will at least find ten different spectra (two o them I only discovered lately). Out of carbonic acid alone he can obtain six. Let him find a sufficient number of possible compounds to account for all these spectra. ARTHUR SCHUSTER

The Annual Parliamentary Grant for Meteorology

THE Meteorological Department of the Board of Trade was, as is well known, constituted by Government in 1856 with the object of collecting and discussing facts and observations too numerous to be collected and discussed by private persons. The Department continued for ten years under the sole direction of Admiral Fitzroy, who, by his self-denying exertions and enthusiasm, and a genius for developing meteorology in certain of its practical applications, gave a great and withal healthy impetus to a sound study of the laws of weather.

In consequence of the recommendations of a committee of inquiry appointed after Admiral Fitzroy's death to review the results of the labours of the department, its control was transferred to a Committee of the Royal Society, who, in return for an annual grant of 10,000*l*., agreed to carry out the duties connected with the office. The Committee were left perfectly free in their method and in their choice of labour, the only condition attached to the grant being that an annual account be rendered to Parliament of the expenditure and of the results obtained in each year.

The support of the public was freely given to the Committee in the work they had undertaken, but in the course of a few years an opinion took root and gradually extended to the effect that the methods of inquiry adopted by the Committee and the work of the Meteorological Office were so seriously faulty as to call for inquiry. To some of these points attention was drawn in NATURE (vol. xii. p 101), your criticism being limited to little more than the baldest statement of facts, which anyone could easily examine for himself, a criticism which, so far as we are aware, still remains unanswered.

Upwards of a year ago the Lords of H.M. Treasury, seeing that the Meteorological Committee had received nearly 100,000*l*., considered that the time had arrived for an inquiry, the grant being so considerable that they did not think they could be justified in continuing it for any lengthened period without satisfying themselves that the results obtained were such as to warrant the application of so large a sum of public money. A Treasury Commission was accordingly appointed on November 2, 1875, to inquire into the work of the Meteorological Committee, particularly that portion of it referring to storm warnings; and, in the event of their deciding to recommend the continuance of the grant, to consider further upon what system it may be best administered. In connection with the latter part of the inquiry the Lords of the Treasury gave expression to their wish that the claims of the Scottish Meteorological Society for aid from the State should receive the consideration of the Commission. The Commission consisted of Sir W. Stirling Maxwell, Chairman, Mr. Brassey, M.P., Mr. Lingen, permanent Secretary of the Treasury, Mr. Farrer, permanent Secretary of the Board of Trade, Dr. Hooker, President of the Royal Society, Mr. F. Galton, and Gen. Strachey. Considering the many scientific questions of a strictly technical character which were to be dealt with, it is to be regretted that such names as Sir G. B. Airy and Prof. Balfour Stewart were not placed on the Commission; and it was perhaps unfortunate that Mr. Galton and Gen. Strachey were on it, seeing that they were also members of the Meteorological Committee whose work was to be inquired into by the Commission. The name of Mr. Milne Home, chairman of the Council of the Scottish Meteorological Society, was on November 29 added to the Commission.

On looking over the Report of the Commission, I am surprised to find an inattention to several important matters remitted to them by the Treasury. I do not find, for instance, that the methods adopted by the Meteorological Committee for the observation of the temperature of the British Isles, to which serious objection has been taken, and the character of the work of the office, to which also serious objections have been made, have been inquired into; and I find that the consideration of the claims of the Scottish Meteorological Society for aid from the State have been all but ignored in the Report of the Commission.

Passing on, however, to the recommendations of the Report we find that it recommends that the annual grant be increased from 10,000*l*. to 14,500*l*.; that, at least provisionally, some assistance be given to the Scottish Meteorological Society; that ocean meteorology be transferred to the hydrographical department of the Admiralty; that the present system of collecting daily information by telegraph and of issuing storm-warnings be continued, an endeavour being made to put into clear shape, for the information of the public, the maxims or principles upon which storm-warnings in future are to be given; that the issuing of daily weather-charts be continued; that a certain number of continuously self-recording stations be retained; that the present system of supplementing self-recording observations by returns from eye-observers, that is, from ordinary meteorological stations, be continued; and, since the science of meteorology at present stands in need of hypothesis and discussion at least as much as, if not more than, of observation, that a part of the annual grant be appropriated to special researches, it resting with the Meteorological Council to select the investigators and fix the remuneration. Several of the recommendations are not put in the clearest shape in the Report, whilst others, such as those relating to the practical applications of the science, which concern the investigation of the relations of weather to health and agriculture, are so expressed as to suggest the idea that the nature of the problems involved in these large national questions has not been apprehended by the Commission, and consequently no provision is made in the Report for their proper investigation.

But by far the most important recommendations are those which refer to the constitution and action of the Meteorological Council, or new governing body, who are to be entrusted with the control of the grant, and the relation of the Council to the meteorological societies, which call for the gravest consideration. The services of the Meteorological Committee of the Royal Society are not to be continued, as suggested by some of its members when under examination before the Commission, the reason assigned being that it is not to be expected that they will continue to give much valuable time to the work under the existing conditions. It is proposed that the Royal Society be invited to recommend to the Government persons eminent in science who shall constitute the Meteorological Council, that they be fewer in number than the present Committee, and that they be remunerated in the shape of fees for attendance. This proposed reform as regards the body to be entrusted with the control of the grant in future is thus more nominal than real, and it is not improbable, looking at the phraseology of this part of the Report, that the Meteorological Council will be substantially the same as those who form the present Meteorological Committee, the only difference being that they will be fewer in number.

The value of the work of the meteorological societies is acknowledged, and it is recommended that co-operation with them be fostered to the utmost The amount, however, of the assistance which the Commission recommends to be given to these societies out of the Parliamentary Grant, is indicated in these words of the Report (Art. 23):—"No payments should be made to them, except for results sought for by the Council." In other words, no assistance, whatever, is to be given to the meteorological societies out of the grant, because, these payments being only for services rendered to the Meteorological Council, cannot be regarded as grants to the societies, and they will neither aid them in conducting their own operations, nor remunerate them for the services which have long been rendered, and continue to be rendered, to Government Departments.

It is not in this way that foreign countries foster the prosecution of meteorology by their different nationalities. Thus, Hungary has its separate grant distinct from that of Austria proper; Norway has its grant distinct from Sweden; many of the Germanic States have their separate grants; and, as the readers of NATURE are aware, France is divided into meteorological departments, all of which are subsidised by the State, and their operations are aided, but not controlled, by the central office in Paris. In all cases, this division of work and responsibility is productive of greater economy and efficiency in carrying on meteorological research. Voluntary local effort is in this way evoked in a degree and to an extent not otherwise possible, and the healthful principle of competition and mutual criticism, so desirable in the present state of the science, is called into active play. Surely some provision ought therefore to be made by our own Government, to subsidise these societies, it being on all hands admitted that voluntary subscriptions alone are inadequate for their permanent efficient maintenance. In no other way can they be placed in a position to discharge the duty of a public department in collecting statistics for the elucidation of the climatology of a country in its details and practical applications.

In the estimated expense of the Meteorological Office on its proposed new footing, I observe that 1,500*l.* is set down annually for "New Land Stations," and in the appended outline of "Duties of Future Council," they are to place themselves in postal and therefore direct communication with about 150 secondary stations in the United Kingdom. What does this mean? Is it intended quietly but surely to supersede, and in a few years supplant the meteorological societies—a course which the Report not only permits to be done if the Council be so minded, but also includes in the grant an annual sum of 1,500*l.* which may be so applied?

It cannot be supposed that any council, composed of persons eminent in science, could be formed at present, possessing the knowledge and technical training required to direct the conduct of the whole field of meteorological research, both physical and climatological. Certainly, keeping in mind the serious mistakes made under the *régime* of the Meteorological Committee, and the manner in which the work of the office has been conducted, to both of which attention may here again be drawn, no other result can reasonably be expected than that the programme, as sketched in the Report of the Commission, is seriously in fault. The fact that the work was not efficiently controlled, was no doubt one of the main reasons of appointing the Commission; and, therefore, virtually to reappoint the same controlling body, only under another name, armed with the means and powers as proposed by the Commission, could scarcely fail to result in work of a more or less unsatisfactory nature, and, besides, in an unnecessarily increased expenditure of public money.

It is difficult to see how this result can be obviated, except by remitting the whole question of local climatology, including its practical applications, to bodies located in each of the three kingdoms, these societies being at the same time intrusted with supplying the Registrar-General, as has been done in the past, and such bodies as the Medical Council and the agricultural societies of the United Kingdom, with the information they may require. If 1,000*l.* were given for this work to each of the societies referred to, and 1,500*l.* to the Admiralty for the work of ocean meteorology, there would still be 10,000*l.* for the central office in London, to be devoted to the issue of storm warnings and to the prosecution of the more purely physical researches of meteorology, of which the science at present stands so much in need, and which is so emphatically the proper work of the central office: and in this case it need scarcely be added that each of the societies would necessarily be represented on the Meteorological Council. ZETA

Centralism in Spectroscopy

PERMIT me to repeat that happy remark of yours, and happy because so true and of wider application than the one meteorological case which called it forth, on p. 427; viz.: "We think centralisation hurtful to science, and we regret that 1,000*l.* a-year has not been granted to Scotland, by which a healthy rivalry would have been gained."

In the Anniversary Report of the Royal Astronomical Society for last month will be seen a statement that the Royal Observatory, Greenwich, amongst a vast deal of other most undoubtedly admirable work, is also now having a large spectroscope constructed on a totally new plan. How many spectroscopes that observatory has had made for itself during the last twenty years I do not know! and I, for one single individual in the nation, do not grudge this new one if it should realise only a third part of the wonderful promises made for it.

In the same Anniversary Report there is also a statement that the Royal Observatory, Edinburgh, has been in want of a proper spectroscope for its special local observations for years and years past; and if at length there is one there now, almost good enough for the required purposes, it is because such a one has been recently made at the private expense of the Astronomer-Royal for Scotland, although his salary is less than that of many a clerk in London.

Of this, also, I am told there is no reason to complain, because I accepted the situation in its poverty-stricken condition, though when the nation itself was also poverty-stricken as compared with its present truly heaven-favoured financial condition. But what I do, merely as an individual, complain of is—that if the new Greenwich spectroscope is to be the *only one* which the centralisation of the British Government in London allows to be built up at the expense of the whole nation, out of taxes levied in Ireland and Scotland as well as England, that it is being made on a principle which goes against the laws of Sir Isaac Newton and nature, and which, though it *may* give with "two or at most three half-prisms" more dispersion than was before obtained by "ten whole ones," does so at the cost of *all definition*, and will be certainly allowed at Greenwich, as well as everywhere else, to be a mistaken step in modern spectroscopy before another anniversary of the Royal Astronomical Society takes place.

PIAZZI SMYTH,
Astronomer-Royal for Scotland
Edinburgh, March 17

Greenwich as a Meteorological Observatory

IN NATURE (vol. xv. p. 421) there appeared a brief abstract of the presidential address of Mr. H. S. Eaton to the Meteorological Society of London on February 21. The increase of temperature at Greenwich in recent years is stated to be in reality due to local causes and not to secular variation, to which it has, as he thinks, been erroneously assigned. The effect of the growth of the population of London from 900,000 at the commencent of the century to 3,500,000 at the present time, and the still greater increase in the comparative consumption of coal, Mr. Eaton considers to be manifested by the rise in the average temperature of the air at the Royal Observatory, and for this reason it is concluded that Greenwich is not a suitable place for a meteorological observatory of the first order.

If the view enunciated by Mr. Eaton be correct, it is evident that the temperature of Greenwich during recent years has been in excess of that of surrounding districts. Is this view borne out by observation? Taking the figures for a number of places in the south-east of England whose mean temperatures have been calculated for the same thirteen years ending 1869, and adding the usual correction for height above the sea, we obtain the following results as their mean winter, mean summer, and mean annual temperatures; Greenwich, 40°·4, 63°·1, and 51°·1; Camden Town, London, 40°·4, 63°·3, and 51°·1; Royston, 40°·5, 62°·3, and 50°·8; Colchester, 39°·4, 62°·8, and 50°·6; Worthing, 41°·1, 61°·2, and 50°·7; Osborne, 42°·0, 62°·5, and 51°·8; Aldershott, 40°·9, 62°·6, and 51°·2; and Oxford, 40°·6, 61°·3, and 50°·4. A simple inspection of these figures is sufficient to show that the consumption of fuel and the vast population of London cannot be said to have had an appreciable influence on the temperature as recorded at the Royal Observatory, and that if the Greenwich observations show a rise of temperature during recent years, the whole of the south-east of England has shared in that rise. This result deduced from observations is such as might have been expected when the position of the thermometers at Greenwich and the mode of escape of the artificially heated air by chimneys into the free atmosphere is taken into consideration. It follows, therefore, that, so far at least as regards the temperature observations, the conclusion drawn as to the future of our great national Observatory as a contributor to the higher meteorological researches is not supported by the facts of observation.

ALEXANDER BUCHAN

Atmospheric Currents

I AM glad to have obtained from such exponents as Capt. Digby Murray and Mr. Murphy a clear statement of the old orthodox creed respecting the movements of the atmosphere.

The former, it is true, finds a difficulty in accepting Maury's belief that the currents cut one another in "curdles" in the equatorial calms, but none in adopting the same as regards the tropical calms, and his view may therefore, as I suppose, be taken as a modification of that which is graphically represented on Plate I. in the "Physical Geography of the Sea."

The question at issue between Capt. Digby Murray and myself amounts to this: Are rapid polar and equatorial upper currents observed over the region of tropical calms? Mr. Murphy's theoretical question appears to me to involve the inquiry—Is the force of the trades derived from the earth's rotation?

In tracing the course of the air particles along the route which he describes, the late Commodore Maury observes that this course is determined in certain particulars by "some reason which does not appear to have been very satisfactorily explained by philosophers." The latter do not as yet seem to have got rid of all the difficulties with which his theory is beset, which rather grow with its development.

I would beg the philosophers to look closely at the actual course of the atmospheric currents as shown by synoptic charts, not by charts of prevailing winds and mean pressures, which represent conditions never found at any one time in nature. The distinction between the "great currents" and the "temporary

than that between mean winds and actual winds; and to explain the mean winds on one principle and the actual winds on the opposite involves a fallacy.

Again and again we see a more or less irregular belt of high pressures, having central calms, extending across the North Atlantic. From the southern edge of this belt we may follow a particle of air in its course to and from the equatorial district of low pressure, also an irregular belt in the middle of which calms exist. The movement originates in the defect of pressure near the equator at the level occupied by the particle. Its velocity is governed by the steepness of the gradient; and its direction, in relation to the surfaces traversed, is affected by the increasing velocity of rotation of those surfaces. In the Doldrums it arrives at a district at which the gradient becomes zero and the horizontal movement has consequently disappeared; but a vertical movement has now been acquired from the difference in the tension of the particles above and beneath, a difference derived from solar heat. When the particle has arrived at a position in which this difference disappears the vertical movement vanishes, and a new horizontal movement commences owing to the defect of pressures on the polar side at the level then reached, and the direction of this movement is also affected in relation to the surfaces by their decreasing velocity of rotation. Where does the new movement terminate? Obviously in some district between the equator and the pole where horizontal pressures on all sides of the particle at its then level are equable, but where a vertical movement has been acquired, the particles near the earth's surface starting on their journey towards the equator. The *onus disputandi* lies with those who deny that such a district is presented by either of the belts of tropical calms.

We now look at the polar side of the calm belt of Cancer, and for this purpose we may take almost any, *e.g.*, of Capt. Hoffmeyer's charts. We see in the majority of cases an aggregate of cyclonic circulations around local barometric minima, interfering and imperfect, and commonly becoming more so as they are propagated towards the pole. But we see no "polar depression" *distinct* from these, on which, as represented in the chart, we can lay the finger and say, "This is the result of centrifugal force; those are due to steam power." Within these systems an upward movement of the air occurs, owing to vapour condensation and the liberation of heat. Consequently towards these the particles of air near the earth's surface at the poleward edge of the tropical calms begin to travel, the earth's rotation deflecting their course in relation to the surfaces traversed. And from these, at a certain elevation, the particles return to the tropical calms for the same reason as that which determines the upper currents over the trades.

From the phenomena observed in the northern hemisphere I argue, *mutatis mutandis*, to those of the southern, and I expect the argument to be admitted by one who, like Mr. Murphy, attributes much less influence than I do to the work of water-vapour, and who even thinks that the mean movements of our atmosphere would be unaffected by the removal of all the water of our globe.

On some occasions pressure is high over all the North Atlantic on the polar side of the tropic, the anticyclones apparently extending nearly to the pole. In these cases we have no surface counter-trades over that district, yet the north-east trades continue to blow on the southward of the tropic as usual.

I repeat that all movements of the atmosphere originate in differences of pressure derived directly and indirectly from solar heat, and not in the force of the earth's rotation. And I must add that it seems to me very strange that any one while regarding the trades and their upper-currents as simply the *effects* of pressure differences in the lower latitudes, should maintain that the south-west and north-west winds of the temperate zones are simply the *causes* of the pressure differences in the higher latitudes. It would be just as logical to regard the south-west and north-west winds as due to pressure distribution, and the trades as the compensation for their eastward movement.

W. CLEMENT LEY

March 10

Electrical Phenomenon

LAST night I noticed a powerful development of electricity in a curious manner. I had thrown a piece of common, thick, white, unglazed paper upon a low fire which was tolerably full of ashes. When it was charred so as to be black and brittle, I happened to take it up and break bits off. To my astonishment they stuck firmly to my fingers. I broke off two pieces each an each was capable of rotating (though with very great friction). When brought near each other they repelled each other forcibly. I experimented with these pieces for several minutes without perceiving any diminution in their electrification. Both sides of the paper seemed to be in the same condition. I then laid them down, and left the room to fetch a piece of sealing-wax to test the nature of the electricity. But by the time I returned, all trace of electricity was gone, and by no means could I repeat the experiment so as to get the slightest charge of electricity.

It is more than probable that the electricity was developed by the chemical action of combustion of the coals, and that the hot air rising up and brushing past the paper acted as a carrier of electricity of one kind to the paper, and of the opposite kind from it, until it acquired a very high potential. But it would be interesting to learn exactly in what manner this action takes place, and whether the electrification was positive or negative.

Andersonian College, Glasgow GEORGE FORBES

Strange Star.—Meteor

ON going out last Saturday evening about 8.55 P.M. my attention was arrested by a large deep red star in Serpens which I had never seen before. Its magnitude was greater than Arcturus, though its deep colour made it seem less bright. About ten minutes afterwards I saw it increase and diminish in magnitude two or three times producing the effect similar to a "flashing" light on the coast, after which it suddenly disappeared.

On the same evening, at 9.56, I saw a very fine meteor of a bright pale blue colour with coruscations of ruby colour at the nucleus. Its course was from Gemini over Aldebaran, disappearing below Pleiades. Of a long pine-cone shape, duration about three seconds. W. M.

Gunnersbury, March 19

SCIENCE IN GERMANY[1]

THIS book forms a continuation of the researches which in vol. i. treated of the season dimorphism as the result partly of exterior influences and partly of atavism. The present (second) volume comprises: (1) the origin of the markings upon caterpillars; (2) on the phyletic parallelism in metamorphous species; (3) on the transformation of the Mexican Axolotl into an Amblystoma; (4) on the mechanical conception of nature. The third treatise was published separately some time ago and was reviewed in NATURE; here we particularly wish to draw the attention of the lovers of natural science to the first paper. Weismann tries in the treatise in question to prove by his observations, and the deductions therefrom, that exterior influences and natural development or adaptation (Naturzuechtung) only can be the causes of the markings upon caterpillars. The observations referred to were made upon the caterpillars of several genera of *Sphingidæ*, and relate to the history of their development.

I. *Chærocampa.*—The caterpillars of *Ch. elpenor*, which have just left the ova, show no markings of any kind in this first stage, being of a uniform greenish colour; after the first change of skin (second stage) they show a bright longitudinal streak on each side, between the dorsal line and the line of breathing apertures (stigmata). To this first streak Weismann gives the name of "subdorsal streak." In the third stage eye-shaped spots form in the fourth and fifth segments, inside of these streaks, and these are completely developed in the following stages, *i.e.*, after the subsequent changes of skin, while at the same time the subdorsal streak decreases and leaves only imperfect traces. In the fifth stage the greenish colour changes to a brownish one, and the horn at the tail of the caterpillar becomes shorter. In the sixth and last stage the other segments begin to show eye-spots, but these are not developed to perfection. *Ch. porcellus* shows the same form and development of the larva, with the only difference that most of the phenomena occur one stage earlier than with *Ch. elpenor*. This conformity and accord of both genera in the order in which the markings upon the caterpillars appear and are developed, lead to the conclusion that the markings were acquired in the same order during the progress of development (phylogeny) of these caterpillars; the oldest form (*a*) therefore showed no markings at all even when perfectly developed; the following form (*b*) had only the subdorsal streaks; then in form (*c*) the eye-spots occurred in the fourth and fifth segments, and finally in all segments (form *d*). It is probable further, that of the two genera of caterpillars now living, *Ch. elpenor* is the original, *i.e.*, older form, on account of its still showing the different stages of development in their completeness; the younger or more advanced form, viz., *Ch. porcellus*, proves that each new marking, acquired during the progress of development, appears first in the later stages and then gradually extends to the earlier stages. The whole of this view is well supported by the markings upon the complete form of the other species belonging to the genus *Chærocampa*, of which the development of the larva is still unknown in its different stages. These other species may be divided into three groups, corresponding to forms *b*, *c*, and *d* of the phylogeny in such a manner that wherever the subdorsal streak remains in perfection, the eye-spots are not developed, and wherever these show themselves the subdorsal streak is decreasing. Form *a* (first group) is known in the full-grown caterpillars of three species (*Ch. syriaca*, *Daraspa myron*, and *D. chærilus*); to the second group (form *c*) belong the above described *Ch. elpenor* and *Ch. porcellus*, together with several others; the last group (form *d*), which shows completely developed eye-spots on all segments, is even more numerously represented by *Ch. bisecta*, *oldenlandiæ*, *alecto*, *actæus*, *tersa*, and *celerio*. The species of the genus *Chærocampa* which Weismann examined, therefore represent three phylogenetic stages of development, and it is interesting that the tropical species are the most advanced ones. It is probable, indeed, of one species, viz., *Ch. celerio*, that in Europe it shows form *c* in the markings of its caterpillars, while in India the larvæ of the same species have already attained form *d*.

II. In a similar way the author shows that markings upon the larvæ of the genus *Deilephila*, to which the well-known *D. euphorbiæ* (commonly called Sphinx) belongs, have passed through seven phylogenetic stages of development, viz., (1) caterpillars without markings; (2) with a subdorsal streak; (3) with a ring-shaped spot upon the last segment but one; (4) with similar but not altogether perfect spots upon all segments; (5) with eleven perfect ring-spots upon the subdorsal streak; (6) with these ring-spots but without the streak; (7) with a double row of ring-spots. Nowhere in the development any deviation from this order is noticed, and the living species of this genus form five groups, the markings of their full-grown caterpillars corresponding to the phylogenetic forms Nos. 3 to 7.

III. A somewhat smaller number of stages of development is apparent in the genera *Smerinthus*, *Macroglossa*, *Pterogon*, *Sphinx*, *Anceryx*, which Weismann investigated less extensively than those mentioned before; however, he points out that upon their larvæ the simple subdorsal streak combines, in the course of development, with other longitudinal or oblique streaks, or becomes less distinct as the others increase in intensity.

Now Weismann considers that the remarkable conformities in the development of all the larva markings he investigated is the surest proof that we are dealing with a phenomenon of inheritance. Indeed three laws may be said to be established by these conformities, viz., (1) the development begins with the simple and progresses to the more complicated markings; (2) new markings first appear in the last stage of individual development; (3) these new markings then gradually pass backwards to the earlier stages and thus replace the older ones, causing them to disappear entirely. Weismann gives the following explanation of the phenomenon referred to in the second law:—Supposing that the respective markings are of use to the caterpillars, that therefore they are retained in subsequent generations by natural adaptation, this use can only be real if the caterpillars are big enough to resemble the different parts of the plants on which they feed, and thus escape being noticed by their enemies; and if a sufficient lapse of time is given for carrying this protection into effect. Both these conditions, however, are united in the last stage of development, where the caterpillars have attained the necessary size, and which is the longest of all stages. The use of the colour of caterpillars, and the markings upon them, is also perfectly evident. The younger ones are green as long as during the day they remain on the leaves of the plants they feed on; they do not then form a contrast with the colour of the leaves themselves. The older caterpillars remain green if the thick foliage of the plants protects them under all circumstances; if, however, the foliage is less dense, so that the caterpillars, as soon as they have grown bigger than the leaves, can be easily distinguished among them, they leave the green leaves in the day-time, and try to hide on the stems of the plants and among withered leaves; in that case, to complete the protection, their colour changes from green to brown. The biological value of the characteristic markings upon caterpillars, quite independently of their colour, may be recognised from the fact that

---

[1] Weismann, "Studien zur Descendenztheorie" ("Researches on the Descent Theory"). Vol. ii. On the last Causes of Transmutations.

the caterpillars which live permanently in the dark, or those of the Microlepidoptera, just as little as those of the first stages of development of most butterflies, have no markings at all; their small size, or their habit of hiding themselves, sufficiently protect them from their enemies; they, therefore, need no markings to insure their safety. When the caterpillars are getting bigger the longitudinal streaks become useful, as through them they do not contrast so much with long-shaped leaves, fir-needles, or stems. The caterpillars with longitudinal streaks, such as those of *Satyridæ*, *Pieridæ*, &c., almost without exception live on fir-trees, grass, or plants growing among grass. The oblique streaks in the segments of other green caterpillars imitate the lateral ribs of the large leaves upon which these species live. The eye- and ring-shaped spots form another means of protection. On the one hand, they may imitate the berries of the plants on which the caterpillars feed, and protect the latter, inasmuch as the berries are still unfit to be eaten at that particular time (*Deilephila hippophaes*). On the other hand, the spots, greatly resembling eyes, most decidedly act as means of frightening the enemies of the larvæ; this is particularly the case with the *Chærocampa* species, as, whenever any danger threatens them they draw their foremost segments into the fourth and fifth ones, and the eye-spots upon these then glare on the puffed-up fore-part of the animal. Weismann has proved this experimentally, by throwing such caterpillars as food before birds, and then watching the expression of fear on the part of the latter. There are other caterpillars the markings upon which cannot possibly be looked upon as means of frightening their enemies, as their repulsive odour or taste alone suffice to ward off the insectivora. Wallace has shown that such insects bear their many coloured marking like a stamp of their unfitness for food, and already by this frighten off insectivorous animals Weismann has proved by some experiments that lizards not only refuse certain caterpillars (*Smerinthus*, *Sphinx*, &c.) at all times, but are even diffident towards others which are marked in a similar manner although quite edible, and only eat them after minute examination.

It is certain that many of these useful markings were acquired by natural adaptation (Naturzuechtung), and it is quite beyond doubt that others have resulted from the internal laws guiding the formation or growth of caterpillars, *i.e.*, through correlation of the different parts of the insect, independently of all usefulness. This is proved by the retrograde movement of the markings acquired in later stages towards the earlier ones, where the markings can but be perfectly useless. The eye-spots, in the same way, first appear through natural adaptation near the head or the tail of the animal, and are then of use; but later on they spread over the other segments also, and here they only reappear, because in articulata the *general* tendency exists to develop all segments in an equal manner. On the other hand the gradual disappearance of certain markings must be ascribed to natural adaptation, because under different conditions of life, more useful markings supplanted the existing ones, which had become useless. If the second phylogenetic form of the *Sphingidæ* caterpillars with single longitudinal streak, seems to indicate that the animals then lived on grass, these streaks became useless and even obnoxious when the caterpillars selected shrubs and trees for their food, and were then replaced by the more appropriate and useful eye-spots.

In short, as far as Weismann investigated the markings of caterpillars, particularly those of *Sphingidæ*, he could prove their development to be caused by external influences (natural adaptation and subsequent correlation), and could consequently reject the assumption of a special creative or form-shaping power.

D'ALBERTIS'S EXPEDITION UP THE FLY RIVER, NEW GUINEA

THE *Sydney Mail* of Saturday, January 20, contains a long account of the expedition of the Italian naturalist, D'Albertis, up the Fly River, New Guinea, translated from his diaries, and communicated by Dr. George Bennett. Signor D'Albertis left Sydney, April 20, 1876, in the mail-steamer, *Brisbane*, and reached Somerset, Cape York, on May 1, where the steam-launch *Neva*, which had been provided for the purpose of the expedition by the liberality of the good citizens of Sydney, was disembarked and equipped. On May 19, after various small casualties, a start from Port Somerset was effected, and Katow, on the coast of New Guinea, reached on the second day. Hence the mouth of the Fly River, already well known to D'Albertis from his previous expedition in the *Ellangowan*, in 1876, was soon entered, and more or less progress was made every day. The land traversed appears to have been mostly low and swampy. On June 20, being on shore, Mr. D'Albertis ascended a hill 250 feet high, and from the summit saw some "very high mountains" in the north-east, fifty or sixty miles distant—probably part of the "great Charles Louis range." On June 28, after having been for some time aground, and only got off by an unusually heavy flood, it was determined to return and to try the western branch of the Fly River. The strong current and other adverse circumstances rendered it necessary to abandon this attempt likewise, after about a week's struggle, and the *Neva* returned to the coast, when the expedition passed several months amongst the islands, and finally returned to Somerset in November. The following is Mr. D'Albertis's summary of his discoveries:—

"After my long narrative I shall conclude with a few words expressing my regret at not having been able to do more. But it is often not the pioneer who shows the way that attains the most glory, but those who follow him; it is easy to hear of a road, but very difficult to find one out. I wish every success to any explorer of this part of New Guinea (should I not be able to return and complete my work), and I hope that the little I have done will be some guide and enable him to find his way more readily than I did mine, and to correct any errors I may have made. By this exploration we are now acquainted with a road into the interior of New Guinea, which is of the more importance, as it is so near to Somerset, where a line of large steamers calls twice every month. We have also found a passage from Moatta to the Fly River, shorter and safer than the one previously known, and a passage which, when properly surveyed, may be found navigable for larger ships. The richness of the land we visited, its vegetable, and probably mineral, products, the soil suitable for many of the most valuable plants, as coffee, sugar, cotton, india-rubber, sago, tobacco, nutmeg, &c., ought to attract the capital of the colony to open up the country. The Dutch from their part of New Guinea, although on a small scale, derive some trade. The part of New Guinea into which we penetrated, was in latitude 5° 30′ S., and ran about 500 miles on the winding river, the course of which may be seen on the chart appended, and it almost forms a line of demarcation between that part of New Guinea claimed by the Dutch, and that remaining as yet unclaimed by any nation.

"About the Fly River, as far as I could judge, the natives appear less numerous than I have seen in other parts of New Guinea, and the land is cultivated in a smaller quantity, so that in this part of New Guinea the settler will not find the same difficulties which I have pointed out on former occasions when speaking of the south-eastern peninsula, where the natives are more numerous, and possess and cultivate all the best land. I have appended Baron von Mueller's report on my collection of dried plants;[1] and on the return of Prof. Liversidge to Sydney he will report on the small collection of minerals, &c., I submitted to him for examination. On a day not far distant I hope to give the ethnological report on the natives, their weapons, &c., also on the mammals and the birds collected, the latter consisting of about fifty species, many of which are new, or only recently described from specimens obtained during my first visit to the Fly River. I have also a rich collection of reptiles, fishes, both of salt and fresh water, some beetles, and some fresh water and land shells. I confidently expect that the voyage of the *Neva* will be remembered by those who take an interest in New Guinea, and by the scientific world."

THE PHYSIOLOGICAL ACTION

II.

DETERMINATION of Electro-motive Force.—Soon after the first experiments were announced, certain physiologists said that although the results of the action of light which I have just described may be observed, to say there was a change in the electro-motive force, as stated in the earlier communications, was not correct. That the effect was due to an alteration in the electro-motive force had been proved, but experimental details were reserved for the second part of the investigations. At first Sir William Thomson's electrometer was used, but the amount of electric potential to be measured was too small to get good results. Another plan of determining the electromotive force was adopted. This was the method introduced by Mr. Latimer Clarke, the eminent electrician, and described in his work on "Electrical Measurements." The instrument devised for this purpose is called by him a Potentiometer, and measures electromotive forces by a comparison of resistances. Practically we found the Daniell's cell far too strong a battery to use as a standard of comparison. A thermo-electric junction of bismuth and copper was substituted for it. One end of the junction was constantly heated by a current of steam passing over it, the other being immersed in melting ice. The electro motive force of this thermo-electric junction, as estimated many years ago by Regnault, is extremely constant, and is about the $\frac{1}{175}$th part of a Daniell's cell. By means of this arrangement the following results were obtained:—The electromotive force of the nerve-current dealt with in experiments on the eye and the brain of a frog varies from the $\frac{1}{300}$th to the $\frac{1}{100}$th of a Daniell's cell. Light produced an alteration in the electro-motive force. This change was, in many instances, not more than the $\frac{1}{10000}$th of a Daniell's cell. But though small it was quite distinct, and proved that light produced a variation in the amount of the electromotive force. By the same arrangement the gastrocnemius muscle of a well-fed frog gave $\frac{1}{38}$th of a Daniell: the same muscle from a lean frog which had been long kept, gave $\frac{1}{210}$th of a Daniell; and the sciatic nerve of the well-fed frog $\frac{1}{480}$th of a Daniell. Dr. Charles Bland Radcliffe states, in his "Dynamics of Nerve and Muscle," p. 16, that he obtained by means of Sir William Thomson's quadrant electrometer, from a muscle a positive charge equal to about the tenth of a Daniell's cell, a much greater amount than ascertained by the method I have just described.

The electro-motive force existing between cornea and posterior portion of the sclerotic in a frog amounts to [illegible] part of a Daniell, and between the cornea and cross section of the brain is about four-fifths of the above.

Effect of Temperature on the Eye of the Frog.—From numerous experiments on the irritability of muscle induced by the excitation of nerve, it has been satisfactorily proved that a temperature of about 40° C. destroys the action of motor nerves in cold-blooded animals. Up to the present time we are acquainted with no observations as to the temperature at which a terminal sense organ becomes incapable of performing its functions. Having satisfactorily proved that *the retina is the structure in the eye producing the electrical variation* observed, it becomes evident that as long as this phenomenon can be detected the retina is still capable of discharging its normal functions. In order to investigate thoroughly the effect of an increasing temperature on the sensibility of the retina, a method of procedure was adopted of which the following may be taken as a general account:—A frog was killed, the two eyes removed rapidly from the body; the one eye was placed on electrodes and maintained at the ordinary temperature of 16° C., while the other was placed on similar electrodes contained in the interior of a water bath having a glass front, the sides of the air chamber being lined with black cotton wool saturated with water. Into this chamber a delicate thermometer was inserted, and the currents coming from the two eyes were alternately transmitted to the galvanometer every five minutes by means of a commutator, the temperature and the electrical variation produced by the same amount of light being noted in each case. The general results are shown in the following table:—

Table showing Comparative Effect of Temperature on Sensibility of Frog's Eye.

Eye kept continuously at 16° C.		Eye at different Temperatures.		
Initial Effect	Final Effect.	Temperature.	Initial Effect	Final Effect.
55	28	16° C.	58	21
61	28	19° C.	55	16
53	27	[illegible] C.	65	14
53	39	29° C.	97	5
53	45	29° C.	103	—4
60	45	37° C	65	—3
60	50	38° C.	65	—4
53	41	43' [illegible]		—5
60	40	43° C.	no effect.	no effect.

The initial amount of current was, however, increased on the whole by the action of the higher temperature, thus showing that the sensibility to light does not depend on the amount of current circulating through the galvanometer. It will be observed, on inspecting this table, that the eye maintained at the temperature of 16° C. remains tolerably constant in its initial action, although it gradually gets more sluggish, whereas the final effect steadily rises. On the other hand, in the case of the eye subjected to a higher temperature, the initial effect seems to have a maximum about 29° C., then gradually diminishes, and vanishes about 43° C., the final effect continuously falling and being actually reversed. To succeed in this experiment it is necessary to heat the electrodes which are to be used in the water bath up to 40° C., in order to be certain that no changes are induced in the electrodes themselves that might be mistaken for those above mentioned. An eye that had been placed in dilute salt solution along with lumps of ice was found to have the usual sensibility to light.

Effect of Temperature on the Eye of Pigeon.—Having succeeded in experimenting with a water-bath in the manner above described, it appeared interesting to ascertain if the eye of a warm-blooded animal would be benefited by being maintained at the normal temperature of the body. The head of a pigeon was placed in the water bath at a temperature of 40° C., the eyes were found sensitive to light, the action, however, being always a negative variation; but instead of vanishing quickly, as it does at the ordinary temperature, kept up its activity for at least an hour. For example, in one experiment, the electrodes being placed on the corneas so that the currents were balanced, sensibility was active for an hour and a quarter, but half an hour later it had almost disappeared. In this experiment the sensibility of the eye is shown by the large deflection produced by a single candle at different distances, thus:—

Distance of Candle from Eye.	Divisions of Galvanometer Scale
9 feet	
6 feet	180
3 feet	230
1 foot	420

Sensibility of the Optic Nerve.—When the retina is entirely removed from the eye-ball, and the optic nerve is

---

[1] Friday evening Lecture by Prof. James Dewar, M.A., at the Royal [illegible] March 31, 1876. See NATURE, vol. viii. p. 204. Continued from

still adherent to the sclerotic, no effect of light can be detected. It now appeared possible to examine this question by repeating Donders's experiment of focussing an image on the optic disc in the uninjured eye, when no electrical disturbance ought to occur. This was done in the eye of the pigeon, but an image free from irradiation on the optic disc could not be produced, and consequently there was always an electrical effect observed.

Exhaustion and Stimulation of the Retina.—When the same light from a fixed position is allowed to act on the eye for successive intervals of time, say two minutes of light and two minutes of darkness, it gradually falls off in electrical sensibility. Thus, a candle at nine inches gives the following results when successively used as a stimulus:—

	Initial Effect.	Final Effect
1st experiment	259	254
2nd "	171	276
3rd "	140	282
4th "	122	274

These figures show a rapid fall of the initial effect. In these circumstances, it is evident that the image being always localised on the same minute portion of the retina, only a few of the rods and cones of that structure are really exhausted. If the eye be allowed repose in the dark for a period of from half an hour to an hour, it will regain as much as triple the exhausted sensibility. But another mode of proving that only a minute portion of the retina was affected was to show that an alteration of position of the image by a slight movement of the luminous body was followed by a new electric variation. In order to vary and extend the action of a retinal image it is necessary to suspend a steady lamp by means of an indiarubber cord or spiral spring, so as to be able, by inducing vibrations in any direction, to stimulate in rapid succession different retinal areas. On oscillating a pendulum of this kind, an electrical variation is observed whenever the amplitude of the vibrations is increased, and by inducing a combination of vibrations, the electrical variation observed corresponds to what would be found if the luminous intensity were sixteen times as great as that of the stationary light. Similar experiments may be made by throwing an image from a small silver mirror connected with a metronome. The rapid exhaustion of the eye may be most readily demonstrated by cutting off the anterior half of the eye, leaving the vitreous humour in contact with the retina, observing the effect of a candle, and then subjecting it to the action of a magnesium lamp. The sensibility will now be enormously diminished. The electrical variations resulting from the respective actions of a candle and a magnesium lamp placed at the same distance from the eye were as follows:—

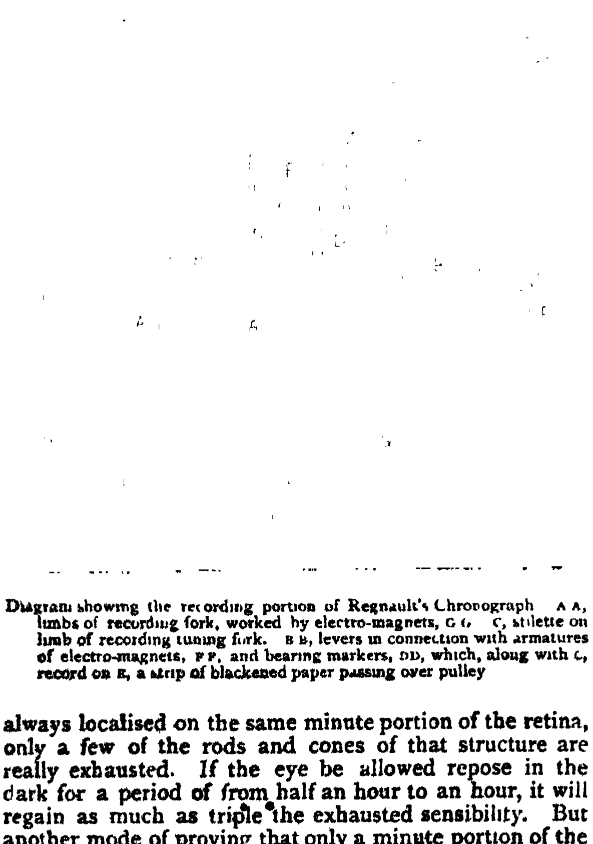

Diagram showing the recording portion of Regnault's Chronograph A A, limbs of recording fork, worked by electro-magnets, G G C, stilette on limb of recording tuning fork. B B, levers in connection with armatures of electro-magnets, F F, and bearing markers, D D, which, along with C, record on E, a strip of blackened paper passing over pulley

	Initial Effect.	Final Effect.
Candle	38	78
Magnesium lamp	120	135

This experiment proves that an increase of 200 per cent. in the illuminating power of a source of light only triples the electrical effect. Thus the eye becomes less sensitive as the illumination increases.

Chronometrical Observations.—A series of experiments have been begun with the object of measuring the time required from the initial impact of light before electrical variation is produced. As the electrical variation has been shown to agree with our consciousness of luminous effects, it became an interesting point to ascertain whether the time occupied by the action of light upon the eye of the frog is similar to the time occupied in its action upon the eye of man. A good many years ago, Prof. Donders and his pupil, Schelske, performed a number of experiments by which they determined that the time required by the human being to observe light and to signal back the impression occupied about $\frac{1}{10}$th of a second. That is to say, $\frac{1}{10}$th of a second is occupied by the action of light on the eye, the transmission of nerve-current to the brain, the change induced in the brain during perception and volition, the time for the transmission of the nerve-current to the muscles, on signalling the result, and the time occupied by muscular contraction. The true period of latent stimulation in the case of man must therefore be a very small fraction of a second. In order to attempt a solution of this problem a chronograph made by Dr. König, of Paris, was employed. A diagram of the recording portion of the instrument is given above. The experimental arrangements were as follows: the galvanometer, the eye apparatus, and the chronograph being in separate rooms, one observer was stationed at the galvanometer for the purpose of signalling the moment the needle worked, which was recorded by one of the markers D in the diagram, the other marker being used to register the time of initial action.

The *first experiment* was to transmit at a known moment, through the eye circuit in the dark room, a quantity of current equal in amount to the electrical variation produced, when the eye was stimulated by a flash of light from a vacuum tube, and to record the difference of time between the origin of the current and the observer's signal from the galvanometer.

The *second experiment* was to flash a vacuum tube at a known moment in a room where the eye was placed, and to record as before the instant the galvanometer was effected. From the first observation we ascertain the minimum amount of time necessary to overcome the inertia of the instrument, the observer's personal equation, and the signalling under the conditions of the experiment. If this result is subtracted from the record of the second observation, the difference will represent the latent period of light stimulation. From a large number of experiments made on the eye of the frog we have found the latent period amounts to less than $\frac{1}{10}$th of a second, but its absolute value must be ascertained by some method not liable to the variations that are inevitable to the process described. Altogether the problem is one of great difficulty, but further investigations are in progress.

J. D.

ASTRONOMICAL BIBLIOGRAPHIES

PROF. HOLDEN, of the Observatory of Washington, U.S., lately read to the Washington Philosophical Society a paper on "Special Astronomical Bibliographies," in which a careful comparison of one section of the "Reference Catalogue of Scientific Papers," by Mr. E. B. Knobel, F.R.A.S. (lately mentioned in these columns), was made with a MSS. catalogue on the same subject (nebulæ and clusters) which Prof. Holden had compiled for his own use. Only one misprint was found (*op. cit.*, p. 377, for *Comptes Rendus*, vol. 28, p. 537, read p. 573) and only one omission of a highly important paper, the "Siderum Nebulosorum Observationes, Havniensis" of D'Arrest. The list of works given by Mr. Knobel might be still further extended, but in its present state it is very accurate and extremely useful.

A list of bibliographical works available to the astronomer for consultation is given, which we extract:–

MENDELEEF'S RESEARCHES ON MARIOTTE'S LAW

IN compliance with your request I hasten to make known, through your esteemed journal, to the scientific public of England, the results of my researches on the Boyle-Mariotte Law. Special reasons which I have explained in the Russian *Journal of Artillery* (August, 1872), urged me to undertake new researches on this law. They are briefly as follows:—

1. It is impossible to admit in theory that under pressures infinitely great gases can be condensed into a volume infinitely small; or, in other words, that it is possible to introduce into a given volume an infinitely great mass of condensed gas. Although infinitely great pressures be practically unrealisable they are perfectly perceptible to the mind; as to an infinite condensation of matter it is quite inconceivable, otherwise we must admit the existence of an atomic substance without volume. The experiment of Cagniard-Latour developed and verified by MM. Wolf Drion, Andrews, and myself lead us to an inevitable conclusion, viz., that at a certain known temperature all gases and vapours can no longer be transformed under any pressure into liquid, but remain in the gaseous state, endowed with elasticity, but deprived of cohesion. At a lower temperature the gas may be transformed into liquid; but at a higher temperature it remains gas, whatever be the pressure. I gave to this temperature (*Lieb. Ann.*, t. 119, p. 11) in 1860 the name of "temperature of absolute ebullition;" in 1872 Dr. Andrews gave it the name of "critical point."

Imagine a mass of gas at a temperature higher than this, and suppose that this mass is subjected to pressures always increasing; if the Boyle-Mariotte Law is accurate the volume ought to diminish in inverse proportion to the pressure. If we represent this same mass of gas at a temperature a little less than that of absolute ebullition, the gas transformed into liquid will cease to be compressed as before, as the Boyle-Mariotte Law requires. Consequently, there is no doubt that we ought to come to the paradoxical conclusion:—A gas can be more compressed than a liquid or solid. As there is reason to believe that oxygen at the ordinary temperature is hotter than at its temperature of absolute ebullition, the Boyle-Mariotte Law being admitted, under a pressure of 2,000 atmospheres, we ought to find a specific weight of oxygen greater than that of sulphuric acid, and the pressure being 10,000 atmospheres, its density would reach that of mercury. But it is impossible to admit this, judging from what we know of the relation which subsists between the atomic weight of the elements and their density in the free state, as well as in their combinations with other elements. It is sufficient to indicate that a very great density is the peculiar property of combinations, the elements of which are endowed with a considerable atomic weight. Consequently, it cannot be admitted that elements having so small an atomic weight as oxygen can be condensed to any very considerable degree, no matter in what state. We must then conclude, *à priori*, that under high pressures the Boyle-Mariotte Law is inapplicable.

2. The researches of Rumford, which date from last century, relating to the density of the combustion gases of powder; also the researches of M. Natterer, on the compressibility of gases like oxygen, the oxide of carbon, hydrogen, and air, made in the years 1850 *et seq.*, are completely in accordance with the conclusions stated above, and show that under high pressure gases are endowed with a positive compressibility analogous to that of solid or liquid bodies. I mean by positive compressibility that property by which bodies, in proportion to the increase of pressure, diminish in volume less rapidly than the pressures increases. In cases where the Boyle-Mariotte Law is found exact, the product pv of the pressure p into the volume v remains constant; and $\frac{d(pv)}{dp} = 0$. When the compressibility is positive this product pv increases together with the increase of the pressure, and consequently $\frac{d(pv)}{dp} > 0$.

3. At the same time MM. Despretz, Regnault, and many others, have conclusively demonstrated that gases like carbonic and sulphuric acid, which are transformed into liquids under considerable pressure, possess a negative compressibility, so that for them $\frac{d(pv)}{dp} < 0$. M. Regnault has found the same negative compressibility for air, nitrogen, and the oxide of carbon under pressures higher than that of the atmosphere as far as thirty. It necessarily follows that if the data of MM Regnault and Natterer are correct, the negative compressibility of air becomes under a certain pressure above thirty atmospheres, equal to zero, and therefore positive. When $\frac{d(pv)}{dp} = 0$, Mariotte's Law is verified. Consequently there is a certain pressure above thirty atmospheres under which Mariotte's Law is applicable; under pressures below that point the compressibility is negative; under pressures above the same, it becomes positive and remains so to the end.

4. Although there is no doubt that the Boyle-Mariotte Law is not rigorously applicable even under moderate pressures, yet the prevailing doctrine, so rich in instruction on the nature of gases, which deduces all their properties from the *vis viva* which animates their molecules, admits the supposition that in the rarefaction of gases the distances between these molecules increase to

such an extent that their mutual attraction is destroyed; and in this case gases comply exactly with the Boyle-Mariotte Law. On this hypothesis the law becomes a limit towards which every gas tends in proportion as the distance between its molecules increases, and in proportion as their *vis viva* and the rapidity of their motion increase. That idea finds no support in facts. If it were accurate, then, at a certain high temperature, gases, especially those whose density is not great and whose particles are endowed with a very great rapidity of movement, ought to conform rigidly to the Boyle-Mariotte Law; but this is inconceivable, leading, in fact, to the paradox examined above. Moreover, the researches of M. Regnault on hydrogen, the lightest of gases, have shown the very opposite, hydrogen being positively compressible under pressures only a little higher than that of the atmosphere. It indubitably follows that in reference to the diminution of a mass of a gas filling a certain volume and the increase of the rate of movement of the molecules, we cannot expect a rigorous compliance with the Boyle-Mariotte Law. But we must make certain of finding positive errors, and the following are the grounds which urged me to have recourse to new experiments in reference to the application to gases of the law with which we are dealing.

These grounds were explained by me in 1872; since then similar ideas have been published by many others. Nevertheless, so far as I know, these ideas are far from having been generally adopted into science. It is evident that to combat an established opinion, a single *à priori* conclusion is insufficient; new researches are necessary, all the more that doubt may arise in the mind on the accuracy of the data of experiments, not only such as those of Rumford and M. Natterer, but even those which the celebrated experiments of M. Regnault have established. On examining critically the processes of the last-named eminent experimenter, we may not be able to discover any cause to explain the positive deviations which he has obtained for hydrogen, although it is possible to admit that the negative deviations depend on some defects in experimenting. New experiments and researches thus became indispensable; above all, for the purpose of verifying the data of MM. Regnault and Natterer, following methods not less precise than those which these observers employed. Thus it was specially necessary to experiment on the compressibility of gases under pressures less than that of the atmosphere, seeing that until 1872 there had been no accurate researches on this point.

I distributed as follows the work undertaken by me in 1872:—I commenced with pressures less than the pressure of the atmosphere, and I passed from that to pressures which exceeded those employed by M. Regnault. For the latter purpose I devised in 1872, and have now constructed, a compound manometer, containing alternate columns of mercury and of water, and permitting the measurement of exceedingly great pressures by means of a large number of very low columns of mercury. However, at present I shall not dwell upon this side of the researches, seeing that the experiments are still being carried on; I shall only endeavour to explain the main points of the practical processes, and the results obtained under small pressures. The first experimental researches made by me on the compressibility of air under pressures less than that of the atmosphere were made by means of very simple apparatus. Imagine a vessel A terminated above and below by tubes. The upper tube is always in communication with a syphon barometer, or, as I call it, a baro-manometer. In this apparatus the height of the column of mercury measures the elasticity of the gas in the vessel. It is easy to make the volume of gas in the baro-manometer remain the same all the time, notwithstanding the variety of pressures. To accomplish this it is only necessary to arrange so that we may at pleasure increase or diminish the quantity of mercury in the baro-manometer. The lower tube of A serves to introduce and to withdraw the requisite quantities of mercury. It is not necessary to see the height of the mercury in the vessel; the mercury here serves only to measure the volumes, and consequently, if we close the feeding-tube by means of a cock, and if by means of an emptying tube we allow all the mercury in the vessel to escape, we may ascertain the capacity of the whole reservoir; by emptying only a part of it we may ascertain the volume of the gas at each moment. Thus the weight of the mercury, directly observed by means of a balance, gives immediately, in all my researches, the volume occupied by the gas in each particular case. The first experiments made in 1873 on air, showed me that air under pressures lower than that of the atmosphere possesses a positive compressibility, and that the smaller the pressure the more are the divergences presented by air from Boyle's Law increased. The first apparatus was constructed in a very simple manner; some errors might be suspected, and this is why I am not confident of the results obtained. I therefore constructed a second and a third apparatus, modifying successively not only the dimensions, but also the very construction of the details of the apparatus. I then arranged a fourth apparatus, by means of which, with Michel Kirpitcheff, whose death is a sensible loss to Russian science, I made numerous observations. The report of these experiments was given by me in 1874 to the Russian Chemical Society, and printed in the *Bulletin* of the St. Petersburg Academy of Sciences. The experiments themselves are described in considerable detail in vol. i. chap. 9, of my work "On the Elasticity of Gases." It is impossible to describe in an article the great number of particulars which belong to these researches; we are limited to the more important details which I have introduced into this inquiry, as also into my subsequent investigations.

The normal metre and normal kilogramme which I employed were compared with the Paris standards at the Conservatoire des Arts et Métiers in concert with M. Tresca; their sub-divisions were then carefully verified.

I had to work a long time at the construction of the barometer, and I found out a new process for constructing this apparatus, which consists specially in terminating the end of the barometric chamber by a capillary tube bent downwards. By means of this tube it is possible to expel the last traces of gas which remain in the vacuum, and thus to show the experiment of obtaining an absolute vacuum, *i.e.*, to construct a barometer such that with the diminution of the volume of the chamber the indications do not vary. The construction of two barometers with a common chamber and a single descending capillary tube affords an easy means of obtaining with the greatest precision the determination of the feeblest tensions in the barometric chamber. It is only necessary to direct the telescope of the cathetometer to the top of the column of mercury in one of the barometers when the mercury in the other is at its maximum height, and when the volume of the vacuum is very small; then pouring out the mercury contained in the other barometer, and thus diminishing the pressure which acts upon the vacuum, we may increase its capacity. Then the least quantity of gas contained in the vacuum will give an increase of height in the barometer observed. By constructing the barometer with the greatest care, and filling it with mercury distilled according to Weinhold's process, it is possible, as our numerous researches with M. Hemilian have proved, to obtain a perfect barometer requiring no correction for the tension of air which may remain in the vacuum. This result is obtained solely by means of the capillary tube referred to above. The process shows, moreover, the possibility of constructing barometers without boiling the mercury and without removing them from the position which they are ultimately to occupy. Here then is an undoubted improvement in the construction of an apparatus so important as the barometer, in a great number of physical researches.

Next a very long time and a great number of trials were necessary in order to attain the desired accuracy in measuring heights. I always employ the comparative method, consisting in placing beside the height to be measured a standard metre, well tried beforehand in all connections. My normal measures are generally in the form of tubes, in the inside of which is introduced water which enables me to appreciate at each moment the temperature of the measure, and if necessary even to change it. The telescopes of all my cathetometers are fitted with micrometer eye-pieces, carefully constructed by our engineer, M. Brauer, justly noted for his long residence at Pulkova, and for the construction of a great number of astronomical and magnetic apparatus. Besides the central cross-wire the micrometer eye-piece is fitted with one movable wire, or still better, with two movable wires. The fixed wires passing by the optical and geometrical centre of the telescope fitted with a level sensible to about 2–3″ are directed towards a point of the object whose height is to be determined. Then both telescopes fastened to the same cathetometer, or better to two small separate cathetometers, are directed to the normal measure arranged at the side, and the double movable wire serves to determine the distance of the fixed wire from the nearest lines of the normal measure. This last is placed at such a distance from the column whose height is being determined, that the measure and the object may be distinctly visible without changing the position of the eye-piece. Every variation in the position of the eye-piece may derange the position of the optical centre; this is why latterly I use exclusively cathetometric telescopes, in which the distance of the eye-piece from the objective cannot undergo any change. On the other hand, it is possible to move the lunette if the cathetometer itself is in the rest where it is fixed; which is not seldom necessary in practice. By using a considerable magnifier and an illuminator of the columns of mercury very carefully combined, it is possible to observe the columns with a precision carried to thousandths of a millimetre; so that the error in appreciating the height does not exceed 0·01 mm. Everyone who has worked with the ordinary cathetometers and who has used their scales for measuring heights, knows that the accuracy of the measurement by means of such apparatus never exceeds $\frac{1}{25}$ mm., and that often he makes errors which reach tenths of a millimetre. It is sufficient to refer to the variations of temperature infallibly due to the presence of the observer. In the construction applied by me, these reasons, as well as many other causes of error, do not exist at all.

Although for the barometers and the baromanometers I always use tubes of large diameter, exceeding 17 and very often even 20 millimetres, nevertheless I have thought it proper to verify the capillary depression of the mercury depending on various diameters of the tube and various heights of the meniscus. A very extensive research has been made in my laboratory by Mlle. Goutkovsky, and the results which she has obtained have obliged me to change the data which we possess on the depression of mercury. I cite one example from many which are in my work on "The Barometric Levelling and on the Application of the *Syssotomer* to that purpose." The diameter of the tube being 8·606, and the height of the meniscus—

0·6 0·8 1·0 1·2 1·4 millimetre,

the depressions are—

0·162 0·235 0·312 0·380 0·458 „

numbers differing from those generally adopted, according to which for a height of the meniscus 1·0, there ought to be a depression of 0·460 for the diameter 8·606.

D. MENDELEEFF

(*To be continued.*)

OUR ASTRONOMICAL COLUMN

THE SUSPECTED INTRA-MERCURIAL PLANET.—M. Leverrier has issued an ephemeris of positions of the hypothetical planet, interior to Mercury, derived apparently from the two orbits to which reference was made last week as representing the observations upon which the general formula was founded, with equal precision, and if the planet should not be met with in transit across the sun's disc between March 21 and 23, use may be made of M. Leverrier's ephemeris to examine with large telescopes the positions of the greatest elongation westward in the two orbits. The differences of right ascension and declination from the sun about these times are thus given:—

	Orbit I.		Orbit II.	
	Diff R.A.	Diff. decl.	Diff R.A.	Diff decl.
	m.	°	m.	°
March 28 ...	− 38·4 ..	− 2·6	− 38·8 .	− 2·6
29 ...	− 40·4 ...	− 2·6	42·0 ..	− 2·8
30 ...	− 40·4 ...	− 2·8	− 44·8 ..	2·9
31 ...	− 39·2 ...	2·6	− 45·2 ...	− 3·0

The observation of Decuppis at Rome in 1839, one of the five utilised by M. Leverrier, was communicated to the Paris Academy of Sciences on December 16 in the same year. It is thus noticed in the *Comptes Rendus* of that sitting: "M. Decuppis announced that on October 2, while continuing the observations which he has made upon the spots of the sun, saw a black spot, perfectly round, and with well-defined contour, which advanced upon the disc with rapid motion, so that it would have traversed the diameter in about six hours. M. Decuppis thinks that the appearances which he has observed can only be explained by admitting the existence of a new planet." The observation is reproduced here, as it appears to have escaped the notice of several writers who have recently entered upon this subject. Haase mentions it, but does not give particulars.

The observation by Mr. Joseph Sidebotham at Manchester, on March 12, 1849, was communicated to the Literary and Philosophical Society of that city, April 1, 1873, and will be found in the *Proceedings*, vol. xii. p. 105. "A small circular black spot" was "watched in its progress across the disc for nearly half an hour," by Mr. Sidebotham and Mr. G. C. Lowe, also a member of the same society.

D'ARREST'S COMET.—If this comet is not detected before moonlight interferes in the mornings, it may probably be observed in the middle of the ensuing month, where the sky is very transparent down to the eastern horizon; it will then rise rather more than two hours before the sun, and the intensity of light will be greater than when it was last seen by Prof. Schmidt at Athens in December, 1870; still its distance from the earth will be considerable (1·7). When theoretically brightest, in May, observations may be made at the observatories of the southern hemisphere. At the Cape, Melbourne, and Sydney, the comet will rise more than four hours before the sun; the perihelion passage takes place on May 10. The following positions will sufficiently indicate its course about that time:—

At Greenwich Noon.

	R.A.			N.P.D.		Distance from Earth.
	h.	m.	s.	°	′	
May 2 ..	23	18	16 ...	91	17·0 ..	1·670
6 ..	23	32	13 ..	90	31·9 ..	1·659
10 ...	23	46	5 ..	89	47·8 ...	1·650
14 ..	23	59	51 ..	89	4·8 ..	1·642
18 ...	0	13	28 ...	88	23·3 ...	1·635
22 ...	0	26	56 ...	87	43·6 ..	1·629
26 ..	0	40	14 ...	87	5·8 ...	1·624

The intensity of light remains sensibly the same during this period. In August and September next observations may be practicable with very powerful instruments, as the comet moves from Taurus into Orion.

According to the elements of M. Leveau, who has continued the investigations on the motion of D'Arrest's comet, commenced on its first discovery in the summer of 1851 by M. Villarceau, the dimensions of the orbit in 1877 are as follow:—

Semi-axis major	3·5414
Semi-axis minor	2·7565
Semi-parameter	2·1456
Perihelion distance	1·3181
Aphelion distance	5·7047

The period of revolution in the ellipse of 1877 is 2434·2 days, or 6·664 years; it has been lengthened 104 days since 1851, by the effect of perturbation from the action of Jupiter, the principal disturbance of its motion having taken place in the spring of 1861, when the comet approached the planet within 0·36 of the earth's mean distance from the sun.

TOTAL SOLAR ECLIPSES.—It might be worth while to collect together and discuss the various notices of the total solar eclipses of 1386, January 1, and 1415, June 7, in the same manner that Prof. Schiaparelli and M. Celoria have done with the eclipses of 1239 and 1241. The eclipse of 1415 in particular was a very notable one from the large excess of the moon's augmented diameter over the diameter of the sun; as Baron de Zach states, "plusieurs historiens et presque tous les astronomes en ont parlé." Both eclipses were total at Montpellier, not a common occurrence at a particular place in an interval of only twenty-nine years.

METEOROLOGICAL NOTES

MEAN ATMOSPHERIC PRESSURE IN RUSSIA IN EUROPE.—A paper on this subject, by M. Rikatcheff, appeared some time ago in the *Repertorium fur Meteorologie*. The work is based on monthly averages for various terms of years for thirty places in Russia, to which are added the averages for thirty-three places situated in other parts of Europe. A valuable part of the paper is that which gives the details of the observations at each place, as regards the errors of the instruments employed and the heights above the sea, so far as known. The heights of places not yet determined trigonometrically are approximated to barometrically by a comparison with other stations whose heights are known. From these data the monthly and annual isobars for each millimetre (0·039 inch) are drawn on thirteen maps. It is to be regretted that so much work, characterised not only by general accuracy, but also by an attention to minute accuracy of detail in certain directions, can only be regarded as to a great extent thrown away, at least in so far as regards the inquiry in hand, viz., the representation of the facts of atmospheric pressure in Russia, as that pressure varies by latitude and season, in their relation to configuration of surface and the relative distribution of land and water. The author has failed to see that, in order to give a satisfactory solution of this problem, one of the first requisites is that the observations at the different stations be for the same terms of years, or be reduced to the same terms of years, by the process of differentiation. As regards the thirty Russian stations, the averages are for periods varying from seven to fifty years, and excepting Lugan and Catherinenburg, no two places are for the same terms of years. As regards the months the result of this method of discussion is great unsatisfactoriness. Thus at several places where the averages are only for a few years, they not unfrequently are very different from the isobars which have been drawn for the districts where they are situated. Still further, the anomalous directions of several of the isobars, such as the isobar of 759 millimetres for March, cannot be accounted for by the physical peculiarities of the region traversed by the anomalous portion of the curve; but an examination of the facts suggests that the anomaly is probably due to the simple circumstance that exceptionally high or low monthly means of particular years are included in the averages of some stations, whilst at other neighbouring stations observations were not made during these exceptional months. The annual isobars are necessarily more satisfactory. It may, however, be noted that if allowance be made for the correction for gravity, according to latitude, which has been employed, a correction which for several reasons is objectionable, the annual isobars for Russia are substantially the same as those published by Mr. Buchan, even though these were confessedly a first approximation, giving only the broad features of the distribution of atmospheric pressure over the globe. Much more is now required than this, seeing that the data since acquired would enable us to draw the isobars with a precision sufficient to show not merely their general change of position with season and latitude, but also the exact forms impressed on the curves by their position with reference to large masses of land and water. In solving this problem, what is required from Russia are tables of the monthly means of each year during which observations have been made at each station, corrected for instrumental errors now ascertained—tables, in short, similar to those published by Dr. Buys Ballot for many places in Europe, in the *Annals* of the Dutch Meteorological Institute for 1870.

METEOROLOGY OF MAURITIUS—The *Mauritius Meteorological Results* and *Meteorological Reports* for 1874 and 1875, have been received, which are deserving of special notice from the increased vigour and efficiency with which they show meteorological research to be prosecuted in that part of the globe. In addition to the usual elaborate summaries, the *Results* for 1875 contain a noteworthy addition in the form of two Tables, one giving the hourly means of the atmospheric pressure of the months during 1875 deduced from the barograph curves, and the other the same means from the term-day observations made at the observatory from 1853 to 1871. Tables showing the hourly readings for each day were prepared but are not printed in the *Results*. If this be due to want of funds to meet the expense of publication it is to be hoped that the difficulty will be got over in next publication, on account of the great value of such hourly readings in many meteorological inquiries, but more particularly in connection with the gales and hurricanes of the Indian Ocean, which are so carefully detailed by Dr. Meldrum in the *Results*. The examination of these readings and the hourly observations of the wind could not fail to suggest conclusions of the utmost value in their bearings on systems of storm warnings for tropical countries such as we recently sketched in NATURE (vol. xv. p. 261) for the Bay of Bengal. In the *Annual Report* for 1875, it is stated in the course of a discussion on sunspots and rainfall, that since the photoheliograph has been in use at the Observatory the sunspots have been compared with the daily weather, and that, so far as the observations have gone, the results are in conformity with those for longer periods, both the rainfall and the velocity of the wind having been greater when the spots were most numerous. This increase of the velocity of the wind with an increase of sunspots is a point of first importance when viewed in connection with Mr. Lockyer's suggestion that increased sunspot area implies increased solar radiation, with Mr. Blanford's confirmation of this idea from an examination of the results of the solar radiation thermometers in India, and with the result arrived at by Mr. Clement Ley, showing that with like conditions of pressure the wind's velocity is greatest during those months of the year when temperature is highest.

EXPLORING BALLOONS FOR METEOROLOGICAL PURPOSES.—Since the beginning of February, M. Secretan, the optician of the Pont-neuf, in Paris, has been sending up regularly every day at noon small exploring balloons for the purpose of ascertaining the direction of the several streams of air and the height of clouds. The results are daily published in the *Petit Moniteur*. The balloons are given gratuitously by the *Grand Magazin du Louvre*, and are of india-rubber filled with pure hydrogen. The diameter is ninety centimetres. M. de Fonvielle finds by calculation and by several experiments, that the mean velocity of elevation is about four metres per second. Hence to obtain the altitude of the clouds it is sufficient to observe the balloon with an opera-glass, to count the number of seconds necessary to lose sight of it owing to the opacity of the clouds, and to multiply the number of seconds by four. It was found that the altitude of clouds varies from 400 to 800 metres, and prospects of fair weather are increased in proportion to the elevation of clouds. The clouds follow the direction of an aerial stream in which they are wholly immersed, and are not placed, as has been repeatedly stated, at the surface of separation. The direction of the air for the first 100 metres is almost always very uncertain and varies according to unknown causes. This shows that anemometers give a very poor idea not only of the velocity but also of the direction of prevailing winds, and that no real progress is to be expected in the knowledge of atmospheric calculation as long as meteorologists confine themselves to taking into account anemometrical observations. Very often two different streams of air are observed, the lower one extending from 100 to 200 or 300 metres; under these circumstances the weather seems to be particularly uncertain and unsettled. Meteorologists, we think, might make use of this method of observation with great advantage.

BIOLOGICAL NOTES

A CHYTRIDIUM WITH TRUE REPRODUCTION.—Botanists are indebted to Dr. L. Nowakowski for a memoir on *Polyphagus euglenæ*, in which they will find recorded for the first time the whole life-history of one of the most interesting of the group of vegetable parasites known as Chytridia. First described in 1855 by Bail, who was a pupil at Breslau of the illustrious F. Cohn, this species has now had all the mysteries of its life cleared up by the researches of Nowakowski, studying at the same university and under the same master. The Euglenæ on which it is parasitic will be well known to microscopists as a group of flagellate Infusoria, at one time found as freely-swimming forms, and at another passing into a resting stage. It is at this period of their existence that the Polyphagus attacks them. The minute spores are furnished with four or more delicate filaments, which project from the body of the spores like rays. One or more of these soon comes into contact with a Euglena, bores through its integument, and penetrates into its protoplasmic contents; it now becomes a haustorium, increases in size, often sends off other filaments, which go on the search for other specimens of Euglenæ; in the meanwhile the body of the spore grows apace, and, if its haustoria be only fairly successful in catching Euglenæ, soon increases to considerable (microscopical) dimensions, and in course develops into a pro-sporangium. Next a little bladder-like projection is seen slowly forcing its way out from this latter, and at last becomes developed into a zoosporangium, from which in time issue the cloud of zoospores, and so after a well-known fashion the vegetative-development of this parasite is carried on. The presence of a true reproduction is, however, the great fact in the memoir. Among the individuals of Polyphagus developing in the interspaces of the dead Euglenæ will be found *two* forms; one larger than the other, and generally spherical in shape, is the female plant; the other, small and more or less club-shaped, is the male plant. From the former there is a tube-ike prolongation which passes into a haustorium; from the atter there are several haustoria; these remain thread-like if they encounter no Euglenæ, or enlarge when they do. These two unicellular plants then conjugate, but after a somewhat strange and novel manner. The protoplasmic contents of the female plant project through an opening in the cell wall, forming slowly an oval mass (gonosphere), with the which a haustorium from a neighbouring male plant, coming into contact, there is a co-mingling of the contents of the two plants, and thereby a zygospore is produced; sometimes these have a quite smooth covering, at other times they are rough, with minute prickles. After a little rest the zygospore develops a zoosporangium, from which issue warm-spores, and the cycle is complete. As the result of these nvestigations, the author would place the Chytridia forms in the group of the Siphomycetes. It will be observed that though the whole contents of two cells go to form the zygospore, yet that the difference in the size of these cells is very marked, and that the behaviour of the gynœciel cell reminds one of what takes place in an oospore. (Cohn's *Beitrage zur Biol. der Pflanzen*, Bd. ii. Heft 2, 1876.)

CRYPTOGAMIC FLORA OF RUSSIA.—We notice the appearance of the first fasciculus of an important Russian work, by M. Sredinsky, being a Catalogue of Russian Cryptogams. The work will be divided into five parts: Vascular Cryptogams, Musci, Lichens, Fungi, Characeæ, and Algæ, each part to appear n several separate fascicules. The first fasciculus is a description of the Vascular Cryptogams of Southern Russia, Transcaucasia, and the neighbourhood of St. Petersburg. Much valuable material, collected by Russian botanists, is already in the hands of he author, and many members of the St. Petersburg Society of Naturalists have promised to supply him with much additional material for his valuable work.

ALGÆ OF THE GULF OF FINLAND.—At the last meeting, February 28, of the St. Petersburg Society of Naturalists, M. Gobi made an interesting communication on the Algæ of the Gulf of Finland. They are not numerous and have migrated from the Atlantic Ocean. Towards the east the red Algæ become rare, and all diminish in number and size. It must be observed also that the red Algæ of the Gulf of Finland have almost nothing in common with those of the White Sea, which circumstance is an argument against the existence of a former communication between the Baltic and the White Sea advocated by some geologists, but more and more discountenanced by the latest explorations. Describing in detail the most important forms of red Algæ of the Gulf of Finland, M. Gobi exhibited a complete collection of them, together with a series of drawings and of microscopical plates from the same.

BOTANICAL GEOGRAPHY OF RUSSIA.—The seventh volume of the *Memoirs* of the St. Petersburg Society of Naturalists contains a most valuable contribution to the botanical geography of Russia, by M. Gobi, "On the Influence of the Valdai-plateau on the Geographical Distribution of Plants, with a Sketch of the Flora of the Western Part of Novgorod Government." The author begins with a detailed description of the orography of the region, of its geological structure, its soil and subsoil, its marshes, lakes, &c., and deals at length with the climate of the country. Further, after a review of former botanical works dealing with the same region, he gives a list of plants growing on the plateau (615 Phanerogams). The fourth chapter is devoted to a delineation of the main topographico-botanical subdivisions of the flora; and the fifth is a detailed discussion of the relations existing between the flora of the plateau and those of neighbouring tracts. After some general remarks the author traces here the boundaries of the regions occupied by about fifty plants, which boundary-lines run either across the plateau or along its slopes. The intrusion of these plants from the north, north-east, and south is graphically shown on three maps accompanying the paper.

NOTES

WE understand that the Council of the new University College, Bristol, intend shortly to appoint a Principal of the College. We presume that the claims of science will be well considered in the appointment, as the movement to which the college owes its origin took its rise in the desire to found a school of science for the West of England and South Wales. In the interests of the higher scientific and literary education, we hope that the Council may be successful in securing the services of an eminent man for so important a post.

AT the monthly meeting of the Council of the University College of Wales, one of the governors present expressed his intention to give 200*l*. a year for three years, to be applied in such form as the Council may deem best in connection with the college for the encouragement of scientific agriculture.

THE President and Fellows of the Chemical Society dined together at Willis's Rooms on Tuesday evening, the company numbering about 200, and including some of the most distinguished names in science. Prof. Huxley, in responding to the toast of the Learned Societies, pointed out that most of the younger London scientific societies are offshoots, or "buds," of the Royal Society; the latter, he maintained, now more than at any other time, needed sympathy and support. Prof. Huxley alluded with some humour to the extraordinary claims put in by some applicants for a share of the government grant, one gentleman alone having asked for 3,000*l*. out of the 4,000*l*. Some of the applicants reminded him of the Irishman who requested government to give him an appointment in any capacity in Church, Army, Navy, or Civil Service, his sole qualifications, the applicant confessed, being an inexhaustible fund of animal spirits and a keen sense of humour.

AN influential meeting was held at the Mansion House on Tuesday in support of the erection of an Imperial Museum for India and the Colonies, to which scheme we have already referred in detail. The proposal met with the warm approval of the meeting, and it was resolved that steps should be taken to move in the matter, and have a building erected on the Thames Embankment, on the site of the now demolished Fife House.

THE *Morning Post* of March 15 contains an article on the present state of the Loan Collection of Scientific Apparatus, and enumerates a number of collections that after the removal of foreign loans still remain to form the nucleus of a permanent museum. It points out that though the galleries have had to be closed in consequence of packing, the lectures have kept up the continuity of the scheme, and the apparatus forming the subject of the lectures have been brought into the lecture theatre as wanted. It adds, "There seems a fair probability that the nucleus of the permanent collection can be thrown open early in May."

THE obstacles hitherto presented to the medical education of women in England appear suddenly to have collapsed. The enabling Act of last session, introduced by the Right Hon. Russell Gurney, which permitted any licensing body to examine women for its diplomas, was first of all accepted by the Queen's University for Ireland and the Royal College of Physicians for Dublin. The example of these bodies has been speedily followed by the University of London. At a recent meeting the Senate reversed its decision of two years ago, and decided, by a majority of fourteen to eight, to admit women to its medical degrees. Among the majority are found the names of two of the most eminent medical men in London, who supported the motion on the ground that it was the duty of the University to give effect to the resolution arrived at by the Medical Council and by Parliament, that women should not be debarred from entering the profession. Since the matriculation examination is the sole avenue to all degrees in the University, this examination is now thrown open to women who present themselves with the intention of following it up by a course of medical studies. All these concessions to the friends of the medical education of women were, however, but barren victories as long as the hospitals closed their doors against the admission of female students to clinical instruction. Every hospital in London to which a medical school is already attached has refused this permission; and one chance only remained. The Royal Free Hospital in Gray's Inn Road is a general hospital containing the maximum number of beds required by any licensing body, and free from the difficulty of having already attached to it a school of male students. At the instance of the London School of Medicine for Women, the subject was last week brought before the Governing Body of this hospital, and a resolution was unanimously passed that, since they were the only body in London in a position to grant this privilege, it was their duty to throw open their hospital to female students. This decision, due mainly to the untiring exertions of the Treasurer to the London School of Medicine for Women in Henrietta Street, Brunswick Square, the Right Hon. J. Stansfeld, M.P., has only come just in time to prevent the breaking up of that institution. The executive committee of that school, at which regular courses of lectures in the whole curriculum of medical study have now been given for three years, had determined that, unless they could, before the close of this winter session, announced to the students that there was a prospect of solving the hospital difficulty in London, they must close the school in the summer, and recommend the students to go abroad for their clinical studies. The winter session closes next week, and it was only last Saturday that the announcement was made, in consequence of the decision of the Governing Body of the Royal Free Hospital, arrived at the preceding Wednesday. For the purpose of making the necessary arrangements, the Medical School for Women has entered into heavy engagements of a pecuniary nature, to enable them to fulfil which they will require the liberal support of the friends of the movement. With regard to the University of London, it is felt that the present position of admitting women to its medical degrees only, and to no others, is not one that can be permanently sustained; but any further extension of its privileges can only be effected by a new charter, or by an enabling Act similar to that of last session, applicable to all degrees.

PROF. GARROD completed on Tuesday his course of lectures at the Royal Institution on "The Human Form, its Structure in Relation to its Contour." Although some of the lectures have consisted of anatomical details, illustrated with diagrams prepared for a medical school, the attendances have been large in comparison with those of other Royal Institution courses, and ladies have formed more than a half of the audiences. Prof. Garrod's object was to describe the parts of the structure of the body which affect the contour in such natural attitudes as are commonly portrayed in works of art. Several ingenious working models to illustrate the action of different parts of the body were devised especially for these lectures, and a colossal wooden model of a disarticulated human skeleton was also specially prepared.

M. WADDINGTON has appointed M. Maindron a Chevalier of the Legion of Honour for services rendered to science in the capacity of secretary of the French Transit of Venus Commission. A new volume will be issued very shortly by the French Academy.

TUNGSTATE of soda has been much talked about lately as valuable, when mixed with ordinary starch, for rendering muslin dresses uninflammable. Prof. Gladstone and Dr. Alder Wright have both brought it before audiences at the Royal Institution, Dr. Wright showing its efficacy by having a muslin dress so prepared for one of his assistants to wear, in which he walked about over flames. In repeating the demonstration in the course of a lecture at South Kensington, on Saturday evening, it was fortunate that Dr. Wright had the dress placed on a dummy instead of being worn by an assistant, for no sooner was a light applied to it than it blazed up and was consumed. Why this happened could not be explained, as it is believed no mistake had been made in the preparation. No doubt the exact conditions under which the tungstate is reliable will be a subject for further investigation.

M. REDIER, barometer maker to the French Association for the Advancement of Science, has devised a barometer for warning miners when the atmospheric pressure is undergoing a sudden depression so that they may be on their guard against fire-damp explosion.

RURAL meteorology is progressing rapidly in France. No fewer than 500 parishes receive by telegraph daily warnings from the observatory. The telegrams summarising the readings taken at seven or eight o'clock in the morning (local time) from Constantinople to Valentia, arrive daily at two o'clock in each parish in connection with the observatory. The number of parishes is being daily increased.

EVERYONE knows that the aneroid barometer is composed of a metallic box exhausted of air and kept in a state of tension by an interior spring. A French optician has conceived the idea of substituting for the spring a weight attached to the exterior by a hook underneath.

IN a forcible article in the *Cape Argus*, for January 23, it is shown how much service could be done to farmers and others by giving them timely warning of approaching unfavourable weather. Such warning can only be based on extensive and carefully collected data, involving work which cannot be done for nothing. The *Argus*, therefore, reasonably urges that it is the duty of the Cape Parliament to provide the means of carrying on work that would undoubtedly benefit the whole colony.

SEVEN warnings have been sent to Europe by the Meteorological Office established by the *New York Herald*, since the end of February. Six of the predicted storms were felt in Paris, having crossed the Atlantic with a velocity somewhat less than had been anticipated.

A BRIGHT violet meteor was observed at St. Etienne on March 11 at two o'clock in the morning, in the southern part of the horizon. It was travelling with great velocity from west to east. No detonation was heard.

IT is stated that on the 5th instant a rather severe earthquake was felt in the districts of Hällsback, Lerbäck, Bodarne, and Sköllersha, in the county of Nerike, Sweden, a distance of about ten English miles. The shocks were strong enough to shake the houses and make china and even heavier objects tumble down. The earthquake was also felt in the Province of Ostergötland. It is stated also that the island of Mull has been visited by an earthquake, which, although it lasted only a minute, caused much commotion in the island.

THE Sedgwick Prize Essays must be sent in to the Registrary on or before October 1, *1879*, not as stated in last week's NATURE (p. 439) on or before October 1, *1880*. The award is to be made in the Lent Term, 1880.

AT the meeting of the Swedish Academy on February 14, Prof. Nordenskjöld read a paper by Dr. Kjelman, on "The Algæ of the Kara Sea," from which it appears that the sea, contrary to current opinion, is full of algæ, which sometimes attain gigantic sizes. The professor exhibited also photographic views of glaciers of the interior of Greenland, taken in 1870, by M. Berggion. They are true representations of views of the glacial period now prevailing in Greenland.

THE *Stockholm Dagladet* states that recently Prof. Nordenskjöld and the companions of his last travel, Messrs. Kjelman Lundström, Tribom, Stucksberg, and Théel, as well as Mr Oscar Dickson, were entertained by the King of Sweden at dinner, where the question as to Prof. Nordenskjöld's expedition in 1878 was discussed. The king promised to place at Prof. Nordenskjöld's disposal the steamer *Sophia* on the same terms as in 1868, and the pecuniary means for the expedition are promised by Mr. Dickson. The expedition proposes to explore the Arctic Ocean east of the Yenissei as far as Behring's Strait. Some Russian naturalists have applied to Prof. Nordenskjöld to be permitted to take part in the explorations.

PROF. AHLQUIST and students Böhm and Bergroth started on February 24 from Helsingfors on their ethnographical journey to the mouth of the Obi (NATURE, vol. xv., p. 207).

AT the last meeting of the St. Petersburg Society of Naturalists the programme of a botanical excursion to the Fergana province and the Pamir plateau, to be undertaken this year by M. Smirnof, was discussed and agreed to.

WE regret to notice the death of Admiral Sir Edward Belcher' whose name is so well known in connection with the Arctic exploration of about a generation ago. Sir Edward was in his seventy-ninth year, and began his naval career sixty-six years ago. He did a great amount of surveying work in various parts of the world. He had almost retired from active work when, in 1852, he was sent out in command of one of the expeditions in search of Sir John Franklin. Although the search was unsuccessful, and the vessel had to be abandoned in 1854, the work then done by Sir Edward Belcher was sufficient to win for him a worthy place among Arctic heroes.

WE notice in the seventh volume of the *Memoirs* of the St. Petersburg Society of Naturalists a paper, by M. Alénitzin, on the existence, in the Aralo-Caspian region, of a rise of land in a direction from south-east to north-west, and on the causes of the change of bed of the Amu-darya. Combining some observations relative to the structure of the shores of lakes Aral and Balkhash, the author proves that the south-eastern shores of both lakes have, during the recent geological period, been rising; and he explains by this circumstance the rapid undermining by the Amu of its right bank, at the point where the river turned in former times sharply to the west. This undermining, assisted by a relative rising of the upper parts of the river, resulted in an excavation of a bed directed to the north. Whatever may be thought of his theories the reader will find in M. Alénitzin's paper interesting information on the structure of the shores of both Central Asian interior seas.

THE same volume contains an interesting note, by Prof. Féofilaktoff, on the diluvial deposits in Kieff and Poltava governments, containing the general results arrived at by the author during his many years' explorations, the details of which will be found in the *Memoirs* of the Kharkof Society of Naturalists for 1874.

THE latest news received by the St. Petersburg Geographical Society from M. Potanin, announces that the expedition was stopped at Khobdo by the arrival of winter. The proposed further route of the expedition is across the great ridge which runs between the Altai and the Khangai, but the masses of snow which usually accumulated in the mountain-passes south of the Djabgan River made any further advance during winter impossible. Staying at Khobdo the expedition will make many important ethnographical observations, and collect information as to the trade of this place. As to Col. Prjevalsky, no news has been received from him, and probably will not for a long time. In November he was at Korleh, on his way to Lob-nor, entering thus on a country which has no communication with Russia. News may be expected only when he returns to Kuldsha, before undertaking his journey to Thibet.

THE secretary of the St. Petersburg Geographical Society announces the return to the capital of M. Wojeikoff from his meteorological journey round the world. The countries he visited last were India, Java, and Japan. The visit to Japan was especially interesting, as M. Wojeikoff made an excursion into a part of the interior never visited before by Europeans, and collected very valuable information as to the Ainos tribe. The observations made during the journey will be the subject of communications to the Geographical Society.

AT a sectional meeting of the Chester Society of Natural Science held last month Mr. J. D. Siddall read a paper on Foraminifera and other Microzoa in neighbouring limestone rocks, during the course of which he announced his discovery of Radiolarians, first, in the Halkin, and afterwards in the Minera limestones. Mr. Siddall had prepared several polished blocks to illustrate his lecture. Two of these showed specimens of beautifully preserved Radiolarians. Other members of this flourishing society have since obtained similar results by following his method of preparing these interesting microscopic objects. In some of the best pieces most of the types to be seen in thin slices of Barbadoes earth are represented, and in as great abundance. This discovery furnishes a capital example of the rewards which sooner or later follow patient scientific investigations. By this discovery Mr. Siddall has thrown back our knowledge of the distribution of Radiolarians in time from Mesozoic, if no from Tertiary, to Palæozoic formations.

THE additions to the Zoological Society's Gardens during the past week include two Orang-outangs (*Simia satyrus*) from Borneo, presented by Dr. R. Sim, F.Z.S.; a Green Monkey (*Cercopithecus callitrichus*) from West Africa, presented by Mr. J. Mason Allen; a Grivet Monkey (*Cercopithecus griseo-viridis*) from North-east Africa, presented by Mr. J. Walter Richardson; a Cape Hyrax (*Hyrax capensis*) from South Africa, a Chinese Blue Magpie (*Urocissa sinensis*) from China, a Red-capped Parrot (*Pionopsitta pileata*) from Brazil, three Red-eared Conures (*Conurus cruentatus*) from South America, a Sarus Crane (*Grus antigone*) from North India, an Arabian Baboon (*Cynocephalus hamadryas*) from Arabia, purchased; an American Jabiru (*Mycteria americana*) from South America, deposited; a Common Badger (*Meles taxus*), born in the Gardens.

IRON AND STEEL INSTITUTE

ADDRESS OF THE PRESIDENT, C. WILLIAM SIEMENS, D.C.L., F.R.S.

THE Iron and Steel Institute opened its London Session on Tuesday, and yesterday Dr. C. W. Siemens gave his presidential address.

Dr. Siemens, after referring to the origin and progress of the Institute, touched upon several topics of interest to those connected with the iron and steel industries.

Speaking of Education, Dr. Siemens said:—Intimately connected with the interests of this institution, and with the prosperity of the iron trade, is the subject of technical education. It is not many years since practical knowledge was regarded as the one thing requisite in an iron smelter, whilst theoretical knowledge of the chemical and mechanical principles involved in the operations was viewed with considerable suspicion. The aversion to scientific reasoning upon metallurgical processes extended even to the authors who professed to enlighten us upon these subjects; and we find, in technological works of the early part of the present century, little more than eye-witness accounts of the processes pursued by the operating smelter, and no attempt to reconcile those operations with scientific facts. A great step in advance was made in this country by Dr. Percy, when, in 1864, he published his remarkable "Metallurgy of Iron and Steel." Here we find the gradual processes of iron smelting passed in review, and supported by chemical analyses of the fuel, ores, and fluxing materials employed, and of the metal, slags, and cinder produced in the operation. On the continent of Europe the researches of Ebelmann, and the technological writings of Karsten, Tunner, Gruner, Karl, Akermann, and others, have also contributed largely towards a more rational conception of the processes employed in iron smelting.

It must be conceded to the nations of the Continent of Europe that they were the first to recognise the necessity of technical education, and it has been chiefly in consequence of their increasing competition with the producers of this country, that the attention of the latter has been forcibly drawn to this subject. The only special educational establishment for the metallurgist of Great Britain is the School of Mines. This institution has unquestionably already produced most excellent results in furnishing us with young metallurgists, qualified to make good careers for themselves, and to advance the practical processes of iron making. But it is equally evident that that institution is still susceptible of great improvement, by adding to the branches of knowledge now taught at Jermyn Street, and I cannot help thinking that a step in the wrong direction has recently been made in separating geographically and administratively the instruction in pure chemistry from that in applied chemistry, geology, and mineralogy. If properly supported, the School of Mines might become one of the best and largest institutions of its kind, but it would be an error to suppose that, however successful it might be, it could be made to suffice for the requirements of the whole country. Other similar institutions will have to be opened in provincial centres, and we have an excellent example set us by the town of Manchester, which, in creating its Owens College, has laid the foundation for a technical university, capable of imparting useful knowledge to the technologist of the future.

Technical education is here spoken of in contradistinction to the purely classic and scientific education of the Universities, but it must not be supposed that I would advocate any attempt at comprising in its curriculum a practical working of the processes which the student would have to direct in after-life. This has been attempted at many of the polytechnic schools of the Continent with results decidedly unfavourable to the useful career of the student. The practice taught in such establishments is devoid of the commercial element, and must of necessity be an objectionable practice, engendering conceit in the mind of the student, which will stand in the way of the unbiassed application of his mind to real work. Let technical schools confine themselves to the teaching of those natural sciences which bear upon practice, but let practice itself be taught in the workshop and in the metallurgical works.

After referring to the question of Labour, Dr. Siemens spoke in some detail on that of Fuel. Fuel, in the widest acceptation of the word, may be said to comprise all potential force which we may call into requisition for effecting our purposes of heating and working the materials with which we have to deal, although in a more restricted sense it comprises only those carbonaceous matters which, in their combustion, yield the heat necessary for working our furnaces, and for raising steam in our boilers.

The form of fuel which possesses the greatest interest for us, the iron smelters of Great Britain of the nineteenth century, is without doubt the accumulation of the solar energy of former ages which is embodied in the form of coal, and it behoves us to inquire what are the stores of this most convenient form of fuel.

Recent inquiry into the distribution of coal in this and other countries has proved that the stores of these invaluable deposits are greater than had at one time been supposed.

I have compiled a table of the coal areas and production of the globe, the figures in which are collected from various sources. It is far from being complete, but will serve us for purposes of comparison.

The Coal Areas and Annual Coal Production of the Globe.[1]

	Area in Square Miles	Production in 1874 Tons
Great Britain	11,900	125,070,000
Germany	1,800	46,658,000
United States	192,000	50,000,000
France	1,800	17,060,000
Belgium	900	14,670,000
Austria	1,800	12,280,000
Russia	11,000	1,392,000
Nova Scotia	18,000	1,052,000
Spain	3,000	580,000
Other Countries . ..	28,000	5,000,000
	270,200	274,262,000

This table shows that, roughly, the total area of the discovered coal fields of the world amounts to 270,000 square miles.

It also appears that the total coal deposits of Great Britian compare favourably with those of other European countries; but that both in the United States and in British North America, there exist deposits of extraordinary magnitude, which seem to promise a great future for the New World.

According to the report of the Coal Commissioners, published in 1871, there were then 90,207 million tons of coal available in Great Britain, at depths not greater than 4,000 feet, and in seams not less than 1 foot thick, besides a quantity of concealed coal estimated at 56,273 millions of tons, making a total of 146,480 millions. Since that period, there have been raised 600 millions of tons up to the close of 1875, leaving 145,880 millions of tons, which at the present rate of consumption of nearly 132 millions of tons annually, would last 1,100 years. Statistics show that during the last 20 years there has been a mean annual increase in output of about 3¼ millions of tons, and a calculation made at this rate of increase would give 250 years as the life of our coalfields.

In comparing however, the above rate of increase with that of population and manufactures, it will be found that the additional coal consumption has not nearly kept pace with the increased demand for the effects of heat, the difference being ascribable to the introduction of economical processes in the application of fuel. In the case of the production of power, the economy effected within the last 20 years exceeds 50 per cent., and a still greater saving has probably been realised in the production of iron and steel within the same period, as may be gathered from the fact that a ton of steel rails can now be produced from the ore with an expenditure not exceeding 50 cwt. of raw coal, whereas a ton of iron rails, 20 years ago, involved an expenditure exceeding 100 cwt. According to Dr. Percy, one large works consumed, in 1859, from 5 to 6 tons of coal per ton of rails. Statistics are unfortunately wanting to guide us respecting these important questions.

Considering the large margin for further improvement regarding almost every application of fuel which can be shown upon theoretical grounds to exist, it seems not unreasonable to conclude that the ratio of increase of population and of output of manufactured goods will be nearly balanced, for many years to come, by the further introduction of economical processes, and that our annual production of coal will remain substantially the same within that period, which under those circumstances will probably be a period of comparatively cheap coal.

The above-mentioned speculation leads to the further conclusion that our coal supply at a workable depth will last for a period far exceeding the shorter estimated period of 250 years, especially if we take into account the probability of fresh discoveries, of which we have had recent instances, particularly in

North Staffordshire, where a large area of coal and blackband ironstone is being opened up, under the auspices of his Grace the Duke of Sutherland, by our member, Mr. Homer.

Dr. Siemens then spoke of Anthracite and the large extent to which it was used in America, of Lignite and Peat, which may be looked on as coal in formation. After referring to natural gaseous fuel he went on to say :—

Although the use of natural gas is not likely to assume very large proportions owing to its rare occurrence, its application at Pittsburg has forcibly reminded me of a project I had occasion to put forward a good many years ago, namely to erect gas producers at the bottom of coal mines, and by the conversion of solid into gaseous fuel, to save entirely the labour of raising and carrying the latter to its destination. The gaseous fuel, in ascending from the bottom of the mine to the bank, would acquire in its ascent (owing to its temperature and low specific gravity), an onward pressure sufficient to propel it through pipes or culverts to a considerable distance, and it would be possible in this way to supply townships with heating gas, not only for use in factories, but, to a great extent, for domestic purposes also. In 1869, a company, in which I took a leading interest, was formed at Birmingham, under the sanction of the Town Council, to supply the town of Birmingham with heating gas at the rate of 6*d.* per 1,000 cubic feet, but their object was defeated by the existing gas companies, who opposed their bill in Parliament upon the ground that it would interfere with vested interests. I am still satisfied, however, that such a plan could be carried out with great advantage to the public; and although I am no longer specifically interested in the matter, I would gladly lend my aid to those who might be willing to realise the same.

With reference to water power, Dr. Siemens said :—The advantage of utilising water power applies chiefly to continental countries, with large elevated plateaus, such as Sweden and the United States of North America, and it is interesting to contemplate the magnitude of power which is now for the most part lost, but which may be, sooner or later, called into requisition.

Take the Falls of Niagara as a familiar example. The amount of water passing over this fall has been estimated at 100 millions of tons per hour, and its perpendicular descent may be taken at 150 feet, without counting the rapids, which represent a further fall of 150 feet, making a total of 300 feet between lake and lake. But the force represented by the principal fall alone amounts to 16,800,000 horse-power, an amount which, if it had to be produced by steam, would necessitate an expenditure of not less than 266,000,000 tons of coal per annum, taking the consumption of coal at 4 lbs. per horse-power per hour. In other words, all the coal raised throughout the world would barely suffice to produce the amount of power that continually runs to waste at this one great fall. It would not be difficult, indeed, to realise a large proportion of the power so wasted, by means of turbines and water-wheels erected on the shores of the deep river below the falls, supplying them from canals cut along the edges. But it would be impossible to utilise the power on the spot, the district being devoid of mineral wealth, or other natural inducements for the establishment of factories. In order practically to render available the force of falling water at this and the thousands of other places under analogous conditions, we must devise a practicable means of carrying the power to a distance. Sir William Armstrong has taught us how to carry and utilise water power at a distance, if conveyed through high-pressure mains, and at Schaffhausen, in Switzerland, as well as at some other places on the Continent, it is conveyed by means of quick-working steel ropes passing over large pulleys. By these means, power may be carried to a distance of one or two miles without difficulty. Time will probably reveal to us effectual means of carrying power to great distances, but I cannot refrain from alluding to one which is, in my opinion, worthy of consideration, namely, the electrical conductor. Suppose water power to be employed to give motion to a dynamo-electrical machine—a very powerful electrical current is the result. This may be carried to a great distance, through a large metallic conductor, and there be made to impart motion to electro-magnetic engines to ignite the carbon points of electric lamps, or to effect the separation of metals from their combinations. A copper rod of 3 in. in diameter would be capable of transmitting 1,000 horse-power a distance of say 30 miles, an amount sufficient to supply one quarter of a million candle power which would suffice to illuminate a moderately sized town.

The use of electrical power has sometimes been suggested as a substitute for steam power, but it should be borne in mind that so long as the electric power depends upon a galvanic battery, it must be much more costly than steam power, inasmuch as the combustible consumed in the battery is zinc, a substance necessarily much more expensive than coal; but this question assumes a totally different aspect if in the production of the electric current a natural force is used which could not otherwise be rendered available.

Dr. Siemens then went on to speak of the processes of manufacture, sketching briefly the history of the improvements in these processes, and concluded by referring to the various applications of steel. Speaking of the means of preserving iron and steel from rust, he referred to Prof. Barff's recently discovered process. This consists in exposing the metallic surfaces, while heated to redness, to the action of superheated steam, thus producing upon their surface the magnetic oxide of iron, which, unlike common rust, possesses the characteristic of permanency, and adheres closely to the metallic surface below. In this respect it is analogous to zinc oxide adhering to and protecting metallic zinc, with this further advantage in its favour, that the magnetic oxide is practically insoluble in sea water and other weak saline solutions.

Dr. Siemens concluded his valuable address by urging upon the Institute, now that it has attained to such importance, to obtain recognition in official quarters and to become possessed of a habitation in a central position, and in such a building as would serve the societies devoted to applied science in the same way that Burlington House does those devoted to pure science.

SOCIETIES AND ACADEMIES

LONDON

Mathematical Society, March 8.—Mr. C. W. Merrifield, F.R.S., vice-president, in the chair.—The following communications were made :—On a new view of the Pascal hexagram, by Mr. T. Cotterill. In a system of co-planar points, the number of intersections of two chords is a multiple of 3. In the case of the hexagram the forty-five points thus derived are divided into four sets of triangles—(1) The three intersections of the chords joining four points form a triad self-conjugate to the conics through the four points. (2) Any three non-conterminous chords intersect in three points, forming a diagonal triangle. In each of these two cases, a derived point determines uniquely its corresponding triad, the number of triads being fifteen. (3) An inscribed triangle determines an opposite inscribed triangle; the three intersections of the pairs of sides supposed to correspond form a triangle, the intersections of two inscribed triangles, the nine intersections of the two triangles forming an ennead. (4) The three intersections of the opposite sides of a hexagon of the system form a Pascal triangle. The number of triangles in each of the two last cases is sixty; to each triangle of one set corresponding a triangle of the other, as well as a triad of the second set, the nine points forming three triads of the first set. Denoting, then, the primitive points by italics and fifteen of the derived points (no two of which are conjugate) by Greek letters, we obtain all the derived points by accenting once and twice the Greek letters to form self-conjugate triads. Tables are then formed in matrices of the nine chords joining the vertices of two opposite triangles and their eighteen intersections, found to consist of six triangles of each of the second and fourth sets. To these corresponds a matrix containing the nine intersections of the two triangles. In the case of a conic hexagram, the properties of the sixty points of intersection of chords with the tangents at the conic points are then examined.—On a class of integers expressible as the sum of two integral squares, by Mr. T. Muir. [The class of integers considered included those whose square root, when expressed as a continued fraction, has two middle terms in the cycle of partial denominators. A general expression was given for all such integers, and an equivalent expression in the form of the sum of two squares.]—Some properties of the double-theta functions, by Prof. Cayley, F.R.S. (founded on papers by Goepel and Rosenhain).—A property of an envelope, by Mr. J. J. Walker.

Chemical Society, March 15.—Prof. Abel, F.R.S., president, in the chair.—The secretary read a paper by Dr. W. A. Tilden and Mr. W. A. Shenstone, on isomeric nitroso terpenes, being a further contribution to Dr. Tilden's previous researches on these compounds. This was followed by a communication entitled "Preparation of Copper-zinc Couples," by Dr. J. H. Gladstone, and Mr. A. Tribe, which was experimentally illustrated; it gave the details of the experiments made to ascertain the conditions for the preparation of a couple of maximum activity. The other papers were on chromium pig iron, by Mr. F. Riley; a note on gardenin, by Dr. J. Stenhouse and Mr. C. E. Groves; two papers by Mr. M. M. P. Muir entitled "Additional Note on a process for estimating Bismuth volumetrically," and "On certain Bismuth Compounds," Part IV.; and a note by Dr. M. Simpson and Mr. C. O'Keeffe, on the determination of urea by means of hypobromite.

Victoria (Philosophical) Institute, February 5.—Dr. C. Brooke, F.R.S., in the chair.—A paper was read by Prof. Birks, of Cambridge, on "The Bible and Modern Astronomy."

GENEVA

Physical and Natural History Society, January 18.—M. Ernest Favre read a paper on the question of the origin of the gravels which are found in the portion of the Alps under the glacial soil, and which are known as the old alluvium. This is formed in the vicinity of the ancient glaciers, as is proved by the following facts: (1) The presence of glacial soil in two localities in the neighbourhood of Geneva, in the very interior of the alluvium, at several metres under the great glacial sheet; (2) the very different heights at which the alluvium is deposited in the interior of the same basin; (3) the fact that it is formed of the same elements, large pebbles and fossil sand at whatever distance it is observed from the foot of the Alps; the disappearance of these depôts begins the limit of the ancient glaciers.—M. Philippe Plantamour has undertaken observations on the variations of the level of the Lake of Geneva, similar to those of Prof. F. A. Forel at Morges. They confirm the theory of the perpetual oscillation to which the surface of the water is subject, as shown by Dr. Forel, and which lasts about an hour and a quarter in the longitudinal direction. The variations of level, or *seiches*, are much greater in the neighbourhood of Geneva, at the western extremity of the lake than at Morges, a little beyond the middle of its length towards the east, and they are in the opposite direction. A registering limnimetre, which is to be erected by M. Ph. Plantamour, will permit of following with a new facility the phases of the phenomenon, and of comparing them with those which occur at Morges.

PARIS

Academy of Sciences, March 12.—M. Peligot in the chair.—The following papers were read:—Theorems relative to series of isoperimetric triangles which have one side of constant size, and satisfy three other diverse conditions, by M. Chasles.—Influence of pressure on chemical phenomena, by M. Berthelot. He cites an experiment of Quincke's showing that the liberation of hydrogen from zinc and sulphuric acid is not stopped by pressure of the gas, but only retarded. It goes on so long as there is acid to saturate or zinc to dissolve.—On a metallic iron found at Santa Catarina (Brazil), by M. Damour. This is supposed of meteoric origin. The small quantities of carbon (0.0020) and silicium (0.0001) in it are like those of the best qualities of iron obtained in industry, while the proportion of nickel (0.3397) considerably exceeds that of meteoric irons hitherto known. To this latter is doubtless due its resistance to oxidation in moist air and to the action of dilute sulphuric and hydrochloric acids. M. Boussingault stated he had had cast in his laboratory 62 per cent. steel and 38 nickel. A polished face of the alloy did not rust in contact with air and water. Of the filings two or three grains took rust, merely showing the alloy was not entirely homogeneous. Alloys with 5, 10, or 15 per cent. nickel oxidised rapidly.—Observations on the native iron of Santa Catarina and on the pyrrhotine and magnetite associated with it, by M. Daubrée. The masses, when at a high temperature, seem to have been subjected to oxidising action of air or water, which action penetrated into the interior by very fine fissures.—On the maintenance of constant temperatures; second note by M. D'Arsonval. He heats the apparatus by means of a thermo-siphon, and the *rôle* of the regulator is to proportion the activity of the circulation to the causes of loss. Thus the fire may be of any strength; it gives its heat to a liquid which distributes it as the regulator allows.—On the annual aberration and annual parallax of stars, by M. Kericuff. He corrects some mistakes in the formulæ made for these.—Applications of a theorem comprising the two principles of the mechanical theory of heat, by M. Levy.—On the periodicity of solar spots, by M. Wolf. In a *brochure* he gives not only all the epochs of maxima and minima since the discovery of the spots, but, for a century and a quarter, by means of a relative number, the monthly energy of the phenomenon. He shows by curves the average course of the phenomena and anomalies, also the indices of a great period embracing sixteen small periods of eleven and a half years, or nearly 168 years.—Measurements of the calorific intensity of the solar radiations received at the surface of the ground, by M. Crova. He calculates that on January 4, 1876, the heat received on a square centimetre at right angles to the direction of the sun's rays from sunrise to sunset, would be 535.0 cal.; that on the surface of the ground 161.2 cal.; for July 11, 1876, the corresponding numbers are 876.4 cal. and 574.1 cal. The heat received at right angles on January 4 is 0.610 of that on July 11; the heat received on the surface of the ground on January 4 is 0.281 of that on July 11.—Metals which accompany iron, by M. Terreil. Their proportions are small; they rarely amount to five thousandths; whereas, in native or meteoric iron, they may be ten per cent. They are chiefly manganese, nickel, cobalt, and chromium, while copper, vanadium, titanium and tungsten occur accidentally.—Chemical study of mistletoe, (*Viscum album*, L.), by MM. Grandeau and Bouton. *Inter alia*, the composition of the stem is very near that of the leaves, and the composition of the mistletoes of different species is widely different. As to nutritive value, the mistletoe of the oak takes rank with meadow grass of good quality or red clover, the leaves of the mistletoe of the corn, lian and pear trees have equal value with good hay or aftermath; while their branches may be compared to the straw of leguminous plants or the husks of cereals.—On the electrotonic state in the case of unipolar excitation of the nerves, by MM. Morat and Toussaint. When the positive pole is applied to the nerve, the current is divergent, from the middle of the nerve it goes towards the two extremities, and thus in the two ends contrary to the proper current of the nerve; hence the negative phase of the electrotonic state. If the negative pole is applied, the battery current converges towards the middle, and is in the same direction with the proper current, which it increases (positive phase of the electrotonic state).—Acute poisoning by acetate of copper, by MM. Feltz and Ritter. It is more active than sulphate. The disorders are more intense and long in fasting animals. One could not swallow the substance in food or drink without perceiving the taste.—On the value of certain arguments of transformism, taken from the evolution of the dental follicle in ruminants, by M. Pietkiewicz. In these animals there is nothing at all like germs of canines and incisors, as Goodsir affirmed.—On the unity of the forces in geology, by M. Hermite.—On the crevasses of the cretaceous system, by M. Robert.

PALMÉN ON THE MIGRATION OF BIRDS

Ueber die Zugstrassen der Vögel. Von J. A. Palmén, Docent der Zoologie an der Universitat Helsingfors. Mit einer lithographirten Tafel. (Leipzig: Engelmann, 1876.)

GRANTING it to be true that truth never dies, it is undeniable that error is hard to kill. A notable instance of this last assertion is furnished by the infatuation which possesses so many people, otherwise, perhaps, not unreasoning, to believe that more or fewer of the birds which commonly frequent these islands in summer, pass the winter in a torpid state—"hibernate," as they are pleased to say. Vainly have travellers or residents on the shores of the Mediterranean, or in the interior of Africa, told us over and over again, how that as the hot weather comes to an end with us, our cuckoos, our swifts, our swallows - nay, almost all our summer birds come crowding southwards. As vainly have the same observers recorded the northward journeys of the same species, though under somewhat different conditions, on the approach of our spring. Of course, no one who merits the title of an ornithologist disregards the plain evidence thus afforded, or entertains a single doubt as to what it proves—however strongly he may recognise the fact that we know little of the paths taken by the migrants, and next to nothing of the faculty whereby they ordinarily reach their ancestral summer-home. But there are not a few persons enjoying among the vulgar of all classes the reputation of being ornithological authorities, and there are thousands of the general public, who still hanker after the ancient faith in "hibernation." It may be said that it is but lost labour to attempt to bring such people to reason, and so, possibly, it is. Still, the apparent gravity with which this absurd notion is from time to time propounded, renders it necessary that its folly should be as often exposed, lest the pertinacity with which it is urged gain for it adherents among those who think that, as they encounter no refutation of it, it may or must be true, and the testimony in its support unanswerable. As a rule, there seems to be an outbreak of the "hibernation" mania every two years or so. It nearly always presents the same essential features. Some one, who with the multitude passes for an ornithologist, sends to a newspaper a second or third-hand story of some nameless person who in some nameless place found a number of torpid swallows in the chink of a chalk-pit, or a drowsy landrail in a haystack—or, on a log of wood being laid on the fire, of a cuckoo that woke from its slumber and, emerging from its retreat, sat on the hob, regardless of its singed plumage and cheerfully singing its accustomed song. Occasionally a brilliant imagination, and the desire of supplying some grateful novelty suggests a diversion of the details, and the swallows are dragged from a horse-pond in a casting-net, or have got themselves into an eel-pot—or the cuckoo is discovered as the billets are being split. The story, which can be fairly compared with the tales of witches' imps, and of our dear old friend the antediluvian toad-in-a-hole, is repeated in many newspapers, and countless correspondents write letters to their respective "organs," citing parallel cases of which they have heard from their grandmothers, and wonder why "Professor" Darwin, Mr. Buckland, or the great "Doctor" Owen, do not favour the public with their views on the matter.

A delightful example of all this occurred not many weeks since, and one, moreover, marked by so much originality of conception as to reveal the hand of a master. A reverend gentleman published the evidence of a friend's friend, or that friend's friend's friend (there was a charming uncertainty on this point, and the final friend was of course nameless), who watched "a brood of young swallows too weakly to be able to follow their parents in their migration." (Here it is to be observed that the "hibernation" advocates of late years don't deny migration *in toto*, and that, as explained by the reverend storyteller, the "swallows must have been martins!") "So the old birds left them in their nests and plastered them up with mud." To cut the story short, it is enough to observe that the ingenious and considerate parents were (as they expected) rewarded, on their return next spring, by finding their offspring "none the worse for their six months' incarceration," and after this happy ending to the tale had been told, the sympathies of the British public were duly roused, and the "hibernation" mania was ready to run its usual course. On this occasion, however, its symptoms were more pronounced than usual, and a philosophical contemporary of ours, always prone to the analysis of conduct—perhaps also seeing in the story a fresh argument against experiments on live animals—hastened to record the story among the news of the week, though admitting that it was "not much in the way of evidence." This admission, however, was prefaced by the very curious statement that "It is at least quite conceivable that a creature which had been a hibernator generations ago, and which had since discovered the preferability of migration to a warmer climate, should yet be able to return to its old habit in case of need." This remark might be allowed to pass if it had only been proved that any bird, since birds ceased to be reptiles, ever had been a "hibernator." As that is not the case it may be sent instantly to the limbo of false hypotheses. Still the admission roused the remonstrances of a correspondent of the same journal, for he not only "was inclined to think" the story "authentic," but adduced in its support an agreeable variation of the fable. His gardener had assured him "that he had himself seen what he described, "layers of young swallows in a hibernating state, when taking up the flooring of some house in that parish [Thorpe Arch] during winter.' '*O fortunatos nimium!*' What sights bless the eyes of gardeners! Layers of young swallows under our boards or bricks! How were the rats and mice kept from feasting on their tender bodies? And then if one did happen to die before the day of release, how sweet would be that superimposed chamber! Inviting as the theme is, we must leave it to record the further progress of this maniacal outbreak.

The next portion of our history introduces us to a new world and to a family of birds never before accused of "hibernating." A second correspondent of the same journal, writing under the honoured initials "R. N.," spins a yarn, fit for the fo'castle (if there happen to be an audience of marines), and tells how humming-birds at

Port Montt (*sic*) pass the winter in hollow trees, and are often brought into the houses cold and stiff, perfectly dormant, and yet when revived by the warmth, able to fly about the room. They only need a refrigerating ship to be brought to, and "acclimatised" in, Ireland, or kept at the Crystal Palace. This is "R. N.'s" idea, not ours, but he makes it, we doubt not, in all sincerity. We now fully expect that the next bird charged with "hibernating" will be an ostrich. The phœnix, if he could be found, would certainly not be safe, but then he is dormant already. Even now it is perhaps not too late to injure the reputation of the dodo, and announce that a Rip van Winkle of the species has been "hibernating," like a tenrec, in some secluded rift of the rocks in Mauritius.

That truth will prevail in due time there can be no doubt, and these tales of "hibernation" will serve to amuse future generations, even as that marvellous and circumstantial account of the evolution of Bernacle-geese from shell-fishes now causes mirth to us—mirth mingled with regret at the stupid credulity of our quasi-scientific forefathers. Yet hardly so. It would be an injustice to the venerable Gerard to put on a par with him these story-tellers of to-day. The old herbalist had but little light, but what little light he had he did not neglect. Our contemporaries shut their eyes and ears to that which is before them. Their wilful ignorance is absolutely criminal, therefore shall they receive greater condemnation. If any of them is open to conviction, let him reflect on this single fact. The young cuckoo, when we last see it in autumn, is clad in a plumage of reddish-brown or liver-colour. When cuckoos reappear in spring, they are, almost without exception, in their proverbial "grey." It is obvious, then, either that the young birds have moulted in the meanwhile, or else they have perished in the process of "hibernation." This latter alternative would soon put an end to the species, and cannot for a moment be entertained. But as regards the former, every physiologist will agree that while an animal is torpid, all growth is suspended—yet on the "hibernation" theory, these young cuckoos must have put off their nestling feathers, and grown those characteristic of maturity, during the time when nearly all the animal functions are at rest. Therefore it simply stands that "hibernation" in the case of the cuckoo is an impossibility. The same, too, with swallows. It is known that they renew their feathers about Christmas. The plumage of the young swallow in its first autumn does not differ so strikingly from that of the adult, as it does in the cuckoo, but any one pretending to ornithological knowledge, must know that the swallow of the preceding year can be equally declared to have changed its feathers since the last autumn, and indeed the fact of this winter-moult has been observed in caged birds, and recorded many years since by Mr. James Pearson, whose account, verified by Sir John Trevelyan, was published by Bewick eighty years ago ("Land Birds," p. 249, Ed. 1797). Hence it follows that neither swallows nor cuckoos—thus moulting in the winter months—do, as has been asserted, "hibernate."

It is indeed somewhat humiliating to be at this day refuting an error which has been so often refuted before, but necessity knows no law, and the widely-spread fallacy creates the necessity. Furthermore, this protest against the sciolism of the age has led us away from our particular object, which is to notice the remarkably careful and painstaking work of Herr Palmén, originally published in Swedish in 1874, and now appearing in a German translation, which will have many more readers. This treatise does not indeed (as will be seen from its title) profess to treat of more than one branch of the migration question. Its scope is properly limited to a consideration of the routes taken by birds of passage in their migration; but on that account it is none the less a valuable contribution to the already extensive literature of the subject, and in this German version the author appends some remarks of more general interest. He seems to have availed himself of all the information, as to his main point, that he could collect, and the wonder, perhaps, is that, living in Finland, he has been able to amass so much. His work is weak, it must be confessed, in detail as to the migratory birds of our own islands, but, as we think, from no fault of his own, since most of those who delight to consider themselves "British Ornithologists" are content to stand on the ancient ways of their forefathers, and to disregard everything that happens beyond the "silver streak" as entirely as if it belonged to another planet. Thus we doubt much if he would have greatly gained by studying the various contributions to "British" ornithology that have appeared since 1856, when the last edition of Garrell's standard work was completed. We must, however, hold that Herr Palmén's assignment of routes to the migratory birds of North-Western Europe is almost purely conjectural. We do not say it is erroneous—far from that. There is much in it which will very likely be proved true whenever British ornithological observers shall be at the pains to observe to some purpose; but, at present, his views can, from the nature of the case, be only accepted provisionally. He has far different and more solid ground to go upon when he treats of the migratory birds of Eastern Europe, and especially of the Russian Empire—whether European or Asiatic, and every ornithologist owes Herr Palmén a debt of gratitude for the compendious abstract he gives from the mighty works of Pallas's successors, and notably from those of Dr. von Middendorff.

As regards the routes taken by the migratory birds of the Palæarctic region, Herr Palmén's investigations have been so concisely summed up by a recent writer in the last edition of the "Encyclopædia Britannica" (iii. p. 768) that we take the liberty of here transcribing them as there given. These main routes are said to be *nine* in number:—

"The first (A—to use his notation), leaving the Siberian shores of the Polar Sea, Nova Zembla, and the North of Russia, passes down the west coast of Norway to the North Sea and the British Islands. The second (B), proceeding from Spitsbergen and the adjoining islands, follows much the same course, but is prolonged past France, Spain, and Portugal to the west coast of Africa. The third (C) starts from Northern Russia, and, threading the White Sea, and the great Lakes of Onega and Ladoga, skirts the Gulf of Finland and the southern part of the Baltic to Holstein and so to Holland, where it divides—one branch uniting with the second main route (B), while the other, running up the valley of the Rhine and crossing to that of the Rhone, splits up on reaching the Mediterranean, where one path passes down the western coast of Italy and Sicily, a second takes the line by Corsica and Sardinia, and a third follows the south coast of France and eastern coast of Spain—all three paths ending in North Africa. The fourth (D), fifth (E), and sixth (F) main routes depart from the extreme north of Siberia. The fourth (D) ascending the river Ob, branches out near Tobolsk—one track, diverging to the Volga, descends that river and so passes to the Sea of Azov, the Black Sea, and thence by the Bosphorus and Ægean, to Egypt; another track makes for the Caspian by way of the Ural River and so leads to the Persian Gulf, while two more are lost sight of on the steppes. The fifth (E) mounts the Jennesei to Lake Baikal and so passes into Mongolia. The sixth (F) ascends the Lena and striking the Upper Amoor reaches the Sea of Japan, where it coalesces with the seventh (G) and eighth (O) which run from the eastern portion of Siberia and Kamchatka. Besides these the ninth (X) starting from Greenland and Iceland, passes by the Færoes to the British Islands and so joining the second (B) and third (C), runs down the French coast."

All these routes are plainly laid down on the map which accompanies the work, and in the absence of more precise information, it will hardly be in the power of any British ornithologist to dispute them, though, as before stated, we must hold them to be in a great measure conjectural. In the following chapters the author shows how necessary it is to know the principal routes taken by birds in their migrations before we can understand or reason intelligibly on their movements, and of very great interest are his remarks on the Genetic Import of Regular and Irregular Lines of Travel, and on the So-called Migratory Instinct (chaps. ix. and x.), greatly amplified in the German version from the brief paragraphs which represent them in the Swedish original. They are, however, it must be confessed, somewhat verbose; but, for all that, they are well worth reading. Though Herr Palmén refers to an article which appeared in these columns some years ago (NATURE, vol. x. p. 415), he does not seem to be aware of the theory subsequently propounded by Mr. Wallace (vol. x. p. 459) as to the possible or probable origin of migratory habits, wherein is expressed, in far fewer words than his own, what appears to be essentially the same thing. For "Migratory Instinct" Herr Palmén substitutes "Experience" as the piloting power, and though there is much to be said in favour of this explanation in many cases, others there are in which it seems to break down utterly. How do the young cuckoos which stay in this country a month or six weeks after their parents (whom, let us remember, they have never known) have departed find their way to Africa? And how do the scores, hundreds, or thousands of rapacious and wading birds, whose elders do not accompany them, manage in their autumnal journeys to arrive more or less punctually at the spot which countless generations of their predecessors have reached before them? They have had no "experience," and though doubtless many perish by the way, a very large proportion year after year hit off exactly, and at the first intention, the ancestral landing-place. What, also, can "experience," which, after all, means only a knowledge of landmarks, do for the species which travel by night, as seems to be the habit of very many birds, or for those which, like at least two of the annual visitants to New Zealand, traverse a waste of waters? At present no solution of the mystery offers itself, at present such knowledge may be too wonderful for us; but, high as it is, our faith in the progress of science forbids us to say that we cannot attain unto it.

OUR BOOK SHELF

Dynamics; or, Theoretical Mechanics, in Accordance with the Syllabus of the Science and Art Department. By J. T. Bottomley, M.A., F.R.S.E., F.C.S. (London and Glasgow: William Collins, Sons, and Co., 1877.)

THIS little text-book is issued by Messrs. Collins as one of their Elementary Science Series, and will prove useful to beginners, by rendering them familiar, at an early stage of their studies, with the more precise definitions and nomenclature which have been introduced by modern writers on dynamics. The distinction, for instance, between the centre of gravity and the centre of inertia is much more clearly pointed out than is usual in elementary works, and the statement that "there is only a limited number of classes of bodies that possess a centre of gravity" will probably be read by many with surprise. The measurement, composition, and resolution of velocities are treated of in the chapter preceding that on force, and the methods of measuring forces in terms either of gravitation units or absolute units are well and fully discussed. The definition of work given in the last chapter might, we think, be amended. As it stands at present it might lead the student to suppose that no work is done by an agent moving a body, unless the motion is created in opposition to a resisting force, though the language employed in some of the examples would be sufficient to correct such a supposition. Throughout the work the author assists the student to obtain "clear physical conceptions regarding the first principles of dynamics," by frequently directing his attention to the experimental proofs of the various laws he enunciates, and by hinting at the physical, rather than the mathematical, developments of his subject.

On these grounds, we have formed a very favourable opinion of Mr. Bottomley's work, and we have no doubt that it will meet with the success it deserves among a wider class of students than that for which it is specially designed.

A. R.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*]

Evolution and the Vegetable Kingdom

MR. CARRUTHERS has embodied in the *Contemporary Review* the substance of his Presidential addresses to the Geologists' Association, on which we would offer a few points for consideration.

Although not agreeing with Mr. Carruthers as to the inferences to be drawn from the present state of our knowledge of fossil vegetable remains, we cannot but admire the earnestness with which he makes a stand in what we regard as a losing cause. We set a high value on his researches in fossil botany, and his work is characterised by unvarying and careful exactitude. Whatever may be his theories, his reputation will rest on a solid basis of work. Palæontologists have to thank him for unvarying kindness and readiness to aid them in their researches, forming a marked exception to the treatment which botanists usually give the subject.

In discussing this question, we must keep well in mind the teaching of Sir Charles Lyell, first as to the insufficiency of the geological record, especially with regard to land-surfaces. Considering the denudation and the wasting action of the waves to which remnants of terrestrial conditions are exposed during the slow process of their submergence beneath the sea, and again during their gradual upheaval, it is surprising to us not that so few records are preserved, but that any vestiges whatever remain. Secondly, with regard to lapse of time, we must get the "chill of poverty out of our bones," and not misinterpret "the sign of successive events, and conclude that thousands of years were implied where the language of nature imports millions." Mr. Carruthers admits the imperfection of the geological record, although scarcely with sufficient emphasis, and compares its fragmentary condition to a tablet containing the remains of an unknown inscription represented by only a few of its numerous letters, each of which occupies its proper relative position to the known and unknown letters of the inscription. This is hardly a happy simile as the relative ages of the beds and strata containing vegetable remains, scattered over the world, are certainly very far from settled, and their correlative sequence is in numerous instances still the subject of great discussion. The relative position of these letters is therefore at present but vaguely known.

Haeckel supposes "that the sub-marine forests of the primordial period were formed by the huge brown algæ or fucoidæ." In the 70,000 feet of sedimentary rocks, from the Laurentian to the Devonian, beds of carbon and graphite are abundant; the only known vegetation throughout that period is of algæ. So far only Mr. Carruthers agrees with Haeckel; from this point his views diverge. During the period of the deposition of these 70,000 feet, time enough surely elapsed (if time only be required) for the evolution of vascular cryptogams from algæ. In the Silurian had vegetation been equally fitted to resist decay, we should probably have had plant evolution indicated side by side with that of animals. Before leaving the subject of algæ, we must differ from Mr. Carruthers, who says that if rich floras had existed, the limestones of the Llandovery rocks at Malvern would have preserved them. In these marine rocks at the most sea-weeds could be expected, and limestone of whatever age do not usually preserve such traces; but we know that floras existed by the carbon and graphite before-mentioned.

Mr. Carruthers urges what he considers as fatal objections to the doctrine of evolution; his arguments may be briefly stated as follows:—

1. The simultaneous appearance of the three principal groups of vascular cryptogams, even in a more highly organised condition than their living representatives.

2. The early appearance of gymnosperms and the want of connecting links between these and the lycopods from which they are supposed to have been developed.

3. The early appearance of monocotyledons.

4. The sudden appearance of dicotyledons, not only in the lower form as Apetalæ, but also as Dialypetalæ and Gamopetalæ.

5. The persistence in specific character of *Salix polaris* from the glacial period until now and over a wide range.

Let us now see on what facts these objections are founded, and whether the facts are not open to other interpretations.

1. The evolution theory requires that lower groups have developed until the amount of organisation was reached required to enable them to fulfil the conditions under which they live, and to occupy vacant ground in the economy of nature. This required amount of development may be more or less quickly attained, and the development of the organism then remains almost stationary. Side by side with this development, other development goes on unceasingly, leading to the gradual evolution of entirely different and more highly organised forms. The cryptogams are paralleled amongst vertebrates by the early and specialised development of reptilia; amongst crustacea by trilobites, &c. In like way the tetrabranchiate cephalopods, the brachiopods, and numerous other mollusca, whose hard shells resisting decay, have enabled us to trace their life history, have come down to the present time, just as these vascular cryptogams have, not in their most complex and differentiated forms. We do not expect to find sustained progressive development in the lower animal and vegetable groups, and are not surprised at evidence of actual reversion.

2. On their first appearance "the Gymnosperms do not," Mr. Carruthers says, "present a generalised type, but a remarkable variety of genera and species, all as highly differentiated as any of the existing forms." Now if this is absolutely the case, and their *first appearance* in life is coincident with their first appearance in the fossil record, there is no doubt that they were specially created, and there is no need of further argument. But the point not yet proved is that the two are coincident. The occurrence of coniferæ in the Devonian is only known by wood with coniferous structure. The fruit and foliage, if known, might possibly afford an indication of the mode in which their course of evolution, as suggested by Haeckel, had taken place. Unger has described anomalous woods from Thuringian rocks of Devonian age. "Had these been of earlier age than Miller's Cromarty wood they might have been looked upon as one of the steps leading up to the true Coniferous structure." These may yet be looked on as steps, for the relative age of these Devonian rocks is still to be fixed. This occurrence of anomalous wood is at all events not to be overlooked, if, as is stated, the gymnosperms both structurally and embryologically form the transition group from ferns to angiosperms. The occurrence of Coniferous wood in Devonian rocks rather shows how great are the gaps to be filled up, and that the evolution of the gymnosperms commenced at an earlier period than was supposed, during the formation of the great carbon layers of the older rocks, and side by side with the development of ferns and lycopods. The common ancestors of the spore-producing lycopod and the seed-bearing gymnosperm are to be sought in remoter times even than the Devonian. There is no evidence that the Devonian woods were those of the higher and diœcious conifers and that conifers first appeared in this form. Little is really known of the earlier coniferæ, but the cycads—the lowest form, and most nearly allied to ferns—were far more abundant formerly than at present. Schimper writes as follows:—"What form the prototype of our conifers took in carboniferous times is not satisfactorily settled, neither fruit nor foliage having been discovered which could be placed in any order with certainty. The few fragments placed in Abietinæ may belong to Lepidodendron."[1] In the Permian rocks conifers are abundant.

3. Concerning the appearance of Monocotyledons at the base of the Trias, the first true monocotyledon, Mr. Carruthers states, is the stem and spike of an aroideous plant from the lowest carboniferous strata near Edinburgh.[2] Recently a number of additional specimens have come to light, but Mr. Etheridge, junior, who is referred to by Mr. Carruthers as having found them, does not we believe regard them to be monocotyledons at all; and in this view, although we have not examined them, we are inclined to concur, because it seems unlikely that so many spikes should be found without foliage. In the *Transactions* of the Botanical Society of Edinburgh, vol. xii. p. 152, Mr. Etheridge points out that the stem of Pothocites was branched, and what was thought by Paterson to be the remains of a deciduous spathe was one of a series of small enlargements which "occur along the course of the stem at regular intervals, jutting out one on each side opposite one another." This additional information throws still greater doubt on the correctness of the determination. At Bournemouth, where aroids are abundant, leaves only have been found without a single spike. This is not the first time monocotyledons have been supposed to be present in the Carboniferous; for example, Cordaites, a plant now acknowledged to be a gymnosperm—but whether a cycad or conifer is still, according to Schimper, a matter of doubt—was formerly supposed to be a palm, and subsequently a Yucca or Dracæna. The curious twisted bodies called Spirangium are assumed to be monocotyledons on very slender grounds, their affinities, according to high authorities, being completely unknown. Nevertheless we find Mr. Carruthers, referring to the Carboniferous, says:—"Including these fruits there are probably eight species of monocotyledons in the later Palæozoic rocks." But *excluding* them there is but one, and that, as just shown, of an extremely doubtful nature. Monocotyledons occur doubtfully in the Trias as Yuccites, and in many forms in the Lias, agreeing so far with Haeckel's table of their pedigree. They gradually increase in number until the present day. Although we question the reality, we think the early appearance of a monocotyledon, even if it had occurred, would no more invalidate the theory of evolution than does the equally unlooked-for occurrence of mammalian remains in secondary rocks, invalidate the theory in reference to animal remains.

4. The next point Mr. Carruthers brings before us is the appearance of dicotyledons, and as their testimony for or against evolution is very important, this testimony deserves examination at some length. Mr. Carruthers regards, as the most fatal objection to the evolution theory, the supposed fact that representatives of all the three great groups appear simultaneously in the Upper Cretaceous rocks. Dicotyledons have been found as low down as the Neocomian, and their discovery in rocks of this age is quite recent. Still the evidence that this is their earliest appearance is purely negative, and no hypothesis is satisfactory which is based entirely on negative evidence. It is probable that dicotyledons may be found in yet earlier rocks—perhaps quite early, although playing an extremely subordinate part. The Wealden has yielded no monocotyledons, yet we know that they must have existed; may not then the earlier forms of dicotyledons also have existed? We may parallel the case of the mammals from the Purbecks. The Purbeck fauna was considered to show no trace of mammals until the examination of a particular

[1] *Pinus anthracina*, Lindley and Hutton, is "certainly a fragment of a Lepidodendroid fruit."—Carr., *Geol. Mag.*, vol. ix. p. 58.

[2] *Pothocites grantoni*, Paterson. *Trans. Bot. Soc. Edinb.*, vol. i. p. 45, pl. 3, f. 1-3. Not mentioned by Haeckel or Schimper.

small area of the Purbeck beds revealed their presence in numbers; had this spot not been quarried it would have been supposed for years that mammalia had made their appearance in Eocene times. Some causes, tending to make the preservation of dicotyledons difficult were discussed in NATURE, vol. xv. p. 281, and need not be further alluded to here. Mere localised patches of plant remains are not an unerring index of the character of a flora at any period. At Bournemouth there are patches just underlying the lowest marine beds, which are crowded with ferns only; other patches contain nothing but ferns, aroids, and gymnosperms. Had these patches been isolated, inferences of a most misleading character would have been drawn.

The upper Cretaceous floras are known to us principally from Aix-la-Chapelle and from America; but as in both these—indeed in most cases—the supposed Cretaceous beds containing plant remains rest on palæozoic rocks, their relative age is a matter of uncertainty. M. Barrois fixes it as contemporaneous with his zone of Belemnitella, but whether he is right in this supposition or not, the flora contains ferns and other plants which seem identical with those of the Bournemouth beds. In America, in the Dakota group, we have leaf beds 400 feet thick of the supposed age of our gray chalk, but the associated marine beds have, mixed with decidedly Cretaceous forms, shells approaching very closely those of our London clay. It seems more logical to determine the age of a rock by the incoming of new types than by the lingering of old, and the whole palæontological evidence shows that these beds are at most intermediate in age between our Eocene and Chalk, the enormous gap between which is probably filled up here by some 2,200 feet of strata. American geologists are not agreed as to their age. It would be out of place to discuss this subject at length, but enough is said to show that the relative ages of these floras is not definitely known, and that no series of arguments based on their relative sequence is, at present, entitled to any weight. M. Lesquereux finds evidence in support of evolution in the flora of Dakota, "in the remarkable disproportion of genera compared to species;" and in the sameness of the leaves, which are "mostly entire, coarsely veined, and coriaceous, the difficulty of separating them into distinct groups, by fixed characters, the numerous forms of leaf which, seen separately, represent different species, or even genera, and which, considered in series or groups, appear undividable into sections." When, however, he theorises, we see that he makes use of the same arguments against evolution as those put forward by Mr. Carruthers. Von Ettingshausen, on the other hand, who has paid much attention to the subject, states that he is able to trace the ancestry of our present floras back to simple elements in Tertiary times, and these to still simpler and more united types in Cretaceous times. In his works a number of examples are given. The flora of Sezanne, whose age as Lower Eocene may be accepted, is closely analagous with that of Bournemouth.

Now let us examine the manner in which determinations of fossil leaves from these earlier rocks have been made, and see whether they are sufficiently reliable to entitle us to form any theories whatever as to the simultaneous appearance of the three divisions of Dicotyledons. Let us take the flora of Dakota.

Of *Polypetalæ* we have Liriodendron, founded on two fragments, and Magnolia on two fragments. These fragments are of simple leaves and possess no character whatever in themselves, upon which they can be determined. Magnolia, for instance, is determined from the similarity in form to leaves described as Magnolia by Heer in the Flora of Greenland, which themselves are supposed to be Magnolia because they resemble (not specifically) Magnolias from the Miocene of Europe. In Menespermites, the third genus, the name indicates that its affinities are vague, and we accordingly see that it had been formerly described as Dombeyopsis, Acer, Populites. The *Gamopetalæ* are represented by three genera. Of these Andromeda is determined on two fragments and one indistinct leaf of simple lanceolate form; Diospyros, formerly described as Quercus, is determined from one simple and ovate leaf resembling Laurus, the other a round and simple leaf; while Brumelia is still more unsatisfactory, and has been previously thought to be either Laurus or Quercus. The determinations have been changed, as we see by the position of the plates and the figures on the plates, many times during the progress of the work, and it is not too much to say that all the determinations of leaves of Polypetalæ and Gamopetalæ from this flora are vague and unsatisfactory, and no one would be more ready to acknowledge this than Mr. Carruthers himself. We do not find fault so much with the determinations themselves, which are probably the best that could be made from such material, but we think it premature to base any theories upon them as to the simultaneous appearance with the Apetalæ of the more highly organised Dicotyledons.

In the Eocene and Miocene we have, however, richer materials, and the variety and completeness of the fossil flora become conspicuous; the forms, as Lyell says, "were perfect, changing, but always becoming more and more like, generically and specifically, to those now living." Von Ettingshausen has traced the direct descent of many living species back to the Miocene, sometimes two or more species to a common parent stock.

5. With regard to the persistence of *Salix polaris*, it appears to be simply a case of a plant becoming thoroughly adapted to certain conditions of life which were met with in England during the glacial period, and are present now in extreme northern regions. Why *Salix polaris* should have varied since glacial times more than mollusca and other animal life is not apparent. The intermediate forms which should connect willows and poplars have not been found, but as poplar-like leaves have been met with in lower cretaceous rocks, it is probable that the order of Salicaceæ is an extremely ancient one, and the single generalised form must be sought for in remoter times even than the Cretaceous.

Our general broad knowledge of the succession of plant life, as testified by the rocks, is too well known to need recapitulating here. Schimper enters in detail into its history. In the Silurian, Algæ; in the Devonian ferns and Lycopods, reaching their apogee of development in the Carboniferous; and in the Permian the conifers first take an important position. The Triassic indicates a great gap, and may be considered the reign of gymnosperms, whilst the incoming of the phanerogams is placed beyond doubt. The Jurassic presents another hiatus, and but little is known of its flora.[1] Heer, however, infers, from the entomological fauna, that there were no leafy trees in the Lias. The oolitic rocks contain abundance of cycads. The Wealden and Neocomian vegetation has left us little more than gymnosperms and ferns. With the upper cretaceous period dicotyledons are abundant, but their incoming is traced to older rocks. The Eocene contains rich assemblages of dicotyledons, principally apetalous, and the Miocene, better known, a still greater variety. We see the same plan of development in the individual; and, as Prof. Huxley recently stated in a lecture at South Kensington, "we can trace living plants from the most gigantic and complicated tree, step by step down through many gradations to the lowest algæ, the lichens, and on down to a piece of animal jelly."

Thus we find on reviewing the evidence that has been brought forward, that other interpretations may be put upon the facts presented to us by Mr. Carruthers. J. S. G.

IN an article in this month's *Contemporary*, entitled "Evolution and the Vegetable Kingdom," Mr. Carruthers refers incidentally to a question that deserves the careful consideration of all who accept the doctrine of evolution; viz., whether the earliest type of flower was hermaphrodite or unisexual. Alluding to the abundance and variety of palæozoic gymnosperms, as evidenced by the numerous fruits that have been discovered in the carboniferous measures, he lays stress on the fact that "they all belong to the Taxineous group of conifers . . . . that the plants of this section are all diœcious, *i.e.* having the sexes on different plants. If the occurrence of the germ and sperm elements in different organs, and even in different individuals, is evidence, as it is held, of higher development in phanerogams, then it is important to notice the order of appearance of diœcious and monœcious groups in relation to those with hermaphrodite flowers. Advocates of evolution hold that dimorphic plants are now in a transition stage progressing towards a diœcious condition. The conifers attained to the highest known development as regards this element of their structure on their first appearance."

If Mr. Darwin be regarded as an exponent of the views held by "advocates of evolution," we find that he expresses himself very differently. From the following passages in his recently published work on "The Effects of Cross and Self-fertilisation in the Vegetable Kingdom," he would seem to consider the primordial condition to be unisexual. "There is good reason to believe that the first plants which appeared on this earth were cryptogamic. . . . . As soon as plants became phanerogamic and grew on the dry ground, if they were to intercross, it would be indispensable that the male fertilising element should be transported by some means through the air; and the wind is the simplest means of transport." . . . . "Therefore the Coniferæ and Cicadiæ, no doubt, were anemophilous, like the existing species of these groups." . . . . "A remarkable fact with respect to anemophilous plants is that they are often diclinous." For reasons which he gives, Mr. Darwin considers that this "may be attributed to anemophilous plants having retained, in a greater degree than the entomophilous, a primordial condition, in which the sexes were separated and their mutual fertilisation effected by means of the wind." . . . . "If this view is correct, plants must have been rendered hermaphrodites at a later though still very early period, and entomophilous at a yet later period, namely, after the development of winged insects." He subsequently points out, however, that "under changing conditions of life . . . . some hermaphrodite plants, descended, as we must believe, from aboriginally diclinous plants, have had their sexes again separated;" and he names as an example, *Lychnis dioica*. It is only in the case of plants thus reverting that dimorphism can be held to be a transitional stage.

---

[1] An extensive Jurassic flora has been described by Heer in *Mém. de l'Acad. Imp. des Sciences de St. Pétersbourg*, vii^{e} série, tome xxii. No. 12, 1876.

Prof. Thiselton Dyer, in his notice of Mr. Darwin's book in NATURE (vol. xv., p. 329), maintains an opposite view. "It would not be difficult to show that all through the vegetable kingdom the hermaphrodite condition precedes the diœcious." Demurring to Mr. Darwin's conclusion that the monœcious condition "is probably the first step towards hermaphroditism," he considers it "not improbable that precisely the converse may be more true." . . . . "To throw light on the question whether the primordial plant was diclinous or not," he discusses the manner in which it probably originated "from some plant-form not distantly related to Selaginella," and arrives at the conclusion that the first flower would probably be extremely inconspicuous, destitute of colour and hermaphrodite.

How would it be, however, if, instead of regarding the sporangiiferous cone or spike of Selaginella as the homologue of a single flower, we compare it rather with the spike of Carex, say, for example, *C. pulicaris?* The spike in this species is, like the other, "composed essentially of an axis having modified lateral appendages." The glumes of the sedge correspond to the scales of the lycopod; in the axils of the upper are found the "male structures"—in Selaginella, sporangia containing microspores; in Carex, anthers containing pollen; in the axils of the lower are found the "female structures"—in Selaginella, sporangia containing macrospores; in Carex, ovaries containing each an ovule. There is then not even the difference that the position on the axis of the male and female structures is inverted. From *C. pulicaris*, with its single spike, the passage is easy to species that have several spikelets, each male at the top and female below; or to others that have the upper spikelets wholly male, the lower ones wholly female. The same arrangement of male and female elements is found in Typha and Sparganium, in most of the Araceæ, to which order belong the oldest fossil monocotyledons, and is preserved even in Sagittaria, although in the last the flowers are of a much higher type, being provided with petalloid perianths. So far as the comparison with Selaginella is concerned, does it not favour the production in the first place of unisexual flowers, at least as much as of hermaphrodite?

The Rocks of Charnwood Forest

SOME letters appeared in NATURE a few months ago upon the rocks of Charnwood Forest. In one of them it was suggested that the syenitic bosses of Markfield and Groby might be more ancient than the surrounding slates and grits. Some of your readers may therefore be interested in learning that we have now ascertained from unquestionable evidence in two places that the syenite is intrusive in these rocks, and, as we believe, in some of the highest and latest rocks of the series. We reserve the details of the sections and localities for a paper which we hope shortly to communicate to the Geological Society.

Ship's Chronometers

WE have read with much pleasure your notice (vol. xv. p. 403) of Sir William Thomson's lecture on Navigation, and are prepared fully to endorse your remarks as to the value of Mr. Hartnup's system of rating ships' chronometers, by which account is taken of the change of rate due to change of temperature.

It is but fair to mention, however, that the principle upon which this system is founded was thoroughly investigated by experiments upon a large number of chronometers by M. Lieusous, of Paris, some thirty or forty years ago; acting upon his suggestions, and after independent investigation conducted in our chronometer manufactory some six years ago, we produced a table for the use of captains and others using ships' chronometers, which was fastened in the chronometer case, with a small thermometer in front of it, in such a way that the top or upper end of the column of mercury indicated, without any calculation whatever, the mean rate that should be given every day to the chronometer until some considerable change of temperature had taken place (say 3°), when the new position of the top of the mercury column again showed the new rate to be used in working the chronometer.

We did not introduce this plan to the navigating public generally, as we feared that sufficient trouble (small though it actually be) would not have been taken in the use of it, also for another reason, *i.e.*, nearly every chronometer that we have tested has been found to require a different daily coefficient for a change of temperature of ± 1°, and ships rarely remain sufficient time in port for us to determine this coefficient after allowing for the time necessary to clean the chronometer.

But, as our system of tabulation may be of interest to your readers and may possibly be available for other purposes, we give it you as briefly as possible.

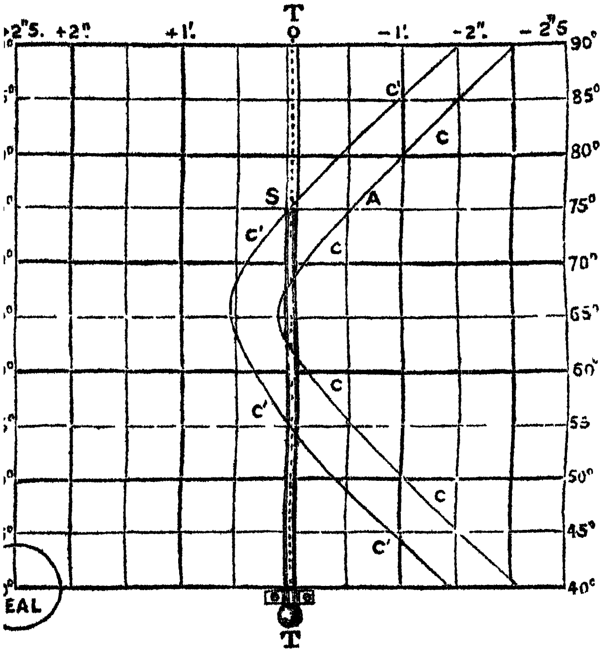
From our experience (which agrees with that of Lieusous and of Hartnup) we find that the ordinary compensation balance without auxiliary, causes the chronometer to go at its fastest rate (or in other words to *lose least*) at a point of the thermometric scale somewhere between 55° and 70° F., usually at 60° or 65°, and that from 25° to 30° above or below that "fastest point" the chronometer loses or goes slower on its fastest rate by an amount that is determined by multiplying the square of the difference in temperature between the new point and the "fastest point" by the coefficient of temperature for a change of 1° above or below the "fastest point," *i.e.*, by the amount that a chronometer goes *slower* for having its temperature increased or diminished by 1°.

This is, however, only true so long as two conditions are adhered to; the first condition being that the "fastest point" (which can be moved at will by the chronometer maker), shall not be taken outside the limits of 55° to 70°, that is, the rule will apply from 30° to 95° but not beyond, even though the "fastest point" should be moved up to 80° or down to 40°; beyond these points a new law applies, and instead of squaring the difference of temperature and multiplying that quantity by the coefficient of temperature, this latter must be multiplied by the difference of temperature (always reckoned from the "fastest point" of the chronometer under trial) raised to a power between the square and the cube, or $x^{\frac{5}{2}}$, for which good reasons can be given.

This being explained, it will be easy to perceive the use of the table or diagram as given below, in which T is a thermometer, C C and C′ C′ are curves drawn after testing the chronometer. For an ordinary voyage in which no extremes of temperature are expected, or which, if they occur, will be of short duration only, we should seal the diagram under the thermometer, so that the temperature line of 65° should coincide with and pass through the apex of the curve, and if the chronometer were neither gaining nor losing at 65° we should draw the curve as C C; if the chronometer were gaining five-tenths of a second per day we should draw the curve as C′ C′.

Then the rate is always to be reckoned from the summit of the mercury horizontally till the line meets the curve; if this line should be to the left of the thermometer the time should be reckoned as *plus* (+) or *gaining*; if to the right, as *minus* (−) or *losing*.

Thus, for example, taking the line S A for a chronometer whose rate at 65° is 0″·0ths, this will give at 75 − 0″ 5ths, or losing half a second daily; or for a chronometer whose rate at 65° (C′ C′) is fast 0″·5ths, at 75° it would be 0″ 0ths for a chronometer whose daily coefficient gives a curve as here drawn.



Of course in determining a daily rate, two or more observations of temperature should be taken, so as to give a mean temperature point from which to reckon the rate, as the day and night temperatures differ considerably.

Prof. Lieusous, in his *brochure*, gives a rule for determining the amount which a new chronometer is likely to *gain* on its rate, owing to the hardness of the balance spring and other causes independent of temperature, but we do not find this latter so reliable as the temperature-correction method as detailed above.

Should this prove interesting to your readers, we may, with your permission, at some future time give a few reasons for the difference that is found to exist between the daily coefficients of temperature of different chronometers.

PARKINSON AND FRODSHAM

4, Change Alley, Cornhill, London, March 12

P.S.—The above system renders the auxiliary compensation unnecessary, and can therefore effect a saving of 4*l*. to 5*l*. on the cost of each instrument.

Lowest Temperature

THERE appears to be something almost abnormal in the climatic conditions to which the observatory at Stonyhurst is subject (vol. xv. p. 399). I remember going into a garden in the neighbourhood of Knaresborough, in Yorkshire, about eight o'clock on the morning of Christmas Day, 1860, and seeing what I suppose had never been seen in England outside a laboratory before that morning, viz., the mercury in a thermometer standing at 8° F below zero, *i.e.*, 40° F. of frost. At Stonyhurst on the same day the thermometer went down only to 6°·7 F., *i.e.*, there were 25°·3 F. of frost.

Again, on March 1, 1877, the lowest temperature registered in the neighbourhood of Knaresborough was only, I believe, 18° F., whilst at Stonyhurst it was 9°·1 F. The differences, therefore, between the temperatures on the two days spoken of at these places, not fifty miles distant from each other, were respectively 2°·4 F. and 26° F., which are so wide apart as to suggest that Stonyhurst is subject to climatic conditions which do not prevail in the Vale of York. I may mention that the record in the *Times* of the temperature on the morning of March 1, was only 25° F., but in country districts in the south of England it was as low as 20° F. Great numbers of oaks, laurels, and other evergreens were killed in Yorkshire by the frost of 1860.

Oxford R. ABBAY

Meteor

A FEW minutes before 10 o'clock on Saturday night I saw a very beautiful meteor towards the western horizon. The meteor passed obliquely downwards towards Orion's belt, moving slowly from right to left. When first seen it was a brilliant white body about ⅙th the apparent diameter of the moon. As it passed onwards it became bluish and pear-shaped with a bright track. Before its final disappearance between the belt and the pleiades it had a purplish hue. It was visible about four or five seconds, and during that period it traversed about ten or fifteen degrees.

Brighton, March 12 W. AINSLIE HOLLIS

I SAW the meteor at 9h. 56m. P.M. of Saturday, March 17, mentioned by your correspondent, "W. M." I was on the sea-shore at Rossall, near Fleetwood, and while looking out to sea, due west, I became aware of a sudden outburst of light on my left. On turning I saw the splendid meteor sailing rather slowly across the sky from a point about 3° north-west of ε Hydræ to a point in Monoceros, whose position I should estimate to be about R.A. = 7h 30m.; Decl. = 20° 0′ south.

March 26 J. H.

DR. SCHLIEMANN ON MYCENÆ

LAST Thursday night will be always regarded as a memorable one in the history of the Society of Antiquaries, when Dr. Schliemann described to an unusually distinguished audience his own and his wife's explorations on the site of the Acropolis of ancient Mycenæ. Taking as his clue the well-known passage in which Pausanias (A.D. 176) speaks of the ruins and traditions of the famous Greek city, Dr. Schliemann was led to the belief that his scholarly predecessors had mistaken its drift. The passage in Pausanias runs thus:—

"Among other remains of the wall is the gate, on which stand lions. They (the wall and the gate) are said to be the work of the Cyclopes, who built the wall for Prœtus in Tiryns. In the ruins of Mycenæ is the fountain called Perseia, and the subterranean buildings of Atreus and his children, in which they stored their treasures. There is a sepulchre of Atreus, with the tombs of Agamemnon's companions, who on their return from Ilium were killed at dinner by Ægisthus. The identity of the sepulchre of Cassandra is called in question by the Lacedæmonians of Amyklæ. There is the tomb of Agamemnon and that of his charioteer Eurymedon. Teledamos and Pelops were deposited in the same sepulchre, for it is said that Cassandra bore these twins, and that, when still little babies, they were slaughtered by Ægisthus, together with their parent. Hellanikos (B.C. 495-411) writes that Pylades, who was married to Electra by the consent of Orestes, had by her two sons, Medon and Strophios. Clytemnestra and Ægisthus were buried at a little distance from the wall, because they were thought unworthy to have their tombs inside of it, where Agamemnon reposed, and those who were slain with him."

Previous explorers had searched in vain for any of the relics here referred to, because they searched in the wrong place, mistaking the wall spoken of for that of the city, whereas Dr. Schliemann's instinct led him to infer that Agamemnon and his companions were buried within the wall of the citadel. Following this clue he began three years ago to sink many shafts in different parts of the Acropolis, and met with such encouraging results near the Lions' Gate mentioned by Pausanias that he devoted his main attention to diggings in this quarter. There were, however, so many hindrances, that it was only in last July he was able to carry out his plans.

In the Acropolis Dr. Schliemann had entirely cleared the famous Lions' Gate, which he went on to describe, discussing also the old question of the symbolism of the lions surmounting the gateway, and of the altar surmounted by a column, on either side of which rest the fore paws of one of the two lions. One theory was that the column related to the solar worship of the Persians, another that the altar is a fire altar, guarded by the lions; a third that we have here a representation of Apollo Agyieus. Dr. Schliemann himself was of this last opinion, which, he thought, was borne out by the Phrygian descent of the Pelopidæ. The lion-cult of the Phrygians was well known. Besides, among the jewels found in the tombs, and especially in the first tomb, this religious lion symbolism re-appeared. On two of the *repoussé* gold plates there found was seen a lion sacrificing a stag to Hera Βοῶπις, who was represented by a large cow's head, with open jaws, just in the act of devouring the sacrifice. On entering the Lions' Gate were seemingly the ancient dwellings of the doorkeepers, of whom some account was given. Further on, as at Troy, was quadrangular Cyclopean masonry, marking the site of a second gate of wood. Still further on were two small Cyclopean water-conduits; to the right of the entrance passage were two Cyclopean cisterns. A little further on came to light that large double parallel circle of closely-jointed, slanting slabs, which has become so famous during the last three months. Only about one-half of it rests on the rock, the other half rests on a 12-feet high Cyclopean wall, which has been expressly built to support it in the lower part of the Acropolis. The double circle had been originally covered with cross slabs, of which six are still *in situ*. Inside the double slabs was, first, a layer of stones for the purpose of holding the slabs in their position. The remaining space was filled up with pure earth mixed with long thin cockles, in the places where the original covering remains in its position, or with *débris* of houses mixed with countless fragments of archaic pottery wherever the covering was missing. This circumstance could leave no doubt that the cross slabs were removed long before the capture of Mycenæ by the Argives (B.C. 468). The entrance to the double circle was from the north side. In the western half of the circle Dr. Schliemann discovered three rows of tomb stelès, nine in all, made of calcareous stone. All stood upright; four only which faced the west had sculptures in relief. One stelè, precisely that beneath which was found the body with the golden plates representing the lion sacrificing the stag to Hera Βοῶπις, represents a hunting scene. The two next sculptured sepulchral slabs represent each a battle scene. The Mycenæ slabs, Dr. Schliemann said, were unique of their kind. The manner in which they fill up the spaces not covered by men and animals with a variety of beautiful spiral ornaments reminds us of the principles of the painting on the so-called Orientalising vases. But in the Mycenæan sculptures nowhere do we see a representation of plants so characteristic of ancient Greek ornamentation of this class. The whole is rather linear ornamentation, representing the forms of the bas-relief. Hereby we have an interesting reference to the epoch in Greek art preceding the time when that art was determined by Oriental influences, an epoch which may approximately be said to reach far back into the Second Millennium (B.C.).

Here then in the Acropolis of Mycenæ are tombs which are no myth, but an evident reality. Who were these great personages entombed here, and what were the services rendered by them to Mycenæ which deserved such splendid funereal honours? It was argued at length that the inhabitants of these tombs could be none other than the very persons spoken of in the extract Dr. Schliemann had cited at the outset from Pausanias. Dr. Schliemann then proceeded to state the details of what he had found below the ruins of the Hellenic city. He spoke of the vast masses of splendidly archaic vases. Iron, he remarked, was found in the upper Hellenic city only, and no trace of it in the prehistoric strata. Glass was found now and then in the shape of white beads. Opal glass also occurred as beads or small ornaments. Sometimes wood was found in a perfect state of preservation, as in the board of a box (νάρθηξ), on which were carved in bas-relief beautiful spirals. Rock-crystal was frequent, for beads and also for vases. There were also beads of amethyst, onyx, agate, serpentine, and the like precious stones, with splendid intaglio ornamentation representing men or animals. When towards the middle of November he wished to close the excavations, Dr. Schliemann excavated the spots marked by the sepulchral slabs, and found below all of them immense rock-cut tombs, as well as other seemingly much older tombstones, and another very large sepulchre from which the tombstones had disappeared. These tombs and the treasures they contained, consisting of masses of jewels, golden diadems, crowns with foliage, large stars of leaves, girdles, shoulder-belts, breast-plates, &c., were described in detail. He argued that as 100 goldsmiths would need years to prepare such a mass of jewels, there must have been goldsmiths in Mycenæ from whom such jewels could have been bought ready-made. He spoke of the necklaces, too, and of the golden mask taken from one of the bodies, which must evidently be a portraiture of the deceased. Dr. Schliemann then proceeded to show that in a remote antiquity it was either the custom, or, at least, that it was nothing unusual that living persons wore masks. That also immortal gods wore masks was proved by the bust of Pallas Athenè, of which one copy was in the British Museum and two in Athens. It was also represented on the Corinthian medals. The treasures of Mycenæ did not contain an object which represented a trace of Oriental or Egyptian influences, and they proved, therefore, that ages before the epoch of Pericles there existed here a flourishing school of domestic artists, the formation and development of which must have occupied a great number of centuries. They further proved that Homer had lived in Mycenæ's golden age, and at or near the time of the tragic event by which the inmates of the five sepulchres lost their lives, because shortly after that event Mycenæ sank by a sudden political catastrophe to the condition of a poor powerless provincial town, from which it had never again emerged. They had the certainty that Mycenæ's flourishing school of art disappeared, together with its wealth; but its artistical genius survived the destruction, and when, in later centuries, circumstances became again favourable for its development, it lifted a second time its head to the heavens.

No doubt Dr. Schliemann's theories will be subjected to much criticism when the full details and drawings appear in his forthcoming work. Of the value of the discoveries themselves there can be but one opinion. Those alone which have been made in the Acropolis of what many have been inclined hitherto to regard as a half mythical city are of themselves sufficient to entitle him to an important place in the field of scientific research. Both to the historian and ethnologist his researches must prove of the greatest value, and all who have been stirred with the recital of the deeds of the Homeric heroes will rejoice to have henceforth reasonable external evidence for regarding them as something more than myths.

FERTILISATION OF FLOWERS BY INSECTS[1]

XVI.

Alpine Species of Gentiana adapted to Lepidoptera.

GENTIANA BAVARICA (Fig. 106-108), *G. verna* (Fig. 109-111), *G. nivalis* (Fig. 112-114), of which I have examined living specimens in the Alps, and *G. imbricata*, *æstiva*, *pumila*, and *utriculosa*, of which I have examined only dried specimens,[2] agree so completely in the structure of their flowers, and in their contrivances for cross-fertilisation by insects, that they all obviously belong to the same section of the genus Gentiana, and are adapted to the same group of visiting insects. They all possess a long narrow corolla (Fig. 106),[3] which contains in its lowermost portion the honey, secreted, as in our two first groups, by an annular swelling at the base of the pistil[5] (*n*, Fig. 106, 111, 113). They all have the entrance to the corolla-tube closed by the bi-lobed stigma being dilated into a circular disc (*st*. Fig. 106, 109, 112), and bordered at its margins with hair-like papillæ (Fig. 108). In all of them small openings are visible in the fully-opened flower between the margin of the stigma and the inclosing corolla (Fig. 109); but as soon as the corolla begins twisting (Fig. 110), these openings are concealed. In all of them the anthers surround the stigma, thus placing their pollen on the way to the honey (*a*, Fig. 106, 110, 114). They can all, therefore, be fertilised only by such insects as have a proboscis sufficiently long to reach the base of the corolla, and at the same time either sufficiently slender to enter through the small openings (Lepidoptera), or sufficiently strong forcibly to enlarge the entrance of the flower (humble-bees). Such an enlargement, indeed, would be possible by the expansion of the same folds between the petals (*f*. Fig. 106, 107, 109, 110, 112), by which the flower is enabled to twist, and to close, as soon as colder weather frightens away its natural fertilisers.

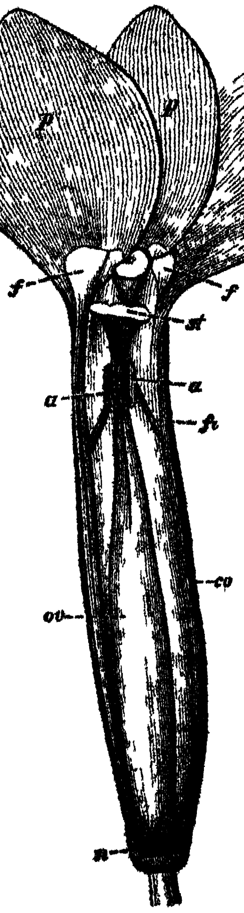


FIG. 106

FIGS. 106-108.—*Gentiana bavarica* FIG. 106.—Lateral view of a flower which begins twisting and closing, the calyx and the anterior portion of the corolla having been removed (3½ : 1). FIG. 107.—The same flower viewed from above (3½ : 1). The margin of the circular stigma is already covered by the revolving corolla. FIG. 108.—The stigma seen from above (7 : 1).[4]

Now, looking about to discover what Lepidoptera and humble-bees might be the natural fertilisers of the present group, I was surprised at the fact that of all the 162 species of Lepidoptera which I had observed visiting flowers in the Alps, *Macroglossa stellatarum* alone has a proboscis sufficiently long (25-28 mm.) to reach the honey in all the species of Gentiana in question, and that of the Alpine humble-bees, even those provided with the longest proboscis of all, *Bombus hortorum* (18-21 mm) and *B. opulentus*, Gerst. (22 mm.), are incapable of reaching the honey in all the above-named species, except by thrusting the whole of their head into the narrow corolla-tube. Moreover, direct observation seems to prove that humble-bees insert at the most their proboscis into these flowers, but never their whole head. For instance, in the Albula Pass, July 28, 1876, I saw a humble-bee flying about for a long time in search of flowers; at length it hastily visited *Gentiana verna*, but having only once thrust its proboscis into a flower, it flew away out of my sight. Likewise near Pontresina, August 4, 1876, I saw *Gentiana nivalis* visited by *Bombus mendax*, Gerst. ♀, but, after having hastily tried one or two flowers in the same

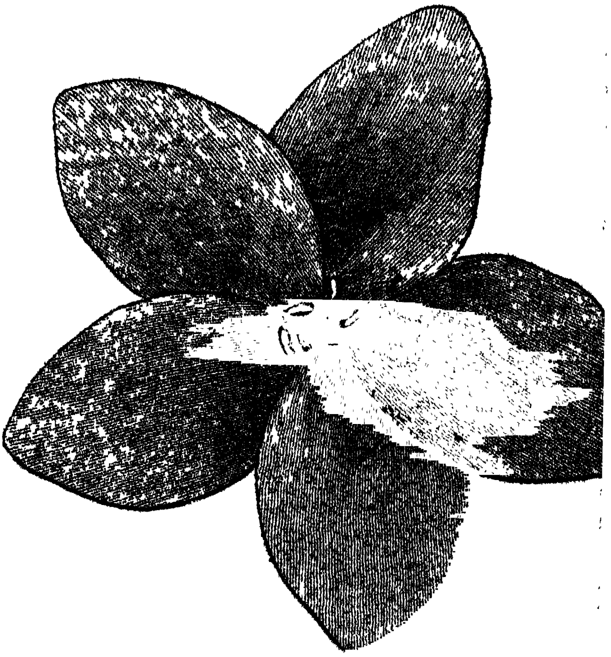

FIG. 107.

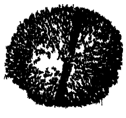

FIG. 108.

---

[1] Continued from p. 319.

[2] For specimens of *G. pumila*, *æstiva*, *prostrata*, *Frœlichii*, and *purpurea*, I am indebted to Prof. Ascherson of Berlin.

[3] Only in *G. æstiva* the corolla-tube seems to be considerably wider than in the other species

[4] The following explanation of the lettering applies to all the figures:—*a* = anthers, *co* = corolla, *fi* = filaments, *n* = nectary, *o* = openings conducting to the honey, *ov* = ovary, *p* = petals, *s* = sepals, *st* = stigma, *f* = folds of the corolla by which its twisting is made possible.

[5] I found the length of the corolla-tube, from the nectary to the stigma, in the species in question as follows: *G. æstiva*, 26-28 mm.; *G. verna* and var. *brachyphylla*, 23; *G. bavarica*, 20-22; *G. utriculosa*, 18-22; *G. pumila*, 16-18; *G. imbricata*, 15; *G. nivalis*, 13-16 mm.

manner, it passed over to *Trifolium nivale*, which it then sucked perseveringly. If from these observations we may infer that the forcible enlargement of the narrow corolla-tube of the species of Gentiana in question is too inconvenient for the humble bees, then the only insects capable of gaining the honey in all the species of the present group and capable of regularly visiting and cross-fertilising them, are *Macroglossa stellatarum*, and perhaps some other Sphingidæ not yet observed by myself in the

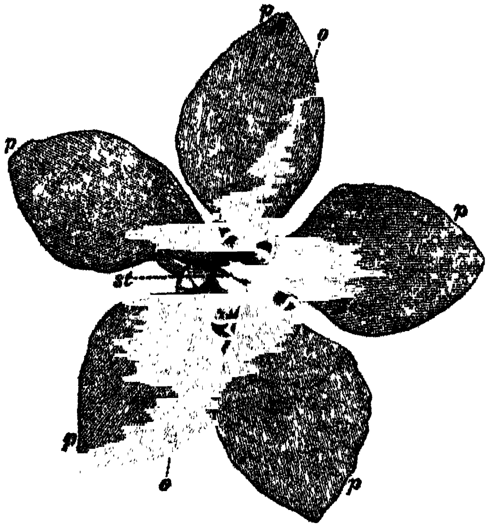

Fig 109.

109-111 —*Gentiana verna* (3½ 1) Fig 109 – Flower, completely opened, seen from above Fig 110 – Upper portion of the same flower, bisected longitudinally, showing the pistil and the anthers. Fig 111 —Lowermost portion of the same flower, showing the nectary

Alps. The smallest of the species in question, *G. nivalis* (13-16 mm.), *G. imbricata* (15 mm.), and *G. pumila* (16-18 mm.), may also be fertilised by some moths[1] and by many butterflies[2] which will all easily insert their slender proboscis into one of the small openings at the base of the corolla-tube, then, withdrawing it smeared with pollen, will leave some pollen-grains on the margin of the stigmatic disc, and, when inserting the proboscis into another flower, will effect its cross-fertilisation by stripping off some of the pollen-grains from the hair-like papillæ at the margin of

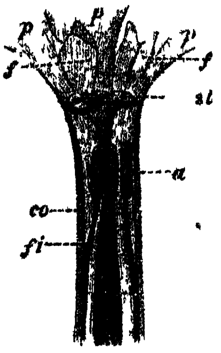

Fig. 110.

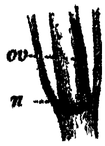

Fig 111.

the stigmatic discs. Humble-bees, on the contrary, at all events, seem to be of very small or no importance as fertilisers of this group. If thus, by indirect inference, we are led to the conclusion that the present group is exclusively adapted to Lepidoptera, we ought embrace this opinion with due precaution; for visits of Lepidoptera, hitherto directly observed by comparison of the length of their proboscis with the length of the corolla-tube, prove to have been only fruitless attempts. On *G. nivalis* (corolla-tube 13-16 mm.), near Pontresina, August 4, 1876, I observed *Cœnonympha satyrion*, Esp. (proboscis, 7 mm.), and

', Rbr. (10-11 mm.); on *G. verna* (corolla-tube, 23 mm.) in the Albula Pass, July 28, 1876, I found *aurinia*, var. *Merope*, Prunn. (7 mm.), *Argynnis pales*, S. V. (9-10 mm.), and *Erebia lappona*, Esp. (8-9 mm.); on *G. bavarica* (20-22 mm.), Kerner[1] observed *Agrotis cuprea* (12 mm.), I myself, upon the Piz Umbrail, July 15, 1875, saw *Erebia lappona*, Esp. (8-9 mm.); in the Albula Pass, July 27, 1876, *E. lappona* and *Melitæa asteria* (5-6 mm.); in the Val del Fain, August 5, 1876, *Melitæa aurinia*, var. *Merope*, Prunn. (7 mm.), all easily inserting their proboscis into the corolla tubes, but all apparently without any advantage to themselves, though, by their repeated fruitless attempts, some cross-fertilisation of the flowers may have been effected. No direct observation

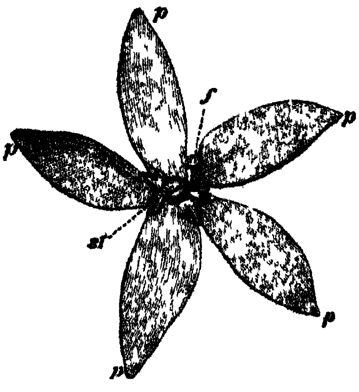

Fig 112 Fig. 113.

Figs 112 114 —*Gentiana nivalis* 3½ : 1) Fig 112 —Flower seen from above. Fig 113 —Pistil Fig 114 – Upper portion of the flower bisected longitudinally, showing one of the anthers (*a*) in contact with the margins of the stigma

of the true natural fertilisers of the species of Gentiana belonging to our fourth group has yet been made.

In former articles I have shown that frequently, of different species of the same genus, those possessing the most conspicuous flowers are adapted to cross-fertilisation by insects, whilst other species of the same genus, possessing less conspicuous flowers, have recourse to self-fertilisation, in case the visits of insects are wanting. This statement is also confirmed by the species of Gentiana in question. For in *G. verna* and *bavarica*, differing from *nivalis* not only by the considerably larger size of the separate flowers, but also by a number of flowers which stand close together, thus being easily seen from a great distance, the possibility of self-fertilisation is excluded by the position of the stigma and the anthers (as shown by Fig. 106 and 110); whereas in *Gentiana* flowers are much smaller and more another, one or some of the anthers contact with the margin of the stigma

, and *V urticæ*, 14-15 mm.

Gäste."

The most striking peculiarity of our fourth group of Gentiana is the sensibility of their flowers to the influence of the weather, which is apparently connected with the sensibility of their natural fertilisers to the same influence. The following observation clearly shows that different species differ widely in this sensibility, even when growing in the same locality. On the Piz Umbrail, July 16, 1874, I had collected some plants of *Gentiana bavarica*, var. *imbricata*, and of *G. verna*, and put them in my sleeping-room in the Quarta Cantoniera, upon a plate filled with water. The next morning, at half-past four o'clock, I found the flowers of *G. bavarica* already opened, those of *G. verna* still closed. I placed the plate outside the window, where the intensity of light was at least as great, but the temperature much lower, and all the opened flowers began twisting. After they had closed, I brought them back into the room, and they opened again. Repeating this trial from half-past four to half-past six o'clock, I saw them two or three times closing and opening again. *Gentiana verna*, standing upon the same plate, during this time, had not yet opened a single flower.

From this observation, the further prosecution of which was prevented by my departure, it is obvious (1) that the opening of the flowers of these species of Gentiana is caused by heat, not by light; (2) that *G. verna* requires a higher temperature for opening than *G. bavarica*, var. *imbricata*. Possibly this is one of the causes which makes *G. verna* descend into sub-Alpine and low lands, whilst *G. bavarica* is confined to the Alpine region.

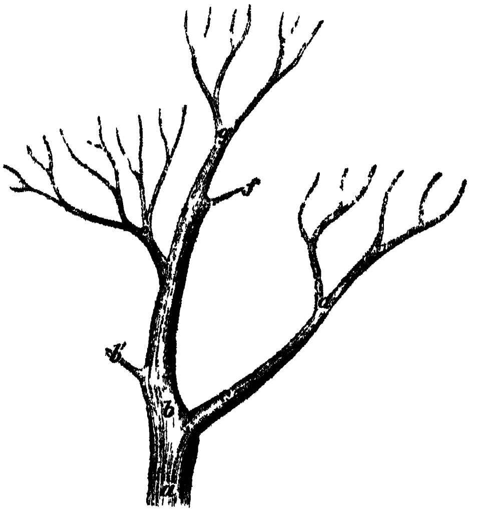

FIG. 115—Pedigree of the species of Gentiana of Germany and Switzerland.

Comparing the present group with the foregoing ones, we need hardly doubt that it is most nearly allied to our second group, from which it differs only by the narrowness of the corolla, by the further development of the folds between the petals, and in connection with this by their greater sensibility, and by the lobes of the stigma being dilated. *Gentiana prostrata*, agreeing in every other respect with our fourth group, has as yet retained the two twisted stigma-branches, and therefore may be considered as a connecting species between the second group and the fourth, which is descended from it.

Summing up the above relations between the species of Gentiana of Germany and Switzerland, we obtain a pedigree like Fig. 115, in which the signification of the lettering is as follows:—

(*a*) Hypothetical ancestral form with fully open flowers, twisted stigma-branches, diverging stamens, and honey secreted at the base of the flower in the angle between the base of the pistil and the corolla. From this ancestral form we see two branches *b* and *c* descend; *b* with the nectary confined to the base of the pistil, *c* with nectaries at the base of the corolla. From the branch *c* has developed the sub-genus *Endotricha* Frœlich (*d*), containing six species:—*G. campestris*, *germanica*, *amarella*, *obtusifolia*, *tenella*, and *nana*, adapted both to Apidæ and to Lepidoptera. Of the branch *b* an original form, *G. lutea* (*b'*), has been preserved, accessible to insects of all orders, but from the same branch has descended the large sub-genus *Cœlanthe* Frœlich (*e*), containing eleven species:—*G. punctata*, *pannonica*, *purpurea*, *cruciata*, *asclepiadea*, *Pneumonanthe*, *Frœlichii*, *frigida*, *acaulis*, *excisa*, and *ciliata*, all adapted to humble-bees. One branch of this sub-genus (*e*), by narrowing the corolla, perfecting the folds between the petals, dilating the stigma-branches, and thus adapting the flowers to Lepidoptera, has further developed the sub-genus *Cyclostigma* (*g*), containing seven species:—*G. bavarica*, *verna*, *æstiva*, *imbricata*, *pumila*, *utriculosa*, and *nivalis*. As a link between the ancestral sub-genus (*e*) and the derived subgenus G., has been preserved *G. prostrata* (*f*).

Lippstadt HERMANN MÜLLER

RECENTLY PROPOSED IMPROVEMENTS IN MUSICAL INTONATION

THE harshness of the present system of tuning has been a source of constant complaint since it was first introduced, about a century and a half ago. But of late years several more or less practical attempts have been made to overcome this defect without interfering with the quality of our musical tones. Instruments with fixed tones, as the organ, piano, and harmonium, lead voices, and the inalterable quality of vocal tone has therefore to be constantly kept in view. The instruments exhibited in the Loan Collection of Scientific Apparatus at South Kensington are enough to show both the objects aimed at and the nature of the mechanical appliances by which it is hoped they may be more or less reached. It is difficult to give an intelligible account of them within the compass of an article, but Dr. Stone's two lectures[1] and Mr. Bosanquet's more recent work[2] will supply details and figures.

On examining musical tones generally,[3] we are led to the conclusion that the first requisite is to have a succession of notes forming perfect Octaves, Fifths, and major Thirds, that is, making numbers of vibrations which the air executes during the same length of time in the ratios 1 : 2, 2 : 3, and 4 : 5 respectively. An examination of prevailing systems of modulation, has shown[4] that a strict fulfilment of this condition would require 117 notes to the Octave—a mechanical impossibility on any instrument with fixed tones. Such a scheme must, however, be made the basis of subsequent work. Moreover if combinations with what is called the harmonic Seventh or 6 : 7 be admitted, then we should require very nearly to double the above number of separate notes. It follows, therefore, that we must either restrict our desires of modulation (which is not likely to happen) or be content to use more or less imperfect intervals, and the question turns upon the degree of endurable imperfection. It must be remembered that these apparently innumerable delicacies of sound present no real difficulty to the singer or violinist when he once knows the theory on which they have to be produced, for they are all generated by extremely simple intervals. The difficulty, indeed, is to avoid them, especially in part music, and to put up with alterations, apparently arbitrary and certainly neither easy to conceive nor to produce. No *temperament*, as such a makeshift intonation is called, could exist except by help of an instrument with fixed tones, and the most practised tuner finds it impossible to produce a satisfactory result, except by mechanical means.[1] How then could we expect a singer to produce at will any of the fifty or more schemes of tuning that have been invented, or even either of the only two that have been a success, the mean-tone and the equal temperaments?[2]

(Macmillan.)

[3] For reasons and details see Helmholtz's "Sensations of Tone."

[4] See my translation of Helmholtz, pp. 669-672

The Greek system of intonation, as we know from Euclid's "Section of the Canon," consisted of a series of perfect Fifths, and may for convenience be represented by F, C, G, D, A, E, B, where it will be found that each note is a Fifth higher than the preceding. It is therefore the simplest and most intelligible that can be imagined, and is in fact at the base of all music. Reduced to the same Octave and played as a major scale this gives C, D, E, F, G, A, B, C. This is perfectly singable, and produces excellent melodic effects. But if we attempt to play the usual major and minor chords of the scale with these notes, as F A C, C E G, G B D, D F A, A C E, E G B, the effect, as I know by frequent experience, is simply hideous, so that there is no difficulty in understanding why the Greeks called Thirds "dissonances" (*diaphōna*), and had no harmony. Observing that in the series of Fifths E is the fourth Fifth above C, we may therefore say that the major Third cannot be identified with the fourth Fifth up, reduced to the same Octave. On calculating out the ratio we find $C : E = 4 : 5 \times \frac{81}{80}$, whereas the real consonance requires 4 : 5. This would be produced by taking a note E_1, as we may write it, which is flatter than E in the ratio of 80 : 81. The result of carrying this out to the extent of modern modulation is the series of 117 notes to the Octave already mentioned.

In the Loan Collection, one instrument, General Perronet Thompson's enharmonic organ, grappled with this problem to the extent of forty notes.[3] But its three finger-boards with occasional extraordinary shapes and colours to the finger keys (figured by Dr. Stone, *op. cit.*, p. 32) might well frighten the uninitiated. Yet General Thompson, himself unable to play, taught a blind organist how to use it, so that in a fortnight she could perform in public, and I have often heard the instrument played by others, who did not complain of any difficulty. Helmholtz (in my translation, p. 636), who also heard it played, speaks of its chords as "extraordinarily harmonious," but the quality of tone (one stop of "metal principals") did not distinguish the consonances effectually at all times, and the compass of forty tones of course materially limited modulation except into tonic and relative minors, which were well provided for.

Mr. Colin Brown has also grappled with perfect tertian harmony, but has exhibited only a model of his keyboard, figured and described by himself in Dr. Stone's book (*ib.* pp. 42-45).[1] His scheme allowed of sufficient modulation into the dominant and sub-dominant major keys, and their first relative minors, but almost utterly ignored the tonic minor, and further minor modulation. As the instrument is an harmonium, the quality of tone is remarkably suitable for bringing out the effects of perfect Fifths and Thirds, and when proper music was selected, the result was most satisfactory. The keyboard is much simpler than General Thompson's, and has the great advantage of being the same in all keys. Such an instrument is of the highest value for lecture illustrations of harmony, and for training of vocalists in perfect intonation. As an independent instrument, its power of modulation is too limited, and the fingering usually simple enough, occasionally becomes very troublesome.[2]

These are the only instruments on which perfect tertian harmony was attempted. In the others some sort of compromise was come to. Mr. Guéroult showed his modification of Helmholtz's double keyboard, each finger-key being cut in half, and the upper half giving, generally, a note flatter than the lower half by a comma.[3]

This is a most convenient instrument for scientific purposes, but from its very limited capacity not so well suited as even Mr. Colin Brown's for playing musical pieces. The fingering is also full of difficulty, having all the imperfections of the ordinary board, with many others superadded, and differs in every key.

We have seen that if we use the fourth Fifth up from any note, when reduced to the same Octave, as the major Third, it is too sharp by a comma, and unbearably dissonant, but if we use the eighth Fifth down, also reduced to the same Octave, the result is a note just $\frac{1}{11}$ comma too flat, which is very much closer than the major Third in actual use (for that is $\frac{7}{11}$ comma too sharp), and is not at all disagreeable, although not by any means as pleasant as the perfect major Third. Thus, going down eight perfect Fifths from C, we get in succession F, B*fl.*, E*fl.*, A*fl.*, D*fl.*, G*fl.*, C*fl.*, and F*fl.*, and the proposal is to use F*fl.* for E_1. On the piano, and all instruments in the usual temperament, these are the same notes, but they are not so when thus tuned, and they are still strictly distinguished in our usual musical notation. Herr Georg Appunn, to whom we are indebted for various excellent acoustical apparatus, and especially for a tonometer (exhibited in the Loan Collection), which is self-verifying, and enables us to measure pitch with wonderful accuracy, likewise showed an harmonium, consisting of three rows of keys, the upper ones in the form of studs, with practically the usual fingering, consisting of thirty-six tones

---

[1] "Mr Ellis has given a practical rule," [for producing the usual, intentionally equal, temperament], "which does not err in its results by much more than the hundredth part of a semitone." (Seldom as much as that.) "It is—make all the Fifths which lie entirely within the Octave c′ c″ [middle C to the C above] beat *once* per second; and make those which have their upper notes above c″ beat *three times* in *two* seconds. Keeping the Fifth f′—c″ to the last, it should beat once in between one and two seconds. See Ellis's "Helmholtz," p. 785. This is a perfectly practicable rule, and tuners ought to be instructed in the use of it. *There are few tuners who can produce a tolerable equal temperament.*"—Bosanquet, *op cit.*, p. 5.

[2] See my paper on Temperament (*Proc. Roy. Soc.*, vol. xiii., pp. 404-422), where more than fifty schemes are calculated and analysed. Mr. Bosanquet has a most interesting chapter on the history of the mean-tone temperament or old organ tuning, the only one known to Handel, and its complete realisation, without its former "wolves," by means of his own fingerboard, pp. 24-40. He rightly considers this temperament most suitable for the organ (p. 58) as the equal temperament is for the pianoforte. But then the voices of a choir might be led by the completed mean-tone system without much injury to the chords, which are shivered by the equal temperament.

[3] These are given by Mr. Bosanquet, *op cit.*, p. 22, arranged according to his own finger-board, which completely does away with the terrors of the original, but also expressed in his own notation, which implies a temperament which General Thompson well knew and repudiated. Hence I add them here in my own symmetrical arrangement (*Proc Roy. Soc.*, December, 1874, vol. xxiii. p. 29, called "the simplest" by Mr. Bosanquet, p 50), in which the columns represent ascending Fifths, and the lines from left to right ascending major Thirds, and where the superior and inferior numbers indicate sharpening or flattening by a comma (this is here published for the first time).

General P. Thompson's Enharmonic System:—

c^1	e			
f^1	a	c_1 *sh.*		
b^1 *fl.*	d	f_1 *sh.*	a_2 *sh.*	
e^1 *fl.*	g	b_1	d_2 *sh.*	f_3 *ssh.*
a^1 *fl.*	C	e_1	g_2 *sh.*	b_3 *sh.*
d^1 *fl.*	f	a_1	c_2 *sh.*	e_3 *sh.*
g^1 *fl.*	b *fl.*	d_1	f_2 *sh.*	a_3 *sh.*
	e *fl.*	g_1	b_2	d_3 *sh.*
	a *fl.*	c_1	e_2	g_3 *sh.*
		f_1	a_2	c_3 *sh.*

[1] The notes used in the figure are comprised in the second, third, and fourth columns of the above scheme of General P Thompson's, but carried further, the second column rising to D *sh.* and descending to F *fl.*, the third rising to B_1 *sh.*, and descending to A_2 *fl*, and the fourth rising to A_3 *ssh.*, and descending to G_3, giving fifty-two notes in all; but the instrument performed on at Dr. Stone's lecture (July 25, 1870) had not so large a compass.

[2] "It is clear that this (Mr. C. Brown's) arrangement adapts itself with some facility to all music in which there is not much modulation, or in which the modulation is of a simple type. It is, however, easy to give instances which will at once involve the performer in difficulties." Bosanquet, *op. cit.* 48-9. Mr. Bosanquet, who is a practised organist, having studied the fingering, and played on the instrument at the Glasgow Meeting of the British Association, is well able to speak to its capabilities.

[3] Disregarding one very slight alteration, the compass of twenty-four notes extended from E *fl.* to B in the second column of General Thompson's, from G_1 to G_1 *sh.* in the Third, and from F_2 *sh.* to B_2 *sh.* in the Fourth. With the exception of Two Fifths (G_1 *sh.* to E *fl.*, taken to be D_1 *sh.*; and B_2 *sh.* to G_2, taken at F_2 *ssh.*), which were too flat by $\frac{1}{11}$ of a comma, as all Fifths ought to be on the piano, this gave a complete succession of dominant modulations, but only admitted of five minor keys.

forming thirty-five perfect Fifths, which, by the contrivance of using the eighth Fifth down as the major Third, into the place of which its finger-key is placed, gives very free play for modulation in all directions with perfect uniformity, although of course slightly imperfect intonation.[1]

To this system of perfect Fifths and major Thirds identified with eight Fifths down, we must attach all the other contrivances for reducing the number of notes necessary to tertian harmony, without seriously offending the ear. The practicability of arranging any number of dozens of such notes in the Octave, up to at least seven dozen, so that they should be entirely under the command of the performer, be fingered precisely in the same way in all keys, and have a style of fingering which is of about the same difficulty as that for three sharps or three flats on the piano, has been proved to demonstration by the "generalised keyboard" of Mr. Bosanquet, exhibited at the Loan Collection, for his enharmonic harmonium, and, up to four dozen finger keys to the Octave, to the Musical Association upon his enharmonic Organ.[2] This keyboard is quite a triumph of ingenious construction, founded on rigorously scientific principles, for the practical solution of an apparently insoluble problem.

The modifications of the perfect Fifth system (to which Mr. Bosanquet seems much inclined, *op. cit.*, p. 57) depend on the discovery that fifty-three perfect Fifths exceed thirty-one Octaves by only about $\frac{36}{1000}$ of an equal semitone, or very nearly $\frac{1}{6}$ of a comma. Helmholtz proposed to reduce every Fifth by $\frac{1}{88}$ of a comma. This would make fifty three of the flattened Fifths to be about $\frac{1}{10}$ of a semitone less than thirty one octaves, too large an interval for good ears not to perceive, being nearly half a comma, but then all his Fifths would be audibly perfect, and all his major Thirds absolutely perfect. Mr. Bosanquet endeavoured to tune a stop on his enharmonic organ in that way, but the effect with stopped pipes did not repay the immense trouble of tuning (*ibid.*), which cannot be truly effected without much mechanical assistance, and is therefore generally impracticable.

The great difficulty of tuning is also an objection which applies to Mr. Bosanquet's own proposal to divide the Octave absolutely into fifty three parts (see *op. cit.*, p. 56). This would flatten the Fifth still less, but of course would also make the major Thirds nearly as flat as those in the system of perfect Fifths, from which his differ only by about $\frac{1}{14}$ of a comma. It is not likely that Mr. Bosanquet has been able to tune to such a degree of accuracy. And as the object of the division of fifty-three is only to modulate *ad infinitum*, such accuracy is needless for general purposes, for which forty-eight perfect Fifths (or, as I believe, six sets of eight perfect Fifths, differing by perfect major Thirds from each other, and hence comparatively easy to tune by Fifths and check by Thirds), would fully suffice.[3]

The instruments exhibited in the Loan Exhibition and the others indicated in the preceding lines may, therefore, be said to have practically solved the difficulty of tertian harmony on instruments with fixed tones, and they have even approached to a solution for septimal harmony (which uses the harmonic Seventh; see Bosanquet, *op. cit.*, p. 41). Voices in part music, when unaccompanied, must sing in just tertian or even septimal harmony, but when accompanied they will inevitably follow the instrument. Violinists can do what they like, but are too much inclined to Greek intonation, which is all very well by itself, but which the performer should learn to modify by something better than a rule of finger, in double-stopped passages and part music. With the bass the comma stop may be made effective to a great extent, and Dr. Stone is trying what he can do with the oboe and clarinet (*op. cit.*, p. 35), so that there are some hopes of improving even the orchestra. Enough, at least, has been done on the instruments mentioned and in the practice and system of study of the Tonic Solfaists (Helmholtz, p. 640) to show that it is practically possible greatly to improve musical intonation.

ALEXANDER J. ELLIS

---

[1] The notes may be considered to be those in Gen. Thompson's second column continued up to A♯♯ and down to A♭♭♭♭ (or A quadruple flat), the names being altered to those of the finger keys corresponding to those on the ordinary piano, so that no more sharps and flats are used than in ordinary notation. Unfortunately the bellows and some parts of the mechanism were injured in the carriage, and hence the full effect could not be appreciated. There were two extra rows of keys to bring out Herr Appunn's favourite minor Third, 16 : 19, which is slightly closer than that on the piano, and very effective in certain cases, but the fingering for these was new and difficult, and could not be considered practical.

[2] The first, with eighty-four notes to the Octave, is figured in Mr. Bosanquet's book (*op. cit.*, p. 23), where it is fully described, and I also explained at length in my Helmholtz, pp. 692–696. In both books the builder's name and address are given, with his prices for compasses of two to seven dozen keys per Octave. Such instruments are indispensable for the scientific cultivation of music. It is also suited for mean-tone intonation.

[3] See the full explanations in my Helmholtz, pp. 656, 657, 783. Tuning by perfect intervals is the only system practicable without mechanical assistance. But even to tune the thirty-five Fifths of Appunn is impossible by ear alone. I find tuners have a difficulty with only eight notes, forming seven successive Fifths. But when the next eight notes are taken as major Thirds to these, all verified by forming Fifths with each other and producing correct differential tones with the original set, we may hope for some correctness. The only really satisfactory way of tuning is by calculating the pitch of each note, and then causing a set of forks, or Appunn reeds, to be constructed, each too flat by four vibrations, which can be done exactly by Appunn's tonometer. After tuning a note roughly to one of these, sharpen it till it beats four times in a second with the standard. Any temperament, even Helmholtz's, the best in existence, can thus be easily and perfectly realised note by note.

ON PHOTO-CHEMICAL PROCESSES IN THE RETINA

IN an article which lately appeared in NATURE (vol. xv., p. 308), I gave an account of certain very remarkable discoveries made by Prof. Kuhne, of Heidelberg, which added additional interest to the startling announcement contained in a recent communication made by Prof. Boll, of Rome, to the Berlin Academy, to wit, that the external layer of the retina is, during life, of a purple colour, which disappears at death, but which is, during life, continually being bleached by the action of light. In my first communication I stated that the account of Boll's researches which I was able to give, was only quoted at second-hand from Kuhne's paper, as the number of the *Proceedings* of the Berlin Academy containing Boll's communication[1] had not yet reached Manchester. Having now had the opportunity of reading that communication, I am able to state that the summary of it contained in my first article was correct in every particular. As the paper is, however, one of peculiar importance I propose, with the concurrence of the Editor of NATURE, to insert a *verbatim* but annotated translation of it in next week's number of NATURE.

It is with great surprise that I have heard that the prominence given to Prof. Kuhne's researches on the "Vision-purple" in my article in NATURE has given some pain to Prof. Boll, who probably feels some disappointment in not having been allowed to remain in sole possession of the promising field of research upon which he had entered. It is with still greater surprise, however, that I have read the remarks which Dr. Warlomont, editor of the *Annales d'Oculistique*, has added to the literal translation of my article which he has published in that journal,[2] and which follows a brief abstract of Boll's paper.

"Nous appelons toute l'attention de nos lecteurs sur les deux articles qu'ils viennent de lire, et qui signalent une découverte propre à révolutionner la physiologie de la rétine, à renverser quelques unes des idées reçues, à en affirmer beaucoup d'autres. *Tout le mérite de la découverte de la coloration propre de la rétine appartient à M. le professeur Boll, avec toutes ses conséquences*, dont M. Kuhne nous paraît s'être prématurément emparé. M.

---

[1] Monatsbericht der königlichen preussischen Akademie der Wissenschaften zu Berlin, November, 1876. Gesammtsitzung vom 23 November, 1876, S. 783–787.

[2] *Annales d'Oculistique*, tome lxxvii., Janvier-Février 1877, pp. 78-81.

Boll avait évidemment entrevu toutes ces conséquences, et il eut été de bon gout, nous semble-t-il, de lui laisser le temps de les dérouler à l'aise. C'est donc sans droit que nous voyons déjà, dès à présent, la presse parler, à propos de ce fait, des 'découvertes de MM. Boll et Kuhne' et le nom de ce dernier associé a celui du *seul inventeur*.

"Deux gamins suivaient un trottoir; l'un d'eux sifflaient un air, dont il n'était qu'à la moitié, quand le second se mit à la continuer: 'Une autre fois,' lui dit le premier le regardant très mécontent, 'tu voudras bien commencer toi-même.'"

If I quote the above sentences it is to show that they are as much opposed to truth as they are to the interests of science, or as they are repugnant to good taste. When a scientific man has published a discovery it is to the interest of the scientific world that all who will or can should be at liberty to repeat the experiments or observations which led to it; if other great discoveries are made by the new labourers it is to the interest of science that they be published.

In the particular case in point it would appear that Prof. Boll re-discovered (and, what is more, *appreciated the full value* of) a fact which had really been observed by some others (Leydig in 1857, and Max Schultze in 1866), but which had certainly not become part and parcel of the common stock of scientific knowledge, viz., that the rods of the retina are red, he observed that under the circumstances of his own experiments the colour faded at death, and arrived at the false conclusion that the colour was a function of the vital condition of the retina. He, however, observed the remarkable action of light in modifying the colour. "During life," he announced in his paper, "the peculiar colour of the retina is continually being destroyed by the light which penetrates the eye. Diffuse daylight causes the purple tint of the retina to pale. The more prolonged, dazzling action of the direct rays of the sun entirely destroys the colour of the retina. In darkness the intense purple colour is again restored. This objective alteration of the peripheral structures of the retina brought about by the rays of light undoubtedly occurs in the act of vision." This was the great discovery which Boll made, and with which his name will ever remain honourably connected. Although, however, he had been in full possession of the facts in the month of June of last year, when he demonstrated them to Professors Du Bois-Reymond and Helmholtz, and only published his paper in November, he did not succeed in making the discoveries with which, justly, the name of Kühne is now associated. Kuhne showed that if the retinal purple is usually destroyed at death, the result is attributable to the action of light, persistence of the colour being by no means necessarily connected with the living condition of the retina. In his beautiful and far-seeing discovery of the true function of the retinal epithelium cells as restorers of the vision purple, he was fortunate enough to make a discovery which it would be very bold for any one—even for Prof. Boll—to say he would have made, had time and opportunities been granted. In saying that Boll had discovered everything referring to the vision purple, M. Warlomont shows that he has not appreciated the fact that two great discoveries have been made, the second supplementing the first, and actually needed in order that the significance of the first should be appreciated.

But I trust that the readers of NATURE do not think that I wish to depreciate the researches of Prof. Boll whilst I act as the champion of one who needs no champion, seeing that he illustrates in himself the truth of the adage, "le grand mérite est toujours probe."

Prof. Boll must reflect that great discoveries are rarely completed by one man, and that it is no shame, and should be no cause of sorrow, to the true man of science, if the conception which he has tried to develop and which he has almost raised to the position of a truth by his own work, receives its final development through the strivings of a fellow-worker.

Abandoning the polemical discussion upon which I felt myself almost compelled to enter, I would give an account of the most recent results obtained by Kühne on the "Vision Purple," and published by him in the *Centralblatt für die medicinischen Wissenschaften* for March 17 (No. 11).

The purple colour of the retina is now shown to depend upon the presence of a substance which can be dissolved and separated in the solid form. The only solvent of the vision-purple as yet known is bile, or a pure glyko-cholate. The filtered, clear solution of the vision-purple is of a beautiful carmine-red, which, when exposed to light, rapidly assumes a chamois colour, and then becomes colourless. As long as it is at all red the solution absorbs all the rays of the spectrum, from yellowish-green to violet, allowing but little of the violet, but all the yellow, orange, and red rays to pass. Accordingly, bloodless retinæ spread out and placed in the spectrum, between green and violet appear grey or black.

Kuhne has exposed retinæ in different parts of a spectrum (obtained by allowing the sun's rays between eleven and one o'clock to fall through a slit 0·3 mm. wide upon a flint glass prism) in which Fraunhofer's lines were shown in great number and with great distinctness, and he has ascertained that in the yellowish green and green regions the vision-purple is bleached most rapidly; the action is less in the bluish green, blue, indigo, and violet; it is still perceptible in the orange and yellow, but not in the red or ultra-violet regions.

March 24 ARTHUR GAMGEE

OUR ASTRONOMICAL COLUMN

THE CAPE ASTRONOMICAL RESULTS, 1871 1873.—Mr. Stone has just circulated the results of meridional observations of stars made at the Royal Observatory, Cape of Good Hope, in the years 1871-1873. His present object has been not so much to furnish extremely accurate places of principal southern stars as to supply reliable positions of stars down to the seventh magnitude within 15° of the South Pole, and it is considered that this volume contains all Lacaille's stars in this region of the sky, and very nearly all sevenths not observed by him. It is the "first published instalment of the materials collected for the projected Catalogue." The separate results for mean R.A. and N.P.D. are given, with catalogues of places for the commencement of each year, the whole number of stars observed being about 1,400. Bessel's reduction constants are appended. This form of publication is perhaps sufficiently ample in the present day, though Mr. Stone alludes to a desire expressed by some astronomers to see the Cape observations printed in detail in the same manner as the Greenwich observations, a plan hardly practicable with the limited staff at his disposal, and which would involve very slow progress of the work with the resources of the Cape press. We are inclined to think that Mr. Stone exercises a wise discretion in limiting his volume to its present form, and thus assuring its comparatively early distribution in the astronomical world. As it is the volume is not produced without a considerable expenditure of time in the routine work of the reductions by the director himself.

VARIABLE STARS.—Mr. J. E. Gore, of Umballa, writes with reference to several stars which may prove to be variable:—(1) Lalande 14088 (Canis Major); this star was observed by Lalande, March 2, 1798, but the magnitude was not registered. It is marked of the ninth magnitude only on Harding's Atlas, but at the beginning of February in the present year Mr. Gore found it a little brighter than the sixth magnitude Lalande 14105, closely south of it, and "decidedly reddish." Argelander observed this star on December 23, 1852, and rated it 6·m. It is as not entered it. There appears a strong suspicion of varia- ility in this case. The star's position for 1877 is in R.A. h. 8m. 11s., N.P.D., 112° 27′·8. (2) Harding has a star 6 m., little south—preceding 40 Leonis Minoris, where in February st Mr. Gore found only a star of about 10 m. The position r 1800, reading off from the Atlas, was in about R.A. 157° 14′, .P.D., 63° 28′. There is no star here in Lalande or Bessel, or in the *Durchmusterung*. (3) About 1° 20′ south—following e 5 m. star 6 Canis Minoris, Harding has a 6 m. which on ebruary 4 was only 7½ m., being less than Lalande 14720, but righter than 14726; it was also less than the 7 m., about 30′ orth-preceding, which is underlined in the Atlas. This star ppears to have been observed as an 8 m. by Bessel (Weisse, II., 780), and is called 8·1 m. in the *Durchmusterung*; arding's place, however, requires a small correction in R.A. if essel's star is the one entered on his map.

BIELA'S COMET IN 1805.—Of the six observed returns of this omet that of 1805 was by far the most favourable for observa- on, and it approached very near to the earth as it sank below e horizon in Europe. At the beginning of December it exhi- ited a well defined planetary disc, according to Huth, sur- ounded by nebulosity 20′ in diameter; on the 8th Olbers found very distinct to the naked eye, and it remained visible without e telescope after the moon had risen, though at a south decli- ation of 23°; the small well-defined nucleus which he had marked in common with other observers he considered to be om twenty to thirty German miles in diameter. The comet as not observable in Europe after December 9, when it had ached 35½° S., but its after-course was a very favourable one r observation in the southern hemisphere, and, as Gauss marked at the time, if observations from thence could ave been obtained, it would have been practicable to deter- ine at this appearance the true form of the comet's orbit, which, s is well known, greatly exercised the calculators of that day, d particularly Gauss and Bessel. The comet's apparent track the southern heavens during the week subsequent to the ssation of observations in Europe was as follows, according a computation from the definitive orbit in 1805, given by the te Prof. Hubbard:—

0h G.M.T.	R.A. ° ′	N.P.D. ° ′	Distance from earth
Dec. 9	350 9	122 26	0·03681
10	344 49	134 38	0·03698
11	337 14	145 49	0·03893
12	326 3	154 53	0·04245
14	288 36	164 36	0·05276
16	250 5	164 23	0·06570

While referring to Biela's comet, it may be noted that if the eriod of revolution had been so lengthened in 1872, as to delay he perihelion passage until December 27, and thus bring the omet, or what remains of it, into close proximity to the earth n the night of the great meteoric display a month previous, its turn in 1879 will take place under nearly the same circum- ances as in 1832, when this body was the object of so much terest.

NOTES

WE understand that the Fullerian Professorship of Chemistry the Royal Institution is likely soon to be vacant by the resig- ation of Dr. Gladstone.

THE Council of the Yorkshire College of Science, Leeds, have ranged to purchase for 13,000*l.*, the Beech Grove Hall Estate, omprising about three and a half acres, and situated a mile om the railway stations, and close to the Grammar School. he total donations to the College have now reached 42,456*l.*

It has been decided that of the statues of the two Humboldts hich are to be erected in Berlin, that of Alexander will be given Reinhold Begens to execute, and that of Wilhelm to M. P. tto.

EVERY Thursday evening M. Leverrier receives at the Paris Observatory the provincial mayors who happen to be in Paris and explains to them the principles used by the Internationa service for telegraphing its warnings all over France.

THE dreaded *Hemileia vastatrix* which has hitherto been confined to the coffee plantations of Ceylon and Southern India has at last made its appearance in Sumatra, and in all probability will find its way before long to the neighbouring islands where coffee is grown.

THE Settle Cave Exploration Committee have issued a circular asking further contributions to enable them to carry on their important work. The valuable contributions already made, both to the historical and prehistoric ethnology of Britain are already well known, but there is good reason to believe discoveries even more interesting than any yet described remain to be made. The Committee are now working in beds of still earlier age than those hitherto explored, and hope by perseverance to throw some light upon the condition of Britain and its inhabitants during some of the most obscure ages of its geological history, the interest and value of the explorations increasing as the work is carried down into lower and earlier beds. Except at the entrance, the rocky floor of the cavern has not yet been found, and it is impossible to say what treasures to science and aids to the unwritten history of man still lie beneath the feet of the explorers. Though liberally assisted by a grant from the British Association, the Committee find themselves obliged to appeal to the public for further funds, without which this interesting work will speedily come to a premature end. We are sure that the wants of the Committee only require to be made known in order to be supplied. The sum required is, after all, very moderate, and we hope that many who read this will send what they can afford to the Hon. Treasurer, Mr. John Birkbeck, jun., Craven Bank, Settle, Yorkshire.

THE present French University will probably be divided into seven or eight local universities—Paris, Nancy, Lyons, Bordeaux, Lille, Marseilles, Montpellier or Toulouse. The competition between the two last has been so sharp that it has been suggested to divide between them the boon sought for. None of the existing Faculties in a large number of provincial towns will be suppressed, but will become affiliated to the nearest university. Each university will be governed by a special Senate or Council, and the Minister of Public Instruction will have authority over all of them. Fellowships will be created by the government, and will be distributed according to merit, after due examination.

ALL who have read Mr. Smiles's "Scottish Naturalist" must remember the crowning incident of Mr. Edward's exhibition of his collection in Aberdeen, when, in his despair at the total unsuccess of his venture, he rushed to drown his misery in the Dee. Mr. Edward was the chief actor in a very different scene in the same city on Wednesday week, when the proverbially hard-headed and close-fisted citizens of Bon Accord tried to make amends for their former almost fatal neglect, by presenting him publicly, through their Lord Provost, with an olive-wood casket containing 333 sovereigns. Mr. Edward, who seems to be taking his sudden eminence very quietly, thanked the subscribers in a short speech spoken in broad Doric and characterised by perfect naturalness and much humour—Scotch, perhaps, but not Highland, as some of the papers characterise it, for Aberdeen and Banff are as much "Highland" as Berwick and Newcastle. Mr. Edward made no allusion to his former treatment by the certainly not obtuse Aberdonians, who, after all, can't be blamed for not making it their business to discover and succour genius, though the gift of the "bit boxie," as Edward called it, looks very like as if meant to be a peace-offering.

THE papers read at the Iron and Steel Institute last week were all of a purely technical nature. The Bessemer Medal was presented by the President to Dr. Percy, who, in his reply, hinted that he is at present engaged in a large new metallurgical work. The Institute unanimously approved of the President's proposal to endeavour to obtain for the applied science societies a common permanent home. The Institute holds its autumnal meeting in Newcastle in September next, Norway having been abandoned, mainly, we believe, on account of the death of the Foreign Secretary, Mr. David Forbes. The Institute of Naval Architects, which also met last week in London, intends, we believe, to have for the first time an autumnal session, Glasgow and the Clyde having been selected for a visit next August.

THE following are the probable arrangements after Easter at the Royal Institution for the Friday evenings:—April 13, Dr. William Spottiswoode, Treas. R.S., Experiments with a Great Induction Coil; April 20, Mr. Frederick Pollock, M.A., Spinoza; April 27, Lieut.-Gen. Richard Strachey, R.E., F.R.S., The Physical Causes of Indian Famines; May 4, Rev. W. H. Dallinger, Researches on the Origin and Development of Minute and Low Forms of Life; May 11, Mr. D. Mackenzie Wallace, M.A., The Intellectual Movements and Secret Societies in Russia; May 18 [blank]; May 25, Mr. G. J. Romanes, The Evolution of Nerves and Nervo-Systems; June 1, Mr. Oscar Browning, The History of Education; June 8, Prof. Tyndall, F.R.S. The lecture arrangements are as follows:—Prof. J. H. Gladstone, F.R.S., Five Lectures on the Chemistry of the Heavenly Bodies, on Tuesdays, April 10 to May 15; Prof. Tyndall, F.R.S., Eight Lectures on Heat, on Thursdays, April 12 to May 31; Mr. Edward Dannreuther, Two Lectures on Chopin and Liszt, on Saturday, April 14, and Thursday, June 7; The Rev. A. H. Sayce, M.A., Three Lectures on Babylonian Literature, on Saturdays, April 21, 28, and May 5; Mr. Walter H. Pollock, M.A., Three Lectures on Modern French Poetry, on Saturdays, May 12, 19, 26; Mr. Charles T. Newton, C.B., Two Lectures on the Recent Discoveries at Mycenæ, on Saturdays, June 2 and 9.

THE first of the letters from Mr. Stanley, already referred to, is published in Monday's *Daily Telegraph*. It is dated Ujiji, August 7, 1876. Mr. Stanley has succeeded in circumnavigating Lake Tanganyika, exploring every indentation, and has made a material addition to our knowledge of this interesting body of water. As might have been expected, he has occasion to supplement and correct the observations of his predecessors. On the mistakes of the latter he dwells at quite unnecessary length, and discusses them in an aggravatingly apologetic tone, which becomes quite irritating, and does not in the least enhance the value of his own discoveries, which require no contrast to bring out their importance. The greater part of Mr. Stanley's letter is occupied with an account of his exploration of the Lukuga, Cameron's supposed outlet of the lake, but which Mr. Stanley maintains, on what appear solid grounds, to be merely a creek, the surface current of which is influenced by the wind. The most extraordinary result, however, of his examination of the lake and of the Lukuga, is that the former is rising with comparative rapidity—several feet since Cameron's visit—and that in the course of a very few years the Lukuga will develop into an effluent river, which will pass over the narrow mud-swamp that separates it from the river Luindi, flowing westwards to the Kamolondo River (it is not a lake), and thence to the Lualaba. Thus, what Cameron discovered, is not the present, but the future outlet of the Tanganyika, which hitherto Mr. Stanley maintains, has had no outlet. It must not be forgotten that this outlet has already been suggested by Livingstone; writing on October 8, 1871, about three years before Cameron's visit, he says, "It may be that the Loñgumba is the outlet of Tanganyika; it becomes the Luasse further down, and then the Luanio before it joins the Lualaba; the country slopes that way, but I was too ill to examine its source." The interest of geologists will certainly be excited, if not satisfied, by some references in Mr. Stanley's letter. He speaks of basalt and trap-rocks as occurring in the district, and of a large portion of the shores of the lake being composed of calcareous tufa; he also, somewhat more obscurely, refers to what he thinks may be volcanic cones; and states that considerable quantities of asphalte have been found floating on the waters of the lake. The theory which Mr. Stanley suggests as explaining the origin of this vast lake is of a sufficiently startling character. At no remote period, his hypothesis is, this part of Africa was a level table-land, westwards across which flowed the Malagarazi, and other rivers along a channel which is now occupied by the Lukuga and Luindi. But a great volcanic convulsion disturbed the region, sinking a deep hollow across the channel of the Malagarazi, which, with other streams, has ever since been filling up the bed. Mr. Stanley supposes he has come upon the lake when it has almost reached its highest level and is about to form an outlet by the Lukuga. Until more detailed and exact information reaches us concerning the structure of the country it would be premature to enter upon a discussion of this theory. Possibly Mr. Stanley's other letter, which will be published to-day, may enable geologists more fully to understand the conclusions at which the traveller appears to have arrived. In the north-west part of the lake, what Burton, Speke, and Stanley himself had thought to be an island, Ubwari, is really a peninsula. This is so indicated on Livingstone's map, with the remark that "a sandy spit connects Mozima Island and the shore."

ON Monday night Sir George Nares read a paper on some of the results and observations of the late Arctic Expedition. He discussed mainly the state of the ice and the limits of life in the most northern channels, and concluded by stating his conviction that unless the coast of Greenland extended beyond lat. 83° 20′, the Pole would not be accessible by the Smith Sound route. In the discussion which followed it was evident that a marked change of opinion has followed the results of the late expedition as to the best route to the Pole, the general opinion being that the Smith Sound route must be abandoned and that by Spitzbergen tried. This must no doubt be gratifying to Dr. Petermann, who has so long advocated the latter route, though this change of opinion is not at all inconsistent with the idea that much valuable scientific information is still to be obtained in the Smith Sound region. Admiral Richards expressed his decided conviction that sledge travelling is at an end, although he does not venture on the opinion that ships would actually *reach* the Pole by the Spitzbergen route. Now that the Presidential excitement is over in America, we may hope to hear of preparations being made for the establishment of the proposed Polar Exploring Colony.

THE National French Committee for the Exploration and Civilisation of Southern Africa has held its inaugural meeting. M. De Lesseps was appointed president. Two delegates were appointed to represent the French Section in the large Committee presided over by the King of the Belgians. They are MM. D'Abbadie, Member of the Institute, and Grandidier, the French explorer of Madagascar.

A SECOND Italian expedition for the exploration of Africa, has arrived at Suez.

THE *Honolulu Gazette* of February 28, reports an extraordinary volcanic outbreak in Kealakeakana Bay, near the entrance to the harbour. The eruption occurred at 3 A.M. on the 24th, appearing like numerous red, green, and blue lights. In the afternoon the water was in a state of peculiar activity, boiling and broken, and heaving up blocks of red-hot lava. A severe shock of an earthquake was felt by the residents of Kannakakiel during the night of the eruption.

MR. STANFORD has just published five more physical wall-maps of the series noticed by us some time since One chief feature of these maps is their exhibition of the orography of he respective countries, and we still think it would be an mprovement if the green could be dispensed with, as by gas-light it and the blue of the water are indistinguishable. We are glad to know, however, that means are being aken to remedy this in future issues, which we think may easily be done by the use of various shades of brown, when this is done he maps will leave little to be desired. They are those of North and South America, Africa, Scotland, and Ireland Each map is up to the latest date, and as physical maps, showing at the same time all the main natural and artificial features of the various countries, they must be quite a luxury to teachers and students, and to all who have to consult maps Africa especially is thoroughly satisfactory, and the compiler has wisely abstained from following any theory as to the course of the fragmental rivers west of Tanganyika, unless indeed one may be led to infer that he believes Lake Chad to be the receptacle of much of the drainage attributed to the Congo and the Ogove, if so, his theory, judging from the little that is known of the rivers themselves, and the various elevations of the region so clearly shown in the map, is quite as probable as any other

M LEVERRIER recently received a requisition from the Chamber of Commerce of Marseilles for the establishment of a special service for the Mediterranean coasts M Leverrier replied that the military government had established in Algeria a special meteorological service which pertinaciously refused to comply with the rules of the international service Consequently it was impossible for him to take advantage of Algerian observations so long as the special rules of the Algerian Meteorological Service were not altered, and without Algeria no reliable service could be established at Marseilles

THE opening meeting for 1877 of the West Riding Consolidated Naturalists' Society will be held at Pontefract on Easter Monday, April 2

WE have to record the death, on the 9th inst, of Dr John Scott Bowerbank, F R S, so well known from his important investigations on sponges Dr Bowerbank, born in 1797, in London, commenced life as a distiller, but being attracted by ological studies, subsequently devoted himself to them In 833 his first paper appeared in the *Entomological Magazine*, on the circulation of the blood in insects, from which time numerous papers by him have appeared in the *Philosophical Magazine*, the *Microscopical Journal*, the *Annals of Natural History*, the *Philosophical Transactions* and the *Proceedings* of the Zoological Society, upon the geological and structural relations of the Spongidæ, upon Pterodactyles, upon the structure of the shells of the Mollusca, and other less important points Dr. Bowerbank was a Fellow of many learned societies, with the foundation of more than one of which he was intimately associated, including the Microscopical, the Ray, and the Palæontological

THE tomb of Croce Spinelli and Sivel, the two *Zenith* aëronauts, will be inaugurated at Pere la Chaise on April 4

THE Annual Congress of the *Sociétés Savantes* will, as usual, take place at Paris on April 3 and following days

A WELL-ATTENDED *soirée* was given by the Northampton Naturalists' Society on Tuesday evening, March 6, in the Science and Art Rooms of the Grammar School A large and valuable series of natural objects were displayed, many of which had been collected during the past year. Amongst those especially worthy of note were a splendid collection of eggs, exhibited by the Rev. G. Nicholson; of butterflies, A. Perry, Esq, of plants, by G. C. Druce, Esq.; and of fossils, by W. Hull, Esq, and C. Jecks, Esq. The opening address was given by the Rev R Winterbotham, and short addresses were delivered in the course of the evening, by the Very Rev Canon Scott, the Rev. W F Aveling, and B Thompson, Esq. A beautiful collection of photographs was exhibited by R G. Scriven, Esq, and H Manfield, Esq, under the superintendence of the Rev S J. W Sanders, and the attractions of the evening were still further enhanced by the exhibition of several excellent microscopes, and other scientific instruments, kindly lent by various gentlemen of the town and neighbourhood.

IN "The Stone Age in New Jersey," by Dr C C Abbott (Washington, Government Printing Office), a valuable mass of facts on the various implements and weapons found in that state is collected and discussed, and illustrated by upwards of 220 cuts.

PART 4 of vol i of the *Proceedings* of the West London Scientific Association contains, among other interesting papers, one on Waves, by Prof F Guthrie, F R S

AMONG other matters that came before the German Ornithological Society at a recent meeting, mention was made by M Mutzel of an osprey which had lived eighty years in captivity on a farm near Neu Damm M Schalow took up the question whether in bad weather birds stop their migratory flight and return, or not. He affirmed that they either went on or remained for a time where they happened to be caught by the weather M von Schleinitz, of the *Gazelle*, stated that several individuals of *Chionis minor* had been brought from Kerguelen's Land to St Paul's It remains to be seen on later visits to St Paul's whether the birds will still be found there

M DECHARME has been studying the comparative pitch of sounds given by various metals and alloys Cylindrical bars of each metal were used, all of the same length and diameter (20 cm and 1 cm) The metals examined rank as follows in ascending series —Lead (fa$_3$, 690 vibrations), gold, antimony and silver (the same), tin, brass, zinc, copper, cast iron, iron, steel, aluminium (fa$_5$, 2,762 vibrations) From lead to aluminium there is thus an interval of two octaves No simple relations, sufficiently exact, were perceived between the pitch of the sounds and the physical or chemical properties of the substances M Decharme's results differ considerably from those of Wertheim

THE circumference (not the diameter) of the exploring balloons for meteorological purposes in Paris, referred to last week, is ninety centimetres They have an ascensional force of about thirty grammes

PROF GARROD illustrated his Royal Institution lectures by a colossal model of a disarticulated human *skull*, not *skeleton*, as we stated last week

THE additions to the Zoological Society's Gardens during the past week include a Puma (*Felis concolor*) from South America, presented by Commander Stanhope Grove, R N; a Nisnas Monkey (*Cercopithecus pyrrhonotus*) from Nubia, presented by Mr B. C Simpson, a Burrhel Wild Sheep (*Ovis burrhel*) from the Himalayas, deposited, two Hairy Tree Porcupines (*Sphingurus villosus*), two White-fronted Guans (*Penelope jacucaca*) from Brazil, two Blue-bearded Jays (*Cyanocorax cyanopogon*) from Para, two Turkey Vultures (*Cathartes aura*) from America, two Upland Geese (*Bernicla magellanica*) from Patagonia, three West Indian Rails (*Aramides cayennensis*), a Common Boa (*Boa constrictor*) from South America, two Great Cyclodus Lizards (*Cyclodus gigas*), a Stump-tailed Lizard (*Trachydosaurus rugosus*) from Australia, purchased, a Zebu (*Bos indicus*) born in the Gardens.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, January 18.—"Residual Charge of the Leyden Jar.—II. Dielectric Properties of Various Glasses," by J. Hopkinson. Communicated by Prof. Sir William Thomson, F.R.S.

The experiments appear to verify the fundamental hypothesis, viz., that the effects on a dielectric of past and present electromotive forces are superposable. Ohm's law asserts the principle of superposition in bodies in which conduction is not complicated by residual charge. Conduction and residual charge may be treated as parts of the same phenomenon, an after effect as regards electric displacement, of electromotive force. The experiments appear to show that the principle of Ohm's law is true of the whole phenomenon of conduction through glass.

February 1.—"The Meteorology of the Bombay Presidency," by Charles Chambers, F.R.S., Superintendent of the Colaba Observatory.

This work consists of four parts—the first dealing with registrations of meteorological phenomena at the Colaba Observatory during a period of twenty-seven years; the second with moderately full observations at five military stations in the Bombay Presidency during a period of nineteen years; and the third with large numbers of observations from civil hospitals and revenue stations, being those of selected registers extending over various periods from not less than a fortnight up to a number of years; in this part the phenomena treated are temperature of the air, winds, and rainfall only; and the extent of territory to which the observations refer includes the whole of the Presidency, Sind, and the western half of Rajputana. In the fourth part are discussed the general distribution (as regards both space and season) of temperature and rainfall, and the variations of the wind; first with respect simply to the physical geography of the country, and then in combination with certain theoretical views, the elucidation of which, by means of the dynamical theory of heat and the kinetic theory of gases, occupies much space.

February 15.—"On Stratified Discharges.—III. On a Rapid Contact-Breaker, and the Phenomena of the Flow." By William Spottiswoode, M.A., F.R.S.

In a paper published in the *Proceedings* of the Royal Society, vol. xxiii. p. 455, I have described a form of contact-breaker designed for great rapidity and steadiness of action. It consisted of a steel rod which vibrated under the action of an electromagnet. As regards sharpness of break and steadiness of the striæ, this instrument left little to be desired. But, as explained in the paper, an alteration in the current not only affected the steadiness directly, but also reacted on the break itself. In order to obviate this inconvenience, I devised another form of contact-breaker consisting of a wheel platinised at the edge, on which a platinum spring rests. In the circumference of the wheel a number (40 in the first instance) of slots were cut, and filled with ebonite plugs so as to interrupt the current. The breadth of the slots was about ·04 inch, and that of the teeth about ·5 inch. The wheel was connected with suitable driving gear, so as to give from 250 to 2,000 currents from the coil in each direction per second.

For some time the experiments were conducted with the platinum spring resting on the wheel; and the effects were varied by altering either the pressure of the spring or the velocity of the wheel; but it was found that actual metallic contact between the spring and wheel was not necessary, provided that a layer or cushion of conducting material were interposed. Such a layer was formed by a thin film of dilute sulphuric acid drawn out by a thread leading from a reservoir and resting on the wheel. The spring, which under these circumstances became unnecessary, was replaced by a point, the adjustment of whose distance from the wheel was simple. This arrangement gave excellent results, even when the number of currents per second was reduced in some cases to 250; added to which the unpleasant and disturbing noise of the friction was entirely avoided. Ultimately, however, I used a light wire in the place of the spring first mentioned.

With the contact-breaker here described effects similar to those produced by the rapidly-vibrating break were obtained. The striæ were formed in a regular manner, and advanced or receded, or remained at rest, in a column usually unbroken so long as the velocity of the wheel was maintained without change.

With a view of ascertaining the nature of the distinction between the ordinary and the steady striæ, careful observations were made with the revolving mirror. It having been noticed that when the wheel-break moved slowly, ordinary or irregular striæ were produced, and that when it moved rapidly, steady striæ resulted, it seemed probable that the latter effect might be due to the short time of contact, and to the consequent absence of many of the features described in Part II. of these researches. This is, in fact, identical with the suggestion there made, that the fluttering appearance was due to the unequal duration of the striæ themselves, and to the irregular positions of the points at which they are renewed at successive discharges of the coil. And such, in fact, proved to be the case; for as the speed of the wheel was increased, the duration of the discharges diminished; the image as seen in the mirror became narrower and simpler in its configuration, until, when the steady effect was produced, each discharge showed only a single column of striæ of a width proportional to the apparent width of the slit. The proper motion, implied by the inclination of the individual striæ to the vertical, was still perceptible, and was directed as usual towards the negative pole.

The phenomena of the flow may be considered to be due to the different positions taken up by the striæ in successive discharges. If in each discharge the striæ occupy positions in advance of those occupied in a previous discharge, the column will appear to advance; if the reverse be the case, they will appear to recede. If the positions remain unchanged, the column will appear stationary.

Experiments were instituted with a view of ascertaining the connection between the flow and resistance. Starting from a condition of current and break for which the striæ were stationary, it was found that an increase of resistance, introduced generally in the primary circuit, produced a forward flow, *i.e.* from the positive towards the negative terminal, while under similar circumstances a decrease of resistance produced a backward flow. Furthermore, if after producing a forward flow the resistance be continually increased, the flow, after increasing in rapidity so as to become undistinguishable by the unassisted eye, gradually appears to become slower, and ultimately to reverse itself.

Another form of contact-breaker was also occasionally used. The principle upon which it was based was the sudden disruption of a thin film of conducting liquid by a discharge between the electrodes of a circuit.

As soon as the current passes, the fluid between the plate and point will be decomposed, and electrical continuity broken. This done, the fluid flows back again, and continuity is restored.

February 22.—"On a New Form of Tangential Equation," by John Casey, LL.D., F.R.S., Professor of Higher Mathematics in the Catholic University of Ireland.

"Addition on the Bicircular Quartic," by A. Cayley, LL.D., F.R.S., Sadlerian Professor of Mathematics in the University of Cambridge.

Geological Society, March 7.—Prof. P. Martin Duncan, F.R.S., president, in the chair.—The Rev. Ebenezer Davies, William Davies, and Henry Davis Hoskold were elected Fellows, and George Garves Brush, Professor of Mineralogy in the Sheffield School of Science, Yale College, Newhaven, Connecticut, Prof. A. L. O. Descloizeaux, of Paris, Prof. E. Renevier, of Lausanne, and Count Gaston de Saporta, of Aix en Provence, Foreign Correspondents of the Society.—The following communications were read:—On the vertebral column and pelvic bones of *Pliosaurus evansi* (Seeley), from the Oxford Clay of St. Neot's, in the Woodwardian Museum of the University of Cambridge, by Harry Govier Seeley, F.L.S., Professor of Geography in King's College, London. In this paper the author described some bones obtained by J. J. Evans in the lower part of the Oxford Clay at Eynsbury, near St. Neot's. They consisted of thirty-seven vertebræ, twenty-one of which are cervical, and apparently complete that series. These presented the characters of the cervical vertebræ of the typical Pliosaurs of the Kimmeridge Clay. The remains of the pelvis included a pubic bone showing a close correspondence in form with those of the Pliosaurs of the Kimmeridge Clay of Ely, and an ischium.—Supplementary notes on the fauna of the Cambridge Greensand, by A. J. Jukes-Browne, F.G.S. This paper was supplementary to one communicated to the Society by the author in 1875, in which he maintained that the Upper Greensand does not extend further in a northwesterly direction than West End Hill, near Cheddington, in Buckinghamshire, that the Cambridge Greensand is merely a nodule-bed at the base of the Chalk Marl, resting unconformably upon denuded Gault, to the upper part of which the greater portion of the fauna belongs, and that the emainder of the fauna, belonging to the deposit itself, consists of pecies proper to the Chalk Marl rather than to the Upper Greenand. The object of the paper was to indicate certain additions to, nd corrections in, the list of fossils upon which these conclusions ere supported. The following Gault species were indicated as ot previously identified in the Cambridge Greensand:—*Nautilus rcuatus*, Desh.; *N. inæqualis*, Sow.; *Turrilites elegans*, D'Orb.; (?) . *emericianus*, D'Orb.; *Ornithopus histocheila*, Gardn.; *rachystoma angularis*, Seeley; *Turbo pictetianus*, D'Orb.; *leurotomaria regina*, Pict. and Roux; (?) *P. itieriana*, Pict. and oux; *Pecten raulinianus*, D'Orb.; *P. subacutus*, D'Orb.; and *ima rauliniana*, D'Orb. The author described as new speies:—*Turrilites nobilis*, *Nautilus*, sp. nov., *Natica levistriata*, *erita nodulosa*, and *Lima interlineata*, and noted several corections in the nomenclature adopted in his former list.—On the eds between the Gault and Upper Chalk, near Folkestone, by . G. Hilton Price, F.G.S. The author described the characters resented by the beds between the Gault and Upper Chalk near olkestone, indicated the fossils contained in them and their range this division of the Cretaceous series, and discussed the classication of the deposits and their equivalence with those recognised y other writers.

Anthropological Institute, March 13.—Mr. John Evans, .R.S., president, in the chair. The President exhibited a hafted ronze celt, with its original wooden handle (which was covered ith brass plates), found near Chiusoe.—Mr. Biddulph Martin xhibited some pottery, shells, and other remains from a supposed kitchen midden at Smyrna, which, the president pointed ut, was of comparatively modern date. Some flint arrow-heads, rapers, &c., from Ditchley, were exhibited by Capt. Dillon.—Mr. Hyde Clarke then read a paper on the Himalayan origin of he Magyar. The object of this paper was to show that lanuages of Nepal, &c., in the Himalayas, formerly called Subravidian, are to be classified as Ugrian, and include Finnish, agyar, Lap, and Samoyed affinities. In connection with the xtension of the Ugrian area and possible centre to High sia, the author entered on the question of the origin of e Magyars. After referring to the Magyar, Khun, &c., the Himalayas, he proposed as a solution that the attack n Pannonda had been made by Avar or Khunzag traders om the Caucasus speaking a Vasco-Kolarian language, and ith a main body of Ugrians, the language of whom prevailed n the extinction of the former. The author dissented from the grian classification of Accad and Etruscan, giving other preistoric examples for the Accad words in Lenormant, claimed y him and M. Sayous as Ugrian. Messrs. Bertin, Salymos, ees, the President, and others, took part in the discussion.—he Director then read the following papers by Mr. Hector cLean:—On the Scottish Highland language and people, and n the Anglicising and Gaelicising of surnames.

Physical Society, March 3.—Prof G. C. Foster, president, the chair.—The following were elected members of the Society:—Mr. J. A Fleming, Mr. P. le Neve Foster, and Mr. S. Hall.—Prof. Foster showed experimentally the polarisation of heat ays, employing two large Nicol's prisms of $2\frac{5}{8}$ inch aperture, and thermopile surrounded by a double jacket and connected with Thomson galvanometer as arranged by Mr. Latimer Clark for howing very slight indications to an audience. When the prinipal sections of the prisms were at 90° to each other only a light movement, doubtless due to an initial heating of one side f the pile, was observed; and the amount of the deflection was ound to increase steadily up to about sixty divisions on the ale as the above angle was diminished. Prof. Foster exhibited e results of experiments made to determine the intensity of a ource of heat by this means, and they were very concordant.—Mr. Latimer Clark then explained the arrangement of the galanometer used. The image of an arrow head or other form of ndex projected by means of a limelight at the further end of the oom traverses a telescopic object-glass about two feet distant from he lamp and falls on a square silvered plate of glass suspended rom the needle of a Thomson galvanometer, which is rendered teady in the ordinary way by a platinum spade in water. The eflected image then traverses the whole length of the room and lls on a large scale placed in front of the audience, and, by such n arrangement, the instrument may be at any distance from the ale, and yet the image will not be unduly magnified. A ethod is employed for bringing the needle rapidly to rest. A w thermo-electric couples are placed above the lamp chimney, nus being kept constantly hot, and the terminals are united by wire which is coiled several times round the galvanometer; the circuit is closed at the moment when this subsidiary current will tend to neutralise the motion of the needle.—Prof. Guthrie incidentally mentioned that the difficulty experienced in separating the fibres of a cocoon thread may be obviated by boiling the thread in carbonate of potash, when the natural resin is saponified and the fibres may be easily split.—Mr. Wilson then explained some difficulties he has met with in constructing a Holtz electrical machine, especially with reference to the windows and armatures, and he exhibited two machines which he recently made, from one of which a spark five or six inches in length can be obtained; this apparatus is so arranged that it can be taken entirely to pieces and packed in a very moderate-sized case. After carefully pointing out the difference between an ordinary machine and the Birch machine, he proceeded to consider the theory of the Holtz machine, and explained how he was led to construct an instrument in which there were no windows, the armatures being placed on the face of the fixed plate next to the moving plate, but the result was not satisfactory. He then made the larger machine provided with six fixed and six moving plates, and the windows were replaced by holes $\frac{1}{8}$ inch in diameter traversed by short pieces of tape glued to the paper armatures. The initial charging of the armatures is effected by means of a disc of ebonite fixed to the main axis of the machine, which is lightly held by the fingers and caused to rotate. Electricity is thus generated and points projecting towards it and communicating with points in the neighbourhood of the armatures cause them to become charged; after this, electricity is generated with great rapidity.—Prof. MacLeod gave some details concerning the working of a large Holtz machine which he drives by a turbine. He finds that after it has been in action for nearly an hour a much greater force is required to work it, and he suggested a theory in explanation of this phenomenon. By keeping the machine dry under a glass shade reversing effects are entirely avoided as well as the necessity for varnishing the plates.

Entomological Society, March 7.—J. W. Dunning, F.L.S., vice-president, in the chair.—Mr. Douglas exhibited a specimen of the Longicorn Beetle, *Monohammus sutor*, brought to him alive, having been captured in a garden in the Camden Road; also a melanic variety of *Orthosia suspecta*, taken at Dunkeld.—Mr. Hudd exhibited some interesting varieties of British Lepidoptera taken near Bristol and in South Wales; amongst them were *Lycæna alexis*, *Sphinx ligustri*, and *Boarmia repandata*, the latter a black variety.—Mr. Champion exhibited specimens of *Cardiophorus rufipes*, a species new to Britain, taken by Mr. J. Dunsmore, near Paisley; also a British example of *Aphodius scrofa* from the collection of Mr. Dunsmore, who unfortunately had no note of its locality.—The Secretary exhibited a specimen of an Isopod Crustacean which had been forwarded to him by Mr. J. M. Wills, surgeon, s.s. *City of Canterbury*, who stated that it was found occasionally parasitic on the flying fish, and generally close to the pectoral fins. Mr. Douglas read an extract from a letter from Dr. Sahlberg, who had recently returned from an excursion to the neighbourhood of the Yenisei River and the extreme north of Siberia, from whence he had brought a large number of insects, principally Coleoptera and Hemiptera. Amongst the Hemiptera were one *Aradus*, one *Calocoris*, two *Orthotylus*, one *Orthops*, one *Pachytoma*, one *Anthocoris*, one *Acompocoris*, five *Salda*, and one *Corixa*, which appeared to be hitherto unknown. The species of *Salda* were from the extreme north, in Tundra territory.—The Secretary read a paper by Mr. W. L. Distant, on the geographical distribution of *Danais archippus*, a North American butterfly which has recently been taken in the south of England.

Mineralogical Society, March 14.—Mr. H. C. Sorby, F.R.S., president, in the chair.—The following papers were read:—On a simple method for roughly determining the index of refraction of small portions of transparent minerals, by H. C. Sorby, F.R.S.—This can be effected by having a small graduated scale attached to the body of the microscope, by means of which the thickness of the crystal and the displacement of the focal point can be easily measured. From these data the index of refraction can be at once calculated with sufficient accuracy to make the result valuable in determinative mineralogy.—On a serpentine from Japan, by A. H. Church, M.A.—Notes on Vauquelinite from Scotland, and Cantonite or Harrisite from Cornwall, by Thomas Davies, F.G.S.—On an easily constructed form of reflecting goniometer, by S. B. Hannay, F.C.S.—On a peculiar form of quartz crystals from Australia, by Rev. J. M. Mello, F.G.S.—On certain black quartz crystals from Boscaswell Down, Cornwall, by

J. H. Collins, F.G.S. The black colour is due to minute crystals of schorl.—On quartz including oxides of iron, by William Vivian.—On the magnetic constituents of minerals and rocks, by J. B. Hannay.—On the water contained in minerals, by J. B. Hannay.—On the Nordenskjöld iron masses from Greenland, by K. T. V. Steenstrup, translated by Mr. Rohde, one of the Danish expedition. The author contends that the iron is a natural constituent of the basalt, and not of meteoric origin.

Institution of Civil Engineers, March 13.—Mr. George Robert Stephenson, president, in the chair.—His Majesty the King of the Belgians was elected by acclamation an honorary member. The paper read was on the transmission of motive power to distant points, by Mr. H. Robinson, M. Inst. C.E.

MANCHESTER

Literary and Philosophical Society, December 4, 1876.—Charles Bailey in the chair.—Notes on a botanical excursion in the Aberdeenshire Islands in July, 1876, by Mr. Thomas Rogers.

December 26, 1876.—A notice of some organic remains from the schists of the Isle of Man, by E. W. Binney, president, F.R.S., &c.

January 9.—E. W. Binney, F.R.S., F.G.S., president, in the chair.—On the poisonous properties of yew-leaves, by James Bottomley, D.Sc.—On the luminous sulphides of M. Ed. Becquerel, by William Thomson, F.R.S.E.—On the types of compound statement involving four classes, by Prof. W. K. Clifford, M.A., F.R.S. Communicated by Prof. W. S. Jevons, M.A., F.R.S.

January 23.—Results of the monthly observations of the magnetic dip, horizontal force, and declination made at the magnetic observatory of the Owens College, from January, 1874, to December, 1876, inclusive, by Prof. Thomas H. Core, M.A. Communicated by Prof. Balfour Stewart, LL.D., F.R.S.

GENEVA

Physical and Natural History Society, February 1.—M. Alphonse Favre presented a geological map of the Canton of Geneva on the scale of $\frac{1}{25000}$, intended to enlighten agriculturists on the management of the soil for their various crops.—Prof. Schiff described the researches he had made on the properties of nicotine as a poison, and on the part played by the liver in such poisoning.

February 15.—M. E. Renevier, professor at Lausanne, exhibited to the Society his geological map of Vaudoises Alps, on the scale of $\frac{1}{50000}$, as also several sections which complete it. It includes principally the mass of the Diablerets and the neighbouring spurs on the right bank of the Rhone.—Prof. Wartmann showed a small apparatus intended to prove the impulse which an induction spark in a rarefied gas is capable of giving in the direction of its length.—M. Raoul Pictet described various experiments made by himself, and proving the great facility with which sulphuric acid is diffused through caoutchouc.

PARIS

Academy of Sciences, March 19.—M. Peligot in the chair.—The following papers were read:—Observations of temperature at the Museum of Natural History, during 1876, with electric thermometers placed at depths of 1 metre to 36 metres under ground, as also in air and under grass-covered and bare ground, by MM. Becquerel. The results are nearly the same as were obtained before. General Morin, remarking that at only 10 to 12 metres depth he found a nearly constant temperature of 11°, suggested the use of underground air, drawn through pipes, to produce a constant temperature where it might be required (as for conservation of meat, &c.)—On the decomposition of bioxide of barium *in vacuo*, at the temperature of dark red, by M. Boussingault. The whole of the oxygen could be thus extracted. On removing the source of heat the bioxide was reconstituted. Bioxide of barium, then, cannot exist *in vacuo* at a dark red heat.—Physical and mechanical actions of incandescent and strongly compressed gases from combustion of powder. Application of the facts to certain characters of meteorites and bolides, by M. Daubrée. The facts of experiment seem to explain:—(1) the alveolar cavities or cupules in meteorites; (2) the peculiar clouds, smoke, or dust, which follow the disappearance of the incandescent mass; (3) the dust of cosmic origin which is thus expanded in our atmosphere, not only by combustion and volatilisation, but by pulverisation at a high temperature.—On the fundamental invariants of the binary form of the eighth degree, by Mr. Sylvester.—On the palæontological origin of trees, shrubs, and bushes indigenous in the south of France, that are sensitive to cold in severe winters, by M. Martins. He considers them to be the survivors of the flora which covered those parts during the Tertiary period. We have here plants exotic as regards *time*, while other plants are exotic as regards *space*. At Montpellier and Marseilles the annual average of absolute minima of temperature are − 9·23° and − 5·95° respectively.—On the experiments made at Prégny by the canton of Geneva, by M. Bouley. He had erroneously given the Swiss Federal Government the credit of the experiments.—M. Hebert was elected member in the section of Mineralogy in room of the late M. Ch. Sainte-Claire Deville.—On the phosphorescence of organic bodies, by Mr. Phipson. *Apropos* of a recent note, he calls attention to his memoir on noctilucine, the first organic body known to be phosphorescent by slow oxidation, like phosphorus in the mineral kingdom.—Propositions of algebra and geometry deduced from consideration of the cubic roots of unity, by M. Appell.—On the curvature of surfaces, by M. Serret.—On a problem comprising the theory of elimination, by M. Ventéjols.—On the suspension of water in a vessel closed below by a tissue with large meshes, by M. Plateau.—On a singular fact of production of heat, by M. Olivier.—On the reform of some processes of analysis used in the laboratories of agricultural stations and observatories of chemical meteorology; first part, Ammonimetry, by M. Houzeau. His method is to use stable vinous red litmus, which will reveal free ammonia in solution in water containing only $\frac{1}{2000000}$ and even $\frac{1}{3000000}$ of its weight of that substance. The proportion is determined by pouring into the litmus-coloured liquor a weak titrated acid till disappearance of the original red.—On the preparation of crystallised acetate of magnesia, and on the fermentation of this salt, by M. Patrouillard.—On a simple mode of production of certain mono-, bi-, and tri-chlorised acids, by M. Demarçay.—Transformation of normal pyro-tartaric acid into dibromo pyrotartaric and dibromo-succinic acids, by MM. Reboul and Bourgoin.—Action of chlorochromic acid on anthracene, by M. Haller.—On the constitution of pseudo purpurine; continuation of researches on the colouring matters of madder, by M. Rosenstiehl. Pseudo-purpurine is sufficiently unstable to produce by its partial destruction the other colouring matters in madder (alizarine excepted).—Experiments on muscular tonicity, by M. Carlet. A muscle generally contracts after section of a nerve, before final relaxation. This is due, the author says, to the increased excitability of the nerve. In rare cases, where the nerve is cut without excitation (at one of Bridge's "nodes" perhaps), relaxation begins at once. Elongation immediately after section is due to *rigidity* not *flaccidity*, the extensor muscles being stronger than the flexors.—On the modifications in the egg of phanerocarpous medusæ before fecundation, by M. Giard.—On the age of elevation of the Margeride, by M. Fabre.—On the formation of thunderstorms, by M. Zundel.—Clinical and therapeutical researches on epilepsy and hysteria, by M. Bourneville. From two analyses of portions of liver from an epileptic patient who had taken, in four months, forty-three grammes of ammoniacal sulphate of copper (and died of pulmonary tuberculosis 2½ months after cessation of the treatment), the total amount of copper in the liver was estimated at 236 milligrammes and 250 mm.

THE GEOLOGICAL SURVEY OF OHIO

Report of the Geological Survey of Ohio. Vols. I. and II. Geology, and I. and II. Palæontology. (Columbus, Ohio: Nevins and Myers, State Printers, 1873-5.)

IN the reports of American Scientific Surveys we have become accustomed to find that the results are as new and interesting as the methods of working are original and ingenious. Few of the States are more richly endowed with the elements of prosperity and stability than Ohio, and yet she has but recently come into the field with her contribution to the knowledge of her own geological structure and natural history. It is gratifying to know that this contribution can well afford to be tried by the high standard attained by the reports already issued by many of the neighbouring States.

The survey just completed is technically the second but practically the first geological survey of Ohio, taking into consideration how long ago the former survey was disbanded, and how short was its term of life.

In 1836 the legislature appointed a committee consisting of Dr. Hildreth, Dr. Locke, Prof. Riddell, and Mr. Lapham, to report on the best method of obtaining a complete geological survey of the State, and to estimate the probable cost. In the summer of that year three of these gentlemen made reconnaissances, while the fourth analysed iron ores and limestones. A year after the appointment of the committee, the legislature, on its recommendation, created a geological corps, comprising a state geologist (Prof. W. W. Mather) and six assistants. During the summer of 1837, the State geologist and three assistants prosecuted geological explorations, two assistants being absorbed by zoology and topography. Next summer the survey was continued on a similar footing, but a financial panic having broken out, "the legislature of 1838-39 made no appropriation for the continuation of the geological survey, and it was at once suspended." In spite of the disadvantages under which this early survey laboured in being almost entirely without palæontological assistance, its two annual reports were much appreciated, and the short-sighted economy that led to its disbandment was soon regretted by the citizens of the State. Although several attempts were made, what with the defalcations of a State treasurer, the building of a costly state-house, and the great Civil War, Ohio was not financially in a position to re-establish a geological survey till the year 1869.

According to its constitution, this new survey was to be begun (and was begun) on June 1, 1869, and was to be finished in three years. It was required "to make a complete and thorough geological, agricultural, and mineralogical survey of each and every county in the State." To the chief geologist the act of legislature allowed three assistants, and a number (generally eight or nine) of temporary local assistants were employed and paid from a fund provided for "contingent expenses." One of the assistant geologists was to be a chemist. We can see in the organic law of the survey no provision for a palæontologist, and presume that the appointment of that officer was authorised by one of the subsequent Acts of Appropriation. At any rate, Prof. J. S. Newberry, having been appointed chief geologist, conjoined with himself two assistants, a palæontologist and a chemist, and it can hardly be disputed that this was the best possible disposition of his forces, however desirable a large increase in the number of assistants might have been.

Such then is the scale on which a State, having an area of 39,904 square miles, plans its geological survey. Considering the number of working days in a year, the number of the field geologists, and the area of the State, many will not hesitate to decide that the character of a reconnaissance was stamped on the survey by its framers from the beginning. But it should not be forgotten that there are circumstances which render the geological mapping of Ohio exceptionally simple. The Palæozoic rocks which form its framework are so undisturbed, that over areas of sometimes thousands of square miles, only one formation makes its appearance at the surface, and outcrops are therefore little more than contour lines. We are accustomed in this country to think of "dip" as something visible to the naked eye, and measurable with a pocket clinometer; and as producing, by its relation to the contour of the ground, endless variety in our geological boundary-lines. In Ohio it appears that the method of ascertaining the degree of dip is to set up half a dozen or so of trigonometrical stations, several miles apart, and carefully take the levels of the outcrop at the several points. So far as we have noted in reading the Reports, there is not a dip in the whole state that would make an appreciably stiff railway gradient. Then we are informed by Prof. Newberry that "faults in which the displacement amounts to more than one foot are very rare in the Ohio Coal-field," and that the greatest known has a down-throw of 3 feet. In Europe the complications produced by faults frequently add the excitement of a puzzle to the labours of the field-geologist and just as often leave an irritating element of uncertainty to embitter the satisfaction with which he is apt to regard his finished work. Then again there are no igneous rocks in Ohio and no metamorphic rocks in the ordinary sense of the term. Indeed it may almost be said that over large tracts there are no rocks at all. Thus in one county, "consisting of twelve towns," *i.e.* 432 square miles—exactly the area, let us say for comparison's sake, of a whole sheet of the 1-inch Ordnance Map of Scotland—the rock is deeply covered with drift and is never seen, having been reached by boring at one point only, at a depth of 110 feet.

On the other hand, the very simplicity of the geology of the State makes it a typical region by which other lands may measure their geological scale, and on this account it becomes necessary to survey it with minuteness and care. If Ohio renders this service to the neighbouring states, each of these has already given an equivalent. As it happened, when the late survey was begun, Ohio was almost surrounded by a belt of states which had got ahead of her in the work, and whose completed labours greatly simplified her task, at the same time that they presented discrepancies which could only be reconciled on her neutral ground.

Although it was originally intended that the survey should be finished in three years, its field work lasted for five, the average annual cost being $17,355.

We have now before us a portion of the final Reports ot the Survey. These consist of two volumes of Geology, two of Palæontology, and two of Sheets of Vertical Sections (a sheet of Vertical Sections, by the way, is called a "Map" the American language). Besides these there have already been published three volumes of Annual Reports of Progress, two of them containing Accounts of the Geology of Counties, in substantially the same form as that followed in the Final Reports. A third volume of Geology, to comprise by far the most important counties in the coal-field, is ready for publication and "awaits the action of the Legislature." "The matter for the third volume," says Prof. Newberry, "has been, to a considerable extent, prepared since the appropriations for the salaries of the geological corps were discontinued. Much of it is, therefore, a gratuitous contribution with which the corps should be credited when a comparison is made between the value of their services and the compensation they have received." Materials for a third volume of Palæontology have been accumulated, but the chief geologist does not speak confidently of his chances of getting a grant to defray the cost of its publication. It would be a thousand pities that the State which has been at the expense of collecting this information should not secure the credit and advantages involved in its official publication. Otherwise, the materials will have to be hunted through the transactions of American and foreign societies, and will be as good as half lost.

A volume on Economic Geology is far advanced, but six months' time and from $4,000 to $5,000 are estimated as necessary to complete it. A volume on the Zoology and Botany of the State is also ready for publication at a trifling expense.

Lastly, "a general geological map of the State can be prepared at a cost not greater than $1,500."

It will thus be seen that there still remain to be published some of the absolutely essential parts of the work of the survey. For scientific purposes the geological map stands first in point of necessity. It is not too much to say that it is chiefly by its general geological map that the survey will be known and judged abroad. It is indeed possible to construct a sort of geological map from the county and other sketch maps and information scattered through the volumes, and the writer has done so for his own satisfaction and as a means of mastering the Reports. But we can affirm with confidence that this is a labour that few will undertake, and which it would be much better that the officers of the Survey should perform once for all. The county maps, as will readily be understood from what has been said about the undisturbed condition of the rocks, are simplicity itself, being generally rectangles, crossed on an average by three boundary-lines inclosing four dabs of colour. But the general map will doubtless contain outcrops of coal and ironstone seams, the positions of oil and brine wells, fossil localities, and numerous other details, whose bearings can only be properly estimated when seen in the mass, or which it is the function of a geological survey to record, since for economic purposes the registration of all mining enterprises, whether failures or successes, is of permanent value. In her own interests we cannot doubt that the State will at once provide for the publication of the volume on Economic Geology, depending as she does to a large extent at present, and as she is certain to do still more in the not very distant future, on mining industries.

If we may judge of the promised volumes on Palæontology, Zoology, and Botany from the results already before us, we are confident that their publication will place scientific workers in Europe as well as America under a debt of gratitude to Ohio, and we trust they will not be withheld.

It appears that when the first volume of the Final Report was ready, the Legislature ordered that the edition should consist of four times the number of copies estimated by the chief geologist as likely to meet the public demand. It is to be hoped that a similar spirit will induce them to complete the Survey's publications. A survey by four geologists, in three years, of a country one-third larger than Scotland, must soon have been felt to be impracticable, more especially if it was meant that the whole of the surveyor's labours, writing as well as field work, were to be compressed within the three years over which it was originally planned that their salaries were to be continued. A conscientious desire to finish their work having kept the officers of the survey in the field (doubtless with the approval of the legislature) for two years beyond the estimated time, the results of their zeal and skill ought not to be thrown away. There need be no hesitation in admitting Prof. Newberry's assertion, when he "claims" "that an honest and energetic use was made of the time and money expended on the Survey, and that its fruits will be worth much more than their cost to the people of Ohio."

We must refer the reader to the Reports themselves for the valuable information with which they are crowded. We can only notice briefly the leading scientific results, and some points of more than usual interest.

The rock-formations exposed in Ohio form an almost unbroken series, ranging from Lower Silurian to Carboniferous, inclusive. The principal feature in the geology of Ohio is undoubtedly the "Cincinnati axis," and to this the late Survey has justly devoted much attention. This great arch, passing through Cincinnati and the west end of Lake Erie, brings to light the oldest rocks of the State. It has hitherto been understood to be a minor flexure of the same date as the elevation of the Appalachian chain, to which it is, roughly speaking, parallel. But the investigations of the recent Survey have proved it to be much older. While the Appalachian chain does not appear to have been elevated until after the Carboniferous epoch, Prof. Orton has made the discovery that a large portion of the Cincinnati region was a land-surface, and suffered erosion towards the close of Lower Silurian times. The denudation of a synclinal arch and consequent exposure of deep-seated strata would not, of course, alone suffice to prove this; but the insular character of the Lower Silurian land of Cincinnati is rendered certain by the occurrence of pebbles derived from it in merates at the base of the Upper Silurian deposits, and by the manner in which calcareous strata of that age, as as well as some Devonian limestones, thin out on approaching what must have been the shores of the island. It is not so clear whether the island was or was not entirely submerged in Devonian and Lower Carboniferous times. On the other hand, Prof. Newberry and his colleagues have satisfied themselves that during the deposition of the Upper Carboniferous or Productive Coal-measures, the Cincinnati land formed a barrier between the marshes of Ohio and Indiana; in other words, that the Alleghany and Illinois Coal-fields were never united, at least as far south as Alabama and Arkansas, where wide-spread tertiary deposits obscure all evidence bearing on the point.

"It is important," says Prof. Orton, "to mark the following fact distinctly, viz., that there is quite a broad tract at the summit of the fold in which the beds have but little dip. It is hard to speak of an axis without involving the idea of a line, but there is probably no part of this region of less than a score of miles that deserves, by way of excellence, the name of the Cincinnati axis. In other words, this fold has a broad and flat axis, rather than a linear one." The elevation has been so gentle and so gradual that direct visible evidence of unconformable succession is hardly to be expected.

No reader will fail to be struck by the important place accorded to chemical geology in the Reports. This portion of the work has been done mainly by Prof. Wormley, and adds greatly to the value of the survey as a whole. He has not confined his investigations to minerals of immediate economic importance, but has placed on record many analyses that must for a long time to come be drawn upon with advantage as the development of the resources of the State goes on. Especially as regards limestones and cement-stones and the amount of sulphur in the various coal-seams, very complete and useful information is given.

More than a score of counties "lie wholly within the limits of the productive coal-measures," and of nearly as many the geological surveyors pronounce without hesitation that "the soil will necessarily always be the source of their greatest material wealth." It sounds strange to hear already from such a rich agricultural district as Western Ohio the cry of exhaustion of the soil, but as all the surveyors without exception sound the note of warning against unskilful farming, it is evident that ere long science will have to be called in to assist nature if the productiveness of the State is to be maintained.

Although doubtless to be discussed more fully in the volume on economic geology, the coal and ironstone seams of the great coal-field, and the salt, oil, and gas industries receive much attention in the various county Reports. Prof. E. B. Andrews furnishes a chapter on coal which is full of interesting facts. Mr. M. C. Read gives a plan of a coal-mine in Trumbull County, which shows how very local was the formation of the seam. The coal thins out on every side, and presents the outline of a long winding swamp with branching creeks.

The importance of the ironstone beds in Ohio is well known. A black-band in Tuscarawas County locally attains, according to Prof. Newberry, a thickness of 12 feet.

The excitement caused by the discovery of the oil-wells of Pennsylvania and Ohio will yet be fresh in the memory of our readers. The conditions under which petroleum occurs are well illustrated in the Reports. There must be a mass of carbonaceous shales from whose organic contents the hydro-carbons are slowly distilled, and an overlying porous rock for the storage of the products—best of all a jointed sandstone with an impervious stratum for a roof—if dome-shaped so much the better. When these conditions are present the oil is ready for the fortunate landowner, and his luck is the greater if he happen to strike a joint where a quantity can collect. So well is this now understood that when a well shows symptoms of giving out, a torpedo is exploded in it to loosen up the rock and open out the way to neighbouring fissures. Carbonaceous shales, yielding oil, are met with at various horizons from the Huron (Devonian) upwards.

Carburetted hydrogen gas occurs under similar conditions and is now expressly bored for. The town of Fredonia, N.Y., has been lighted up with natural gas for more than forty years. In Knox County, Ohio, two wells were sunk to the Huron shale. "At a depth of about 600 feet, in each well, a fissure was struck from which gas issued in such volume as to throw out the boring tools and form a jet of water more than 100 feet in height. . . One of these wells constantly ejects, at intervals of one minute, the water that fills it. It thus forms an intermittent fountain 120 feet in height. The derrick set over this well has a height of 60 feet. In winter it becomes encased in ice, and forms a huge translucent chimney, through which, at regular intervals of one minute, a mingled current of gas and water rushes to twice its height. By cutting through this hollow cylinder at its base and igniting the gas in a paroxysm, it affords a magnificent spectacle, a fountain of mingled water and fire which brilliantly illuminates the icy chimney. No accurate measurement has been made of the gas escaping from these wells, but it is estimated to be sufficient to light a large city." Unfortunately there is no large city to light.

Geologists had a right to expect from Ohio an important contribution to their knowledge of the Glacial period, and Prof. Newberry and his colleagues have not disappointed them. The chief geologist sums up the results of the Survey in a masterly essay, and it is satisfactory to find that his views to a great extent corroborate the conclusions at which glacialists in Europe have arrived. Want of space compels us to allude to these in the briefest manner. The cold came on at a period when the land stood considerably higher than at present, as is proved by numerous river channels deeply buried beneath the drift. A wide-spread boulder clay or hard-pan, the product of a land ice-sheet radiating from the Canadian Mountains marks an early, and the greatest, development of the cold. A subsidence followed on the retreat of the ice-sheet, and a stratified clay was deposited over low-lying portions of the hard-pan. Then a forest covered a large portion of the glacial *débris*, and this furnishes remains of the mammoth, mastodon, and giant beaver. Another submergence covered the forest-bed with the loess of the Mississippi Valley, and icebergs strewed boulders from Canada over the State. Much of the older drift was reassorted and heaped up into kaims or eskars. Lastly, the sea gradually retired, occasionally pausing, and giving rise to terraces in the river valleys.

Intimately connected with the Glacial period were the hollowing out of the great lake-basins, and numerous important changes in the drainage-system of the continent. Taking Lake Erie as the simplest case, it is clear that its basin was not excavated during the greatest extension of the ice-sheet, which, as shown by the striæ on the higher ground, passed directly *across* the valley. But in the bottom of the valley the striæ point *up* the lake, and this fact makes it probable that the excavation of the basin was the work of local ice, in other words, that it dates from a time when the valley-glaciers had ceased to coalesce. The islands near the upper end of the lake are wrought out of hard Corniferous sandstone and Waterlime exposed on the crown of the Cincinnati anticline. This hard barrier, Prof. Newberry believes, opposed an obstinate resistance to the passage of the glacier, and was consequently left in comparative relief.

The Ohio geologists without exception appear to be sub-aërialists, and indeed, the scenery of the State—such as it is—could hardly admit of any other explanation. It would not be easy to connect valleys of some hundreds of feet in depth with faults of less than a yard.

Of the palæontology of the Reports, we need only say that it is a remarkable proof of the enthusiasm, energy, and success of the late Prof. Meek and the naturalists who assisted him, several of them without any compensation. The publication of the Survey as a whole marks an epoch in culture as well as in material progress, in which all the well-wishers of the State must rejoice.

OUR BOOK SHELF

History of Nepal. Translated from the Parbatiya, by Munshi Shero Shunker Singh and Pandit Shri Gunānand. With an Introductory Sketch of the Country and People of Nepal, by the Editor, Daniel Wright, M.A., M.D. (London, Cambridge Warehouse; Cambridge, Deighton, Bell, and Co., 1877.)

THE Cambridge University Press have done well in publishing this work. Such translations are valuable not only to the historian but also to the ethnologist; perhaps more so to the latter than the former, as the very myths with which a people are apt to adorn their own history may become, in the hands of a cunning ethnologist, a clue to their racial connections. Dr. Wright's Introduction is based on personal inquiry and observation, is written intelligently and candidly, and adds much to the value of the volume. The coloured lithographic plates are interesting.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*]

The First Swallow at Menton

THE first swallow arrived here alone in the rain on Monday, March 19. It entered the best room of the *curé* by one of the windows which chanced to want a pane, and the good old man immediately removed a pane from the other window, by which the swallows have been in the habit of going in and out. I did not hear of the arrival of this summer resident until the 23rd, when I immediately paid it a visit. It is still solitary but not uncomfortable; it flits about the room from place to place, and from nest to nest, twittering very contentedly; and when a bright hour comes it flies out, where, sporting in the sun it soon makes a hearty meal. But it has arrived decidedly too soon, for it has found as yet mostly wet and rather cold days with snow-covered mountains for its immediate surrounding. Such, however, is the climate of this place, difficult to conceive by untravelled Englishmen, that I at this moment bask outside in the sun, soothed by the singing of birds, surrounded by flowers and butterflies, and the green trees with their golden fruits. I am in the midst of summer, and yet I have but to turn my head, and there, close at hand, are the mountains white with snow.

The coldest weather we have had this winter began with this month. The only time I have seen ice was on the morning of March 1. (On the preceding night, I see by a letter to NATURE, vol. xv. p. 399, that the thermometer at the Stonyhurst Observatory went down to 9°·1 F., the lowest temperature there recorded during the last sixteen years.) That morning, cheated by the serene stillness and the bright sunshine, I, before getting out of bed, resolved to make a journey to the sea-side—a distance of about three miles. A lunch was immediately packed up and the donkey of the *curé* borrowed for the occasion. As soon as I descended into the valley—Cabrolles, consisting of some dozen houses, all the dwellings of peasants, and hung on the mountain side like so many birds' cages or birds' nests on the back wall of a court, open only to the south, is 300 feet above the level of the sea, and enjoys a climate superior to that of the much vaunted Menton. I am, however, the first *étranger* who has ventured to brave the isolation, the inconvenience, and want of accommodation.—Well, as I have said, on descending into the valley, a change of temperature suggested that it would be preferable to have my Italian cloak around me, instead of carrying it before me on the donkey. Proceeding a little farther, I saw with astonishment large quantities of ice in the torrent, and in turns of the road looking northward, icicles, thick as my arm—which, however, is one of the thinnest—hanging from the rocks. Still I went forward quite irrationally, carried along solely by the force of the impetus with which I started, for, as I approached Menton, I had to make way in the face of a biting cold wind. But I would certainly have shivered over my cold lunch among the rocks or ruins at Cap Martin, had not my progress received a check at Menton, in the for the moment irritating discovery that the key of the provision-bag had been, I may now say providentially, lost. I accepted the hospitality of a kind English clergyman, who gave me a nice warm lunch, after which I slowly wound my way back to my mountain retreat, where I dwell almost as completely removed from the winter visitants of these shores as is the now lonely swallow from its companions, the summer visitants, which have not unwisely made a halt somewhere by the way.

After this long digression I must return for a moment to the swallows of Cabrolles. They live in the rooms with the people, attaching their nests generally to the beam which supports the ceiling. On their arrival, whether it be by night or by day, they enter at once and take possession of their old habitations. Madame Valetta, an old woman of seventy-three, has two or three times given me a graphic account of how, when she was a young woman and had her husband by her side, they were both frightened almost to death one night by something which from time to time gave a flap-flap against the glass of the window. Madame, however, summoned courage to urge her husband to get up and open the window, which, though "all of a shake," he did, when whish! very like a spirit, a weary swallow glided past him and was the same instant peacefully reposing in its nest.

DOUGLAS A. SPALDING

Cabrolles, près de Menton, France,

Coal Fields of Nova Scotia

IN his address to the Iron and Steel Institute (NATURE, vol. xv., p. 462), Dr. Siemens stated that the area of the Coal Fields of Nova Scotia was 18,000 square miles, and the production in 1874 1,052,000 tons. If Dr. Siemens will refer to Dr. Dawson's "Acadian Geology," the Reports of the "Canadian Government Geologists," and Brown's "Coal Fields and Coal Trade of Cape Breton," he will find that he has greatly overstated the area of the Nova Scotia Coal Fields. From these sources which I believe are perfectly reliable, I make out that the whole area of the Nova Scotia Coal Fields does not amount to 1,00 square miles, distributed over the following counties:—

	Square Miles.
Cumberland	250
Picton	34
Cape Breton	194
Victoria	6
Inverness	40
Richmond	10
	534

To this amount, however, must be added the portions of the Cape Breton and Inverness Coal Fields lying under the sea, which, supposing the seams can be worked a distance of five miles beyond high-water mark, will make the total area of the Nova Scotia Coal Fields 859 instead of 18,000 square miles.

The production in 1874 has also been greatly overstated in Dr. Siemens' Table, as I find by reference to the Government Inspector's Report for the year 1876, that the production in 1874 was only 749,127 tons.

R. B.

[Dr. Siemens informs us that the difference referred to by our correspondent chiefly arises from the fact that in American reports Nova Scotia is made to include the maritime province of New Brunswick as well as Cape Breton Island, both of which contain large areas of coal-fields, although those fields are as yet very imperfectly developed. The figures given in the address were taken from Macfarlane's very elaborate work on the "Coal Regions of America." With reference to the coal production, this should be for the year 1873, and is also given on the authority of Macfarlane, who quotes from the Report of the Department of Mines.—ED.]

Greenwich as a Meteorological Observatory

A CAREFUL examination of the interesting communication by Mr. Alexander Buchan to the Scottish Meteorological Society, on "The Temperature of the British Islands," based on observations for the thirteen years ending 1869, fails to support his conclusion (NATURE, vol. xv., p. 450) that the proximity of London does not appreciably influence the temperature as recorded at the Royal Observatory, and that the temperature of Greenwich during recent years has not been in excess of that of surrounding districts. The evidence is quite the reverse. Extracting the figures, given by Mr. Buchan in the paper referred to, for all the stations within a radius of sixty miles of the metropolis, sixteen in number besides Greenwich, it appears that their mean is 50°·1, that of Greenwich being 50°·6. Allowing for elevation, the values are respectively 50°·68 and 51°·13. Omitting, however, several stations such as Camden Town, which, forming part of London, is clearly inadmissible for the comparison, and Maidstone and Canterbury, where observations were made on two years only of the thirteen, the temperature of the ten remaining stations is 50°·59. Thus, according to data furnished by Mr. Buchan himself, Greenwich is warmer than the south-east of England generally by more than half a degree (0°·54). It may be added that, from the same data, the temperature of the district under consideration north of the Thames is 50°·5, and south of the river 50°·8.

H. S. EATON

Centralisation of Spectroscopy

IN his letter (NATURE, vol. xv. p. 449) Prof. Smyth makes a statement respecting the new "half-prism" spectroscope which I cannot help thinking must be founded on a misapprehension of the principle involved. This will, I trust, be made clear when my paper is published in the forthcoming number of the *Proceedings* of the Royal Society; but meanwhile, as Prof. Smyth appears disinclined to wait for a full explanation of the instrument, I shall be most happy to answer his objections when he informs me what particular "laws of Sir Isaac Newton and nature" are in opposition to the principle of this spectroscope.

Against Prof. Smyth's confident assertion that all definition is lost in this instrument, which he has never seen and of which he can only know by hearsay, I have only to set the statement that a small experimental spectroscope on the new plan, with two "half-prisms," is, as a matter of fact, decidedly superior in definition, as well as in brightness of spectrum, to the large Greenwich spectroscope, with ten large compound prisms, of which the excellence is sufficiently attested by the accordance of the results obtained for the sun's rotation by its means. This statement is based on a careful comparison of the sodium lines, and also of the *b* group in the solar spectrum, as seen with the two instruments, b_3 and b_4 with the finer lines in their neighbourhood being shown with remarkable distinctness in the new form of spectroscope, small though it is. In this assertion, I think, I shall be fully borne out by several astronomers to whom I have shown the action of the new spectroscope.

Though I am not in any way concerned with Prof. Smyth's argument in the earlier part of his letter, I may mention for his information that "during the last twenty years" only *two* spectroscopes have been made for Greenwich Observatory (one of these having only a single prism of small dispersion), and that our second or powerful spectroscope was only made *three* years ago; whilst the Edinburgh observatory has, for the past *four* years, possessed *three* spectroscopes which are almost precisely identical with those used with such effect by Dr. Huggins.

W. H. M. CHRISTIE

Royal Observatory, Greenwich, March 27

Morphology of "Selaginella"

BEFORE instituting a comparison it is generally prudent to ascertain that the things to be compared are comparable. I am afraid Mr. Comber, who has done me the honour of making some remarks on what I have said in the pages of NATURE on the primordial type of flowers, has neglected this precaution. If I understand him rightly, he suggests that the "spike" of *Selaginella* is the homologue of the spike of *Carex pulicaris*. He compares, then, the scales bearing macrosporangia of the former with the lower glumes bearing each an ovary of the latter.

Now in the first place, if he had studied the matter a little more (if he will allow me to say so), he would have seen that the ovule, and not the ovary, is the equivalent of the macrosporangium, and that the embryo sac, and not the ovule, is the equivalent of a macrospore. This leaves the ovary unaccounted for, and the homology hopelessly breaks down on that point.

But this is not all. Mr. Comber has omitted all notice of the singular structure, the perigynium, and also of the equally singular structure, the "seta," which it contains along with the ovary, and which happens to be particularly well represented in *Carex pulicaris*. If he will take the trouble to look at a short paper which I have published in the *Journal* of the Linnean Society (Botany) vol. xiv., pp. 154-156, pl. xii., he will find that I have carefully discussed the morphology of the female flower of this very plant. I think I have succeeded in showing that far from being a simple racemose inflorescence it is a compound raceme or panicle reduced in a very peculiar manner. I am afraid, therefore, that Mr. Comber has been led away by resemblances of a very superficial character, and that the fact *Selaginella* has a "spike" and that *Carex* has a "spike," is a point of contact between the two about as significant as the existence of a river in both Macedon and Monmouth.

In fact, far from being plants of a primitive type, the *Cyperaceæ* are generally regarded as reduced representatives of plants of much more fully developed character, the exact nature and relationship of which we have no materials for at present estimating.

W. T. THISELTON DYER

Tungstate of Soda

WITH regard to your note (NATURE, vol. xv. p. 460) upon muslin rendered uninflammable by tungstate of soda, will you allow me to say that when properly prepared the muslin is fairly uninflammable. I say uninflammable—not fireproof. There can be no doubt from experiments made in Prof. Gladstone's laboratory that muslin prepared with a sufficient quantity of the salt will not catch fire by ordinary means, but no one could reasonably expect it to stand an *auto da fe* such as that to which I saw Dr. Wright subject his dummy, and fortunately not his assistant, last Saturday fortnight.

MATTHEW W. WILLIAMS

Chemical Laboratory, Royal Institution

Traquair's Monograph on British Carboniferous Ganoids

WILL you kindly permit me through the medium of your journal, to correct and apologise for a very awkward blunder which occurs in the first part of my monograph on British carboniferous ganoids, recently published by the Palæontographical Society? In the introduction I have advocated the retention of the *Dipnoi* as a distinct order of fishes, but at page 41, in a manner unaccountable to myself, for I certainly did not mean it, I have included them as a sub-order of the Ganoidei. That this "slip of the pen" was not detected in the revision of the proofs must have been due to an amount of carelessness of which I am justly ashamed.

R. H. TRAQUAIR

Edinburgh, April 2

ALEXANDER BRAUN

WE regret to announce the death of the well-known German botanist, Prof. Alexander Braun, which took place at Berlin, on March 29. He was born in Ratisbon, May 10, 1805, and after the completion of his university studies entered upon the duties of Professor of Botany in the University of Freiburg, in Baden. Here he published his first important book, "Vergleichende Untersuchung über die Ordnung der Schuppen an den Tannenzapfen," in which he formulated the theory with regard to the position of the leaves on plants now essentially recognised by botanists. In 1850 he accepted a call to the University of Giessen, and issued shortly after his most notable work, "Betrachtungen über die Erscheinung der Verjungung in der Natur, insbesondere in der Lebens- und Bildungsgeschichte der Pflanze." The extensive series of observations, and the numerous valuable theoretical deductions recorded in this suggestive work, formed one of the most noteworthy contributions to vegetable morphology, and placed the author at once among the leading botanists of the day. In 1852 he removed to Berlin, where he had been appointed Professor of Botany and Director of the Botanical Gardens, positions which he occupied up to the time of his death. The unwearied activity of Braun during this period is evidenced by the large number and variety of the contributions made by him to botanical literature. Of these his investigations on cryptogamia assume the foremost rank, embracing papers on the families *Marsilia*, *Pilularia*, and *Selaginella*, African varieties of *Chara*, Movements of the Juices in the Cells of *Chara*, Vegetable Individuals in their relations to Species, Some New Diseases of Plants caused by Fungi, New Varieties of Single-celled Algæ, &c.

Among his more prominent publications on phanerogamia should be mentioned the papers on parthenogenesis, polyembryony, and budding of *cœlebogyne*, and the oblique direction of woody fibre in its relations to twisted tree stems. His efforts in all investigations were chiefly directed to perfecting our knowledge of vegetable morphology, and by comparative studies in this region, to the establishment of well-defined laws with regard to the growth of plants, and the relationship between different varieties. Braun's theories on the latter subject led to the formation of a system, which, although not accepted in all points, is yet regarded by many botanists as the most perfect approach to a natural classification of plants which we at present possess. A contemporary botanist describes the leading feature of his character as consisting in an "earnest striving to bring all the widely diverse families of the vegetable kingdom, fossil as well as existing, within his grasp, and by means of thorough, comparative study to advance toward the true natural classification."

The merits of Prof. Braun were recognised by the bestowal of numerous German orders, and from the King of Prussia he received the title of "Geh.-Regierungs-Rath." He was a prominent member of the Berlin Academy of Sciences and the Botanical Society, occupying the presidency of the latter for a number of years. His papers appeared chiefly in the *Transactions* of these two societies; the classification of plants being given, however, in Ascherson's "Flora of the Province of Brandenburg," in 1864.

THE LOAN COLLECTION OF SCIENTIFIC APPARATUS

THE last of the "present series" of free lectures in connection with the Loan Collection of Scientific Apparatus was given on Saturday, in the lecture theatre of the South Kensington Museum. Major Festing, R.E., took the chair, and the theatre was, as usual, crowded. The lecture was given by Mr. W. Stephen Mitchell, M.A., on "The *Challenger* Soundings and the Lost Island of Atlantis." An abstract of this will shortly appear. At the end of the lecture Mr. Mitchell said he thought that as this was the last—at any rate of this series—it would be in accordance with the wish of the audience that a few words should be said by way of *résumé*, to mark the occasion. He regretted that his place was not occupied by some one eminent in science. When the Loan Collection of Scientific Apparatus was opened there were planned in connection with it conferences, demonstrations, lectures to science teachers, and the free evening lectures. The conferences lasted as planned during May and June, the lectures to science teachers were carried out as proposed, and the demonstrations were given till December 31. At that date, in consequence of packing the cases for returning the collections lent from abroad, which were lent for a definite period only, it was necessary to close the galleries to the public. The free lectures, however, had been continued, and the apparatus from the galleries had been brought into that theatre, as it had been found necessary, to illustrate the lectures. The lectures had thus kept up the continuity of the collection. He believed he was right in saying that from the outset the promoters of the Loan Collection had looked forward to the establishment of a permanent physical science museum somewhat in imitation of the Conservatoire des Arts et Métiers of Paris. Such a museum was recommended by the Royal Commission on Scientific Education, under the presidency of the Duke of Devonshire, and composed of some of the most distinguished men of science in this country. For a building to contain such a museum the commissioners of the Exhibition of 1851, under the presidency of the Prince of Wales, have voted 100,000*l.*, and offered it to the Government. A petition in favour of the establishment of such a museum had, since the opening of the collection, been signed by officers and fellows of learned societies, and presented to the Duke of Richmond and Gordon. At this last lecture of the series they would naturally ask what was likely to be done for the future. As he was in no way officially connected with the museum he was not in a position to give any certain information; but this much he could tell them, a number of instruments that would otherwise have been returned had been acquired by purchase, a number had been presented, a number were left on loan for an indefinite period, and many were left under certain conditions. The galleries at the present time contained a collection of fair size to commence a permanent collection. Here, as in considering the lost island of Atlantis, they must be careful to discriminate between facts and inferences to be drawn from facts. No announcement had been made by the Government as to its intentions. The present condition of the Collection, as he had stated it, was a fact, and they would draw for themselves inferences as to what this might mean. He had seen a statement that the permanent museum might be open in May, but he could not say how far this represented official intentions. The crowded audiences at the lectures in that theatre was, he said, a proof that they wished the Collection and the lectures in connection with it to continue.

Mr. F. S. Mosely moved, and Mr. J. Heywood, F.R.S., seconded the following resolution:—"We who form the audience at this, the last of the present series of lectures in connection with the Loan Collection of Scientific Apparatus, desire to thank the Board of the Science and Art Department for having arranged this series of lectures. We would wish to take this opportunity to express the hope that the Loan Collection of Scientific Apparatus may lead to a permanent collection of a similar nature. We beg the chairman to convey the terms of this resolution to the head of the department."

The motion was put to the meeting and carried unanimously with loud applause.

Major Festing said that, as representing the department, he was sorry he could give no more information than the lecturer had. The Government had not yet announced its intention as to what it would do in the matter. It had lately had many other matters on hand. With regard to the lectures, it was felt that it was hardly fair to continue to ask men of science to give their services gratuitously, and until some arrangement for fees could be made, he thought the lectures would probably remain in abeyance. It would give him pleasure to forward the resolution so unanimously carried to the head of his department as requested.

THE DEVELOPMENT OF BATRACHIANS WITHOUT METAMORPHOSIS

METAMORPHOSIS, or the transition of the animal through an intermediate stage between the ovum and the adult, has hitherto been considered by modern naturalists a special characteristic of the Batrachians amongst the Vertebrates, and as one of the main features which distinguish them from the true Reptiles, with which they were formerly united. It is, therefore, surprising to learn, as we do from a recent communication of Dr. Peters to the Royal Academy of Sciences of Berlin, that there are cases in which no such metamorphosis takes place, and the young frog is developed directly from the egg without showing any signs of what is usually called the "tadpole" stage.

Dr. Peters's noteworthy discovery is based upon observations made by Dr. Bello, Herr Krug, and Dr. J. Gundlach, in Porto Rico, on the development of a West Indian tree-frog—*Hylodes martinicensis*, which seems to be not uncommon in Porto Rico, and is there generally known by the vernacular term *Coqui*.

Five years ago Dr. Bello stated[1] that a tree-frog in Porto Rico called *Coqui* was remarkable from the fact that the young came out of the eggs in a perfect condition, and fit for life in the air. "In 1870," he says, "I observed in a garden an example of this species upon a liliaceous plant, on which about thirty eggs were clustered together in a cotton-wool-like mass; the mother kept close to them as if she intended to incubate. A few days afterwards I found the little frogs from two to three lines long just born, with all their four feet perfectly developed, springing about, and enjoying life in the air. In a few days they attained their full size. This garden is surrounded by walls six feet high, and there is no water in it. The so-called lily (which appears to be an introduced species of *Crinum*) always contains a little water in the receptacles, but is not a water-plant."

The translator of these observations rightly remarks that the exclusion of the animal out of the egg was not actually witnessed in this case, and that it was possible even in the short time which elapsed between when the eggs were seen and the young frogs appeared, some metamorphosis might have taken place, especially as the subsequent development seems to have been uncommonly quick.

These short observations of Dr. Bello appear to have attracted the less attention inasmuch as the development of tree-frogs from eggs placed in dry situations in frothy masses had been already observed and described in tropical countries. In 1867 Herr Hensel published some interesting observations on *Cystignathus mystacinus*, in the forests of Rio Grande do Sul,[2] and last year Dr. Peters laid before the Academy of Berlin the extraordinary discoveries of Buchholz concerning the egg-masses of *Chiromantis guineensis* laid upon trees in Guinea. Besides this the development of *Alytes obstetricans* between the hind-legs of the male in the ordinary way, and, through Herr Weinland's brilliant investigations, the metamorphosis of the young in the dorsal sacs of the females of *Opisthodelphys* and *Nototrema*, were facts so generally known that it seemed highly improbable that any Batrachian should be developed without metamorphosis.

Under these circumstances it is of the greatest interest to be able to state that Dr. Bello's information has been fully corroborated by recent observations of Dr. Gundlach and by preparations which he has transmitted to Berlin.

"On May 24, 1876," Dr. Gundlach says, "I heard a singular call like that of a young bird, and went to see what it was. Between two large orange-blossoms I perceived a leaf frog, and on taking hold of it, found I had captured three males and a female of the *Coqui*. On putting them into a damp glass, one of the males quickly placed himself on the female and grasped around her. Not long afterwards she had laid from fifteen to twenty eggs, which, however, mostly soon disappeared—perhaps eaten.

"There were subsequently laid five eggs, round, with a transparent covering, which I removed and placed on some wet slime. The inner yelk, of a whitish or pale straw-colour, contracts a little, and then the tail is seen forming. In eight days this was quite clearly visible, as well as the eyes, and the red pulsating blood-vessels. Later on traces of the legs became manifest. I was now absent for some days, and when I returned, on June 6, found the eggs still, but on the next morning, the young were out, and had no trace left of the tail.

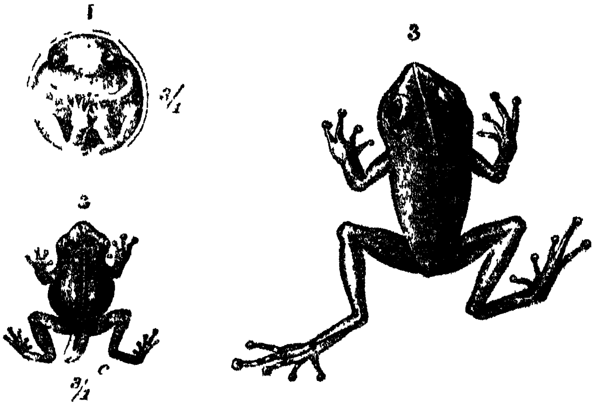

Fig. 1.—Egg of *Hylodes martinicensis*, twelve days old, lower surface Fig. 2.—Young of *Hylodes* as it leaves the egg; *c*, tail. Fig. 3.—Adult male *Hylodes*, natural size

"Afterwards I found between two leaves of a large Amaryllid, just like Dr. Bello, a batch of more than twenty eggs, upon which the mother was sitting. I cut off the leaf, along with the eggs—upon which the mother jumped off—and placed them in a glass with some damp earth at the bottom. About the fourteenth day, having returned from an excursion, I found, at 9 A.M., all the eggs hatched, and I remarked on the young ones a little white tail (see Fig. 2, *c*), which by the afternoon had altogether disappeared."

Dr. Gundlach's collection, as Dr. Peters tells us, contains four eggs of this frog, with embryos. They consist of a transparent vesicle of from 4·5 to 5·5 mill. in diameter, which is partly occupied by an opaque flaky white mass. The vesicle is filled with a transparent fluid, which allows one to see every part of the swimming embryo quite clearly. The embryo, as in the case of mammals, is curved together on the lower surface, so that the head approaches the lower extremities, which, as well as the anterior extremities, are drawn together under the belly and lie close to the body.

[2] Sitz. d. Ges. Nat. Freunde zu Berlin 1867, p 10, and Arch. , Nat. xxiii, t. 1, p. 129.

The tail is likewise curved up underneath, and lies with its broad surface towards the body, turning either towards the right or the left, and thickening part of the hinder extremities. In three examples the extremities are fully developed, and even show the characteristic discs on the tops of the toes. In the fourth example all four extremities present short stumps, and as yet show no traces of toes, whereas, as is well known, in the *Batrachia anura* generally the hinder extremities and the ends of the feet first appear. Neither of branchiæ nor of branchial slits is there any trace. On the other hand, in the last-mentioned example, the tail is remarkably larger, and has its broad surface closely adherent to the inner wall of the vesicle, and very full of vessels, so that there can be no doubt of its function as a breathing organ. As development progresses, the yelk-bag on the belly and the tail become gradually smaller, so that at last, when the little animal, being about 5 mill. long, bursts through the envelope, the tail is only 1·8 mill. in length, and after a few hours only 0·3 mill. long, and in the course of the same day becomes entirely absorbed. Examples of the same batch of ova, which were placed in spirit eight days after their birth, have a length of from 7·0 to 7·5 mill., whence we may conclude that their growth is not quicker than in other species of Batrachians.

The development of this frog, Dr. Peters observes (and probably of all the nearly allied species), without metamorphosis, without branchiæ, with contemporaneous evolution of the anterior and posterior extremities, as in the case of the higher vertebrates, and within a vesicle, like the amnion of these latter, if not strictly equivalent to it, is truly remarkable. But this kind of development is not quite unparalleled in the Batrachians, for it has long been known that the young of *Pipa americana* come forth from the eggs laid in the cells on their mother's back tailless and perfectly developed. In them, likewise, no one has yet detected branchiæ, and we also know from the observations of Camper,[1] that the embryos at an earlier period are provided with a tail-like appendage, which in this case also, may be perhaps regarded as an organ of breathing, possibly corresponding to the yelk-placenta of the hag-fish. As regards this point, also, Laurenti says of the *Pipa*: "Pulli ex loculamentis dorsi prodeuntes, metamorphosi nulla?" (Syn. Rept., p. 25.)

It would be of the highest interest, Dr. Peters adds, to follow exactly this remarkable development on the spot. The development of the embryo of these Batrachians in a way very like that of the scaled Reptilia makes one suspect that an examination of the temporary embryonic structures of *Hylodes* and *Pipa* would result in showing remarkable differences from those of other Batrachians. The general conclusions which might be drawn from this discovery are so obvious, says Dr. Peters, in conclusion, that it would be superfluous to put them forward.

A subsequent communication of Dr. Peters to the Academy informs us that it had escaped his notice that M. Bavay, of Guadaloupe, had already published some observations on the development of *Hylodes martinicensis*.[2] According to his observations, on each side of the heart there is a branchia consisting of one simple gill-arch, which on the seventh day is no longer discernible. On the ninth day there is no longer a trace of a tail, and on the tenth day the little animal emerges from the egg. M. Bavay also observed the contemporaneous development of the four extremities, and hints at the function of the tail as an organ of breathing.

The observations of Dr. Gundlach, therefore, says Dr. Peters, differ in some respects from those of M. Bavay. It would be specially desirable, however, to ascertain whether the arched vessel on each side of the heart is really to be regarded as a gill-arch, or only as the incipient bend of the aorta.

TYPICAL LAWS OF HEREDITY[1]

We are far too apt to regard common events as matters of course, and to accept many things as obvious truths which are not obvious truths at all, but present problems of much interest. The problem to which I am about to direct attention is one of these.

Why is it when we compare two groups of persons selected at random from the same race, but belonging to different generations of it, we find them to be closely alike? Such statistical differences as there may be, are always to be ascribed to differences in the general conditions of their lives; with these I am not concerned at present, but so far as regards the processes of heredity alone, the resemblance of consecutive generations is a fact common to all forms of life.

In each generation there will be tall and short individuals, heavy and light, strong and weak, dark and pale, yet the proportions of the innumerable grades in which these several characteristics occur tends to be constant. The records of geological history afford striking evidences of this. Fossil remains of plants and animals may be dug out of strata at such different levels that thousands of generations must have intervened between the periods in which they lived, yet in large samples of such fossils we seek in vain for peculiarities which will distinguish one generation taken as a whole from another, the different sizes, marks and variations of every kind, occurring with equal frequency in both. The processes of heredity are found to be so wonderfully balanced and their equilibrium to be so stable, that they concur in maintaining a perfect statistical resemblance so long as the external conditions remain unaltered.

If there be any who are inclined to say there is no wonder in the matter, because each individual tends to leave his like behind him, and therefore each generation must resemble the one preceding, I can assure them that they utterly misunderstand the case. Individuals do *not* equally tend to leave their like behind them, as will be seen best from an extreme illustration.

Let us then consider the family history of widely different groups; say of 100 men, the most gigantic of their race and time, and the same number of medium men. Giants marry much more rarely than medium men, and when they do marry they have but few children. It is a matter of history that the more remarkable giants have left no issue at all. Consequently the offspring of the 100 giants would be much fewer in number than those of the medium men. Again these few would, on the average, be of lower stature than their fathers for two reasons. First, their breed is almost sure to be diluted by marriage. Secondly, the progeny of all exceptional individuals tends to "revert" towards mediocrity. Consequently the children of the giant group would not only be very few but they would also be comparatively short. Even of these the taller ones would be the least likely to live. It is by no means the tallest men who best survive hardships, their circulation is apt to be languid and their constitution consumptive.

It is obvious from this that the 100 giants will not leave behind them their quota in the next generation. The 100 medium men, on the other hand, being more fertile, breeding more truly to their like, being better fitted to survive hardships, &c., will leave more than their proportionate share of progeny. This being so, it might be expected that there would be fewer giants and more medium-sized men in the second generation than in the first. Yet, as a matter of fact, the giants and medium-sized men will, in the second generation, be found in the same proportions as before. The question, then, is this:—How is it that although each individual does *not* as a rule leave his like behind him, yet successive generations resemble each other with great exactitude in all their general features?

[1] Lecture delivered at the Royal Institution, Friday evening, February 9, by Francis Galton, F.R.S.

It has, I believe, become more generally known than formerly, that although the characteristics of height, weight, strength, and fleetness are different things, and though different species of plants and animals exhibit every kind of diversity, yet the differences in height, weight, and every other characteristic, are universally distributed in fair conformity with a single law.

The phenomena with which it deals are like those perspectives spoken of by Shakespeare which, when viewed awry, show nothing but confusion.

Our ordinary way of looking at individual differences is awry; thus we naturally but wrongly judge of differences in stature by differences in heights, measured from the ground, whereas on changing our point of view to that whence the law of deviation regards them, by taking the average height of the race, and not the ground, as the point of reference, all confusion disappears, and uniformity prevails.

It was to Quetelet that we were first indebted for a knowledge of the fact that the amount and frequency of deviation from the average among members of the same race, in respect to each and every characteristic, tends to conform to the mathematical law of deviation.

The diagram contains extracts from some of the tables, by which he corroborates his assertion. Three of the series in them refer to the heights of Americans, French, and Belgians respectively, and the fourth to strength, to that of Belgians. In each series there are two parallel columns, one entitled "observed," and the other "calculated," and the close conformity between each of the pairs is very striking.

These Tables serve another purpose; they enable those who have not had experience of such statistics to appreciate the beautiful balance of the processes of heredity in ensuring the repetition of such finely graduated proportions as those they record.

The outline of my problem of this evening is, that since the characteristics of all plants and animals tend to conform to the law of deviation, let us suppose a typical case, in which the conformity shall be exact, and which shall admit of discussion as a mathematical problem, and find what the laws of heredity must then be to enable *successive* generations to maintain statistical identity.

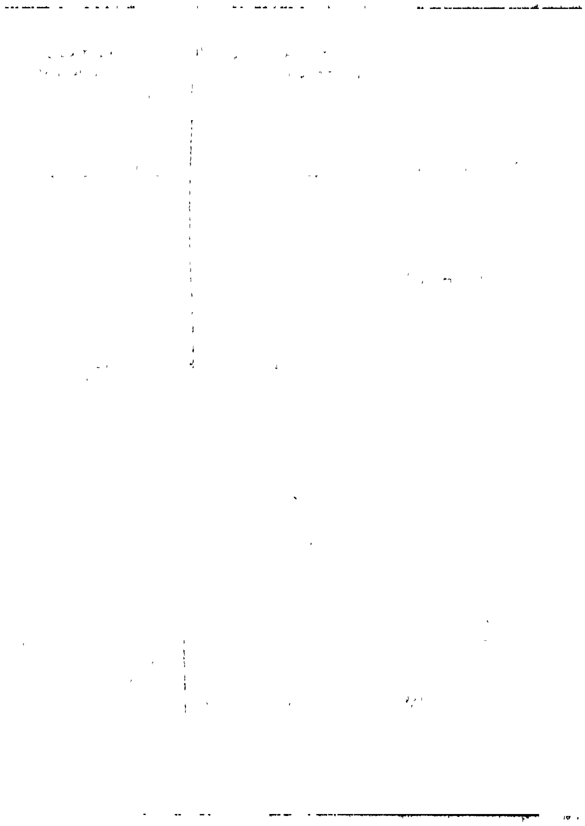

FIG. 1.

I shall have to speak so much about the law of deviation, that it is absolutely necessary to tax your attention for a few minutes to explain the principle on which it is based, what it is that it professes to show, and what the two numbers are which enable long series to be calculated like those in the tables just referred to. The simplest way of explaining the law is to begin by showing it in action. For this purpose I will use an apparatus that I employed three years ago in this very theatre, to illustrate other points connected with the law of deviation. An extension of its performance will prove of great service to us to-night, but I will begin by working the instrument as I did on the previous occasion. The portion of it that then existed and to which I desire now to confine your attention, is shown in the lower part of Fig. 1, where I wish you to notice the stream issuing from either of the divisions just above the dots, its dispersion among them, and the little heap that it forms on the bottom line. This part of the apparatus is like a harrow with its spikes facing us; below these are vertical compartments; the whole is faced with a glass plate. I will pour pellets from any point above the spikes, they will fall against the spikes, tumble about among them, and after pursuing devious paths, each will finally sink to rest in the compartment that lies beneath the place whence it emerges from its troubles.

The courses of the pellets are extremely irregular, it is rarely that any two pursue the same path from beginning to end, yet notwithstanding this you will observe the regularity of the outline of the heap formed by the accumulation of pellets.

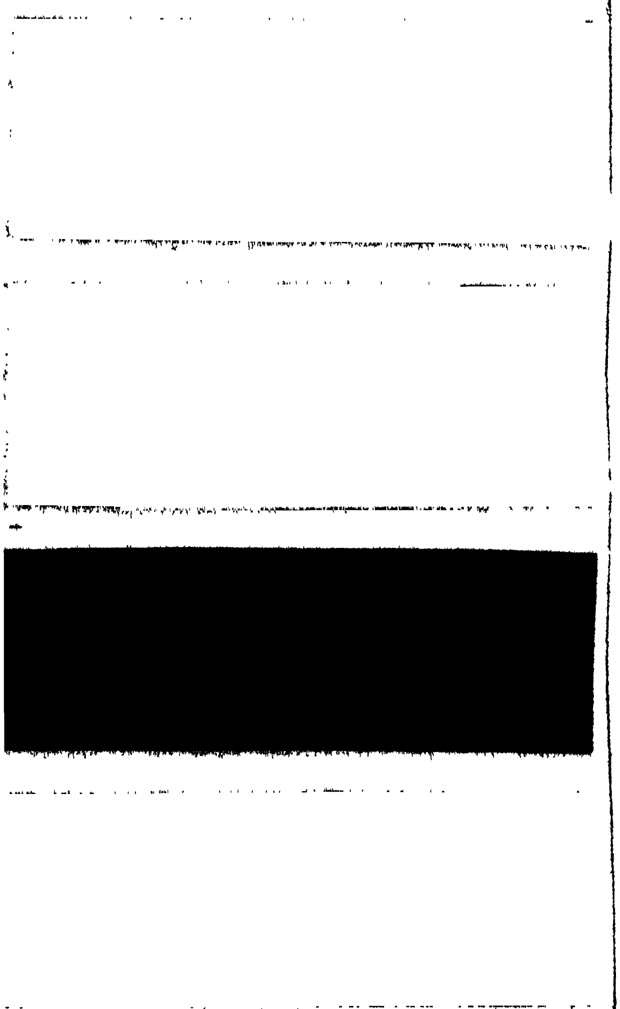

Fig. 2.

This outline is the geometrical representation of the curve of deviation. If the rows of spikes had been few, the deviation would have been slight, almost all the pellets would have lodged in a single compartment and would then have resembled a column; if they had been very numerous, they would have been scattered so widely that the part of the curve for a long distance to the right and left of the point whence they were dropped would have been of uniform width, like an horizontal bar. With intermediate numbers of rows of teeth, the curved contour of the heap would assume different shapes, all having a strong family resemblance. I have cut some of these out of cardboard; they are represented in the diagrams (Figs. 2 and 3). Theoretically speaking, every possible curve of deviation may be formed by an apparatus of this sort, by varying the length of the harrow and the number of pellets poured in. Or if I draw a curve on an elastic sheet of india-rubber, by stretching it laterally I produce the effects of increased dispersion; by stretching it vertically I produce that of increased numbers. The latter variation is shown by the successive curves in each of the diagrams, but it does not concern us to-night, as we are dealing with proportions, which are not affected by the size of the sample. To specify the variety of curve so far as dispersion is concerned, we must measure the amount of lateral stretch of the india-rubber sheet. The curve has no definite ends, so we have to select and define two points in its base, between which the stretch may be measured. One of these points is always taken directly below the place where the pellets were poured in. This is the point of no deviation, and represents the mean position of all the pellets, or the average of a race. It is marked as 0°. The other point is conveniently taken at the foot of the vertical line that divides either half of the symmetrical figure into two equal areas. I take a half curve in cardboard that I have again divided along this line, the weight of the two portions is equal. This distance is the value of 1° of deviation, appropriate to each curve.

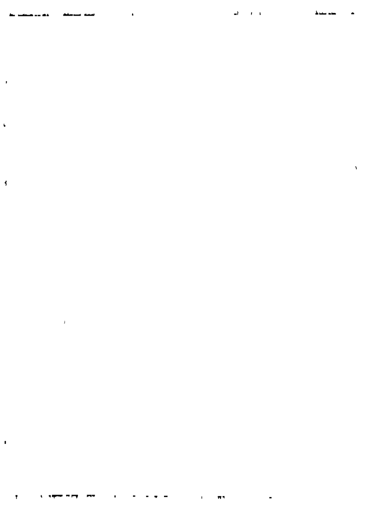

Fig. 3

We extend the scale on either side of 0° to as many degrees as we like, and we reckon deviation as positive, or to be added to the average, on one side of the centre say to the right, and negative on the other, as shown in the diagrams. Owing to the construction, one quarter or 25 per cent. of the pellets will lie between 0° and 1°, and the law shows that 16 per cent. will lie between + 1° and + 2°, 6 per cent. between + 2° and + 3°, and so on. It is unnecessary to go more minutely into the figures, for it will be easily understood that a formula is capable of giving results to any minuteness and to any fraction of a degree.

Let us, for example, deal with the case of the American soldiers. I find, on referring to Gould's Book, that 1° of deviation was in their case 1·676 inches. The curve I hold in my hand has been drawn to that scale. I also find that their average height was 67·24 inches. I have here a standard marked with feet and inches. I apply the curve to the standard, and immediately we have a geometrical representation of the statistics of height of all those soldiers. The lengths of the ordinates show the proportion of men at and about their heights, and the area between any pairs of ordinates give the proportionate number of men between those limits.

It is indeed a strange fact that any one of us sitting quietly at his table could, on being told the two numbers just mentioned, draw out a curve on ruled paper, from which thousands of vertical lines might be chalked side by side on a wall, at the distance apart that is taken up by each man in a rank of American soldiers, and know that if the same number of these American soldiers taken indiscriminately had been sorted according to their heights and marched up to the wall, each man of them would find the chalked line which he found opposite to him to be of exactly his own height. So far as I can judge from the run of the figures in the table, the error would never exceed a quarter of an inch, except at either extremity of the series.

The principle of the law of deviation is very simple. The important influences that acted upon each pellet were the same; namely, the position of the point whence it was dropped, and the force of gravity. So far as these are concerned, every pellet would have pursued an identical path. But in addition to these there were a host of petty disturbing influences, represented by the spikes among which the pellets tumbled in all sorts of ways. The theory of combination shows that the commonest case is that where a pellet falls equally often to the right of a spike as to the left of it, and therefore drops into the compartment vertically below the point where it entered the harrow. It also shows that the cases are very rare of runs of luck carrying the pellet much oftener to one side than the other. The law of deviation is purely numerical; it does not regard the fact whether the objects treated of are pellets in an apparatus like this, or shots at a target, or games of chance, or any other of the numerous groups of occurrences to which it is or may be applied.[1]

I have now done with my description of the law. I know it has been tedious, but it is an extremely difficult topic to handle on an occasion like this. I trust the application of it will prove of more interest.

(To be continued.)

ON THE STRUCTURE AND ORIGIN OF METEORITES[2]

THE study of meteorites is naturally divisible into several very distinct branches of inquiry. Thus in the first place we may regard them as shooting stars, and observe and discuss their radiant points and their relation to the solar system. This may be called the astronomical aspect of the question. Then, when solid masses fall to the ground, we may study their chemical composition as a whole, or that of the separate mineral constituents; and lastly, we may study their mechanical structure, and apply to this investigation the same methods which have yielded such important results in the case of terrestrial rocks. So much has been written on the astronomical, chemical, and mineralogical aspect of my subject by those far more competent than myself to deal with such questions, that I shall confine my remarks almost entirely to the mechanical structure of meteorites and meteoric irons, and more especially to my own observations, since they will, at all events, have the merit of greater originality and novelty. Time will, however, not permit me to enter into the detail even of this single department of my subject.

In treating this question it appeared to me very desirable to exhibit to you accurate reproductions of the natural objects, and I have therefore had prepared photographs of my original drawings, which we shall endeavour to show by means of the oxyhydrogen lime-light, and I shall modify my lecture to meet the requirements of the case, exhibiting and describing special examples, rather than attempt to give an account of meteorites in general. Moreover, since the time at my disposal is short, and their external characters may be studied to great advantage at the British Museum, I shall confine my remarks as much as possible to their minute internal structure, which can be seen only by examining properly prepared sections with more or less high magnifying powers.

By far the greater part of my observations were made about a dozen years ago. I prepared a number of sections of meteorites, meteoric irons, and other objects which might throw light on the subject, and my very best thanks are due to Prof. Maskelyne for having most kindly allowed me to thoroughly examine the very excellent series of thin sections, which had been prepared for him. During the last ten years my attention has been directed to very different subjects, and I have done little more than collect material for the further and more complete study of meteorites. When I have fully utilised this material I have no doubt that I shall be able to make the subject far more complete, and may find it necessary to modify some of my conclusions. I cannot but feel that very much more remains to be learned, and I should not have attempted to give an account of what I have so far done, if I had not been particularly asked to do so by Mr. Lockyer. At the same time I trust that I shall at all events succeed in showing that the microscopical method of study yields such well marked and important facts, that in some cases the examination of only a single specimen serves to decide between rival theories.

In examining with the naked eye an entire or broken meteorite we see that the original external outline is very irregular, and that it is covered by a crust, usually, but not invariably black, comparatively thin, and quite unlike the main mass inside. This crust is usually dull, but sometimes, as in the Stannern meteorite, bright and shining, like a coating of black varnish. On examining with a microscope a thin section of the meteorite, cut perpendicular to this crust, we see that it is a true black glass filled with small bubbles, and that the contrast between it and the main mass of the meteorite is as complete as possible, and the junction between them sharply defined, except when portions have been injected a short distance between the crystals. We thus have a most complete proof of the conclusion that the black crust was due to the true igneous fusion of the surface under conditions which had little or no influence at a greater depth than $\frac{1}{100}$th of an inch. In the case of meteorites of different chemical composition, the black crust has not retained a true glassy character, and is sometimes [illegible]th of an inch in thickness, consisting of two very distinct layers, the internal showing particles of iron which have been neither melted nor oxidised, and the external showing that they have been oxidised and the oxide melted up with the surrounding stony matter. Taking everything into consideration, the microscopical structure of the crust agrees perfectly well with the explanation usually adopted, but rejected by some authors, that it was formed by the fusion of the external surface, and was due to the very rapid heating which takes place when a body moving with planetary velocity rushes into the earth's atmosphere—a heating so rapid that the surface is melted before the heat has time to penetrate beyond a very short distance into the interior of the mass.

When we come to examine the structure of the original interior part of meteorites, as shown by fractured surfaces, we may often see with the naked eye that they are mottled in such a way as to have many of the characters of a brecciated rock, made up of fragments subsequently cemented together and consolidated. Mere rough fractures are, however, very misleading. A much more accurate opinion may be formed from the examination of a smooth flat surface. Facts thus observed led Reichenbach to conclude that meteorites had been formed by the collecting together of the fragments previously separated from one another in comets, and an examination of thin transparent sections with high magnifying powers and improved methods of illumination, proves still more conclusively their brecciated structure. The facts are, however, very complex, and some are not easily explained. Leaving this question for the present, I will endeavour to point out what appears to be the very earliest history of the material, as recorded by the internal structure.

---

[1] Quetelet, apparently from habit rather than theory, always adopted the binomial law of error, basing his tables on a binomial of high power. It is absolutely necessary to the theory of the present paper, to get rid of binomial limitations and to consider the law of deviation or error, in its exponential form.

[2] Abstract of lecture delivered by H. C. Sorby, F.R.S., &c., at the Museum, South Kensington, on March 10.

It is now nearly twenty years since I first showed that the manner of formation of minerals and rocks may be learned from their microscopical structure. I showed that when crystals are formed by deposition from water or from a mass of melted rock, they often catch up portions of this water or melted stone, which can now be seen as cavities containing fluid or glass. We may thus distinguish between crystalline minerals formed by purely aqueous or by purely igneous processes; for example, between minerals in veins and minerals in volcanic lavas. In studying meteorites it appeared to me desirable, in the first place, to ascertain whether the crystalline minerals found in them were originally formed by deposition from water or from a melted stony material analogous to the slags of our furnace or the lava of volcanoes. One of the most common of the minerals in meteorites is olivine, and when met with in volcanic lavas this mineral usually contains only a few and small glass cavities in comparison with those seen in such minerals as augite. The crystals in meteorites are, moreover, only small, and thus the difficulty of the question is considerably increased. However, by careful examination with high magnifying power, I found well-marked glass-cavities, with perfectly fixed bubbles, the inclosed glass being sometimes of brown colour and having deposited crystals. On the contrary I have never been able to detect any trace of fluid-cavities, with moving bubbles, and therefore it is very probable, if not absolutely certain, that the crystalline minerals were chiefly formed by an igneous process, like those in lava, and analogous volcanic rocks. These researches require a magnifying power of 400 or 600 linear.

Passing from the structure of the individual crystals to that of the aggregate, we find that in some cases we have a structure in every respect analogous to that of erupted lavas, though even then there are very curious differences in detail. By methods like those adopted by Daubrée, there ought to be no more difficulty in artificially imitating the structure of such meteorites than in imitating that of our ordinary volcanic rocks. It is, however, doubtful whether meteorites of any considerable size uniformly possess this structure. The best examples I have seen are only fragments inclosed in the general mass of the Petersburg meteorite, which, like many others, has exactly the same kind of structure as that of consolidated volcanic tuff or ashes. This is well shown by the Bialystock meteorite, which is a mass of broken crystals and more complex fragments scattered promiscuously through a finer-grained consolidated dust-like ash.

Passing from this group of meteorites, which are more or less analogous to some of our terrestrial volcanic rocks, we must now consider the more common varieties, which are chiefly composed of olivine and other allied minerals. The Mezö Madaras meteorite is an excellent illustration, since the outline of the fragments is well seen, on account of the surrounding consolidated fine material being of dark colour. In it we see more or less irregular spherical and very irregular fragments scattered promiscuously in a dark highly consolidated fine-grained base. By far the larger part of these particles do not either by their outline or internal structure furnish any positive information respecting the manner in which they were formed, but careful examination of this and other analogous meteorites, has enabled me to find that the form and structure of many of the grains is totally unlike that of any I have ever seen in terrestrial rocks, and points to very special physical conditions. Thus some are almost spherical drops of *true glass* in the midst of which crystals have been formed, sometimes scattered promiscuously, and sometimes deposited on the external surface, radiating inwardly; they are, in fact, partially devitrified globules of glass, exactly similar to some artificial blow-pipe beads.

As is well known, glassy particles are sometimes given off from terrestrial volcanoes, but on entering the atmosphere they are immediately solidified and remain as mere fibres, like *Pele's hair*, or as more or less irregular laminæ, like pumice dust. The nearest approach to the globules in meteorites is met with in some artificial products. By directing a strong blast of hot air or steam into melted glassy furnace slag, it is blown into spray, and usually gives rise to pear-shaped globules, each having a long hair-like tail, which is formed because the surrounding air is too cold to retain the slag in a state of perfect fluidity. Very often the fibres are the chief product. I have never observed any such fibres in meteorites. If the slag be hot enough, some spheres are formed without tails, analogous to those characteristic of meteorites. The formation of such alone could not apparently occur unless the spray were blown into an atmosphere heated up to near the point of fusion, so that the glass might remain fluid until collected into globules. The retention of a true vitreous condition in such fused stony material would depend on both the chemical composition and the rate of cooling, and its permanent retention would in any case be impossible if the original glassy globule were afterwards kept for a long time at a temperature somewhat under that of fusion. The combination of all these conditions may very well be looked upon as unusual, and we may thus explain why grains containing true glass are comparatively very rare; but though rare they point out what was the origin of many others. In by far the greater number of cases the general basis has been completely divitrified, and the larger crystals are surrounded by a fine-grained stony mass. Other grains occur with a fan-shaped arrangement of crystalline needles, which an uncautious, non-microscopical observer might confound with simple concretions. They have, however, a structure entirely different from any concretions met with in terrestrial rocks, as for example that of oolitic grains. In them we often see a well-marked nucleus, on which radiating crystals have been deposited equally on all sides, and the external form is manifestly due to the growth of these crystals. On the contrary the grains in meteorites now under consideration have an external form *independent of the crystals*, which do not radiate from the centre, but from one or more places on the surface. They have, indeed, a structure absolutely identical with that of some artificial blowpipe beads which become crystalline on cooling. With a little care these can be made to crystallise from one point, and then the crystals shoot out from that point in a fan-shaped bundle, until the whole bead is altered. In this case we clearly see that the form of the bead was due to fusion, and existed prior to the formation of the crystals. The general structure of both these and the previously described spherical grains also shows that their rounded shape was not due to mechanical wearing. Moreover, melted globules with well-defined outline could not be formed in a mass of rock pressing against them on all sides, and I therefore argue that some at least of the constituent particles of meteorites were originally detached glassy globules, like drops of fiery rain.

Another remarkable character in the constituent particles of meteorites is that they are often mere fragments, although the entire body before being broken may originally have been only one-fortieth or one-fiftieth of an inch in diameter. It appears to me that thus to break such minute particles when they were probably in a separate state, mechanical forces of great intensity would be required. By far the greater number of meteorites have a structure which indicates that this breaking up of the constituents was of very general occurrence.

Assuming then that the particles were originally detached like volcanic ashes, it is quite clear that they were subsequently collected together and consolidated. This more than anything else appears to me a very great difficulty in the way of our adopting Reichenbach's cometary theory. Volcanic ashes are massed together and consolidated into tuff, because they are collected on the ground by the gravitative force of the earth. It appears to me very difficult to understand how in the case of a comet there could be in any part a sufficiently strong gravitative force to collect the dispersed dust into hard stony masses like meteorites. If it were not for this apparent difficulty we might suppose that some of the facts here described were due to the heat of the sun, when comets approach so near to it that the conditions may be practically almost solar. Comets may and probably do contain many meteorites, but I think that their structure indicates that they were originally formed under conditions far more like those now existing at the surface of the sun than in comets.

The particles having been collected together, the compound mass has evidently often undergone considerable mechanical and crystalline changes. The fragments have sometimes been broken *in situ*, and "faulted;" and crystallisation has taken place, analogous to that met with in metamorphic rocks, which has more or less, and sometimes almost entirely, obliterated the original structure. The simplest explanation of this change is to suppose that after consolidation meteorites were variously heated to temperatures somewhat below their point of fusion. Those which have the structure of true lava may in some cases be portions which were actually remelted. We have also this striking fact, that meteoric masses of compound structure, themselves made up of fragments, have been again broken up into compound fragments, and these collected together and consolidated along with fresh material, to form the meteorites in their present condition. L'Aigle is a good example of this complex structure.

Another remarkable fact is the occurrence in some meteorites of many veins filled with material, in some respects so analogous to the black crust, that at one time I felt induced to believe that they were cracks, into which the crust had been injected. Akburfur is a good example of this, and seems to show that under whatever conditions the veins were found, they were injected not only with a black material, but also with iron and magnetic pyrites.

Taking, then, all the above facts into consideration, it appears to me that the conditions under which meteorites were formed must have been such that the temperature was high enough to fuse stony masses into glass; the particles could exist independently one of the other in an incandescent atmosphere, subject to violent mechanical disturbances; that the force of gravitation was great enough to collect these fine particles together into solid masses, and that these were in such a situation that they could be metamorphosed, further broken up into fragments, and again collected together. All these facts agree so admirably with what we know must now be taking place near the surface of the sun, that I cannot but think that, if we could only obtain specimens of the sun, we should find that their structure agreed very closely with that of meteorites. Considering also that the velocity with which the red flames have been seen to be thrown out from the sun is almost as great as that necessary to carry a solid body far out into planetary space, we cannot help wondering whether, after all, meteorites may not be portions of the sun recently detached from it by the violent disturbances which do most certainly now occur, or were carried off from it at some earlier period, when these disturbances were more intense. At the same time, as pointed out by me many years ago, some of the facts I have described may indicate that meteorites are the residual cosmical matter, not collected into planets, formed when the conditions now met with only near the surface of the sun extended much further out from the centre of the solar system. The chief objection to any great extension of this hypothesis is that we may doubt whether the force of gravitation would be sufficient to explain some of the facts. In any case I think that one or other of these solar theories, which to some extent agree with the speculations of the late Mr. Brailey, would explain the remarkable and very special microscopical structure of meteorites far better than that which refers them to portions of a volcanic planet, subsequently broken up, as advocated by Meunier, unless indeed we may venture to conclude that the material might still retain its original structure, due to very different conditions, previous to its becoming part of a planet. At the same time so little is positively known respecting the original constitution of the solar system, that all these conclusions must to some extent be looked upon as only provisional.

I will now proceed to consider some facts connected with meteoric irons. The so-called Widmanstatt's figuring, seen when some of these irons are acted on by acids, is well known; but in my opinion the preparations are often very badly made. When properly prepared, the surface may be satisfactorily examined with a magnifying power of 200 linear, which is required to show the full detail. We may then see that the figuring is due to a very regular crystallisation, and to the separating out one from the other of different compounds of iron and nickel, and their phosphides. When meteoric iron showing this structure is artificially melted, the resulting product does not show the original structure, and it has therefore been contended that meteoric iron was never in a state of igneous fusion. In order to throw light on this question, I have paid very much attention to the microscopical structure of nearly all kinds of artificial irons and steels, by studying surfaces polished with very special care, so as to avoid any effect like burnishing, and then acting on them very carefully with extremely dilute nitric acid. In this manner most beautiful and instructive specimens may be obtained, showing a very great amount of detail, and requiring a magnifying power varying up to at least 200 linear. In illustration of my subject I will call attention to only a few leading types of structure. In the first case we have grey pig-iron, showing laminæ of graphite promiscuously arranged in all positions, on the surface of which is a thin layer of what is probably iron uncombined with carbon, whilst the intermediate spaces are filled up with what are probably two different compounds of iron and carbon.

White chilled refined iron has an entirely different structure and more uniform crystallisation, the structure is very remarkable and beautiful, mainly due to the varying crystallisation of an intensely hard compound of iron and carbon, and the two other softer compounds met with in grey pig.

Malleable bar iron has an entirely different structure, and shows fibres of black slag, and a more or less uniform crystallisation of iron with a varying small amount of carbon.

Cast steel differs again very much from any of the previous. It shows a fine-grained structure, due to small radiating crystals, and no plates of graphite.

The difference between any of the above and meteoric iron is extremely great.

In the case of Bessemer metal we have a crystalline structure approaching in some places more nearly to that of meteoric iron. We see a sort of Widmanstatt's figuring, but it is due to the separation of free iron from a compound containing a little carbon, and not to a variation in the amount of nickel.

The nearest approach to the structure of meteoric iron is met with in the central portion of thick bars of Swedish iron, kept for some weeks at a temperature below their melting point, but high enough to give rise to recrystallisation. We then get a complete separation of free iron from a compound containing some carbon, and a crystalline structure which, as far as mere form is concerned, most closely corresponds with that of meteoric iron, as may be at once seen on comparing them.

These facts clearly indicate that the Widmanstatt's figuring is the result of such a complete separation of the constituents and perfect crystallisation as can occur only when the process takes place slowly and gradually. They appear to me to show that meteoric iron was kept for a long time at a heat just below the point of fusion, and that we should be by no means justified in concluding that it was not previously melted. Similar principles are applicable in the case of the iron masses found in Disco, and it by no means follows that they are meteoric because they show the Widmanstatt's figuring. Difference in the rate of cooling would serve very well to explain the difference in the structure of some meteoric iron, which do not differ in chemical composition; but, as far as the general structure is concerned, I think that we are quite at liberty to conclude that all may have been melted, if this will better explain other phenomena. On this supposition we may account for the separation of the iron from the stony meteorites, since under conditions which brought into play only a moderate gravitative force, the melted iron would subside through the melted stone, as happens in our furnaces; whilst at the same time, as shown in my paper read at the meeting of the British Association in 1864, where the separating force of gravitation was small, they might remain mixed together, as in the Pallas iron, and others of that type.

In conclusion I would say that though from want of adequate material for investigation I feel that what I have so far done is very incomplete, yet I think that the facts I have described will, at all events, serve to prove that the method of study employed cannot fail to yield most valuable results, and to throw much light on many problems of great interest and importance in several different branches of science.

MENDELEEF'S RESEARCHES ON MARIOTTE'S LAW[1]

FROM researches on the depression of the mercury results the possibility of introducing a precise correction relative to the volume of gas contained between the surface of the mercury and the horizontal plane which touches the summit of the meniscus. In all my researches I introduce each time a correction relative to this volume.

The volume of the reservoir which contains the mercury and the gas under various pressures undergoes two kinds of variations; first, those which are due to the difference between the pressures which act on the two sides of the vessel, and second, those which depend on differences in the volume of mercury. The compressibility of the reservoirs employed in the researches has been always determined by experiment, and their change of volume produced by the introduction of mercury can be determined by surrounding the vessel filled with mercury by another filled with the same material. When the height in the two vessels is the same, the capacity of the vessel is that which exists at the time of equality of pressure on the external and internal surfaces of the vessel. If we empty a part of the external vessel the capacity of the vessel changes in the same manner as when we fill or when we empty the vessel. Experiments of this kind have shown the possibility of determining the changes of capacity depending on the quantity of mercury. The relative corrections have in each case been introduced into the calculations.

All the practical side of the subject—the desiccation of the gas, the complete abstraction of the remains of the gas from the apparatus, the hermetical junction of the parts of the apparatus by means of mastic and mercury stop-valves, the means of maintaining the gases and the mercury at a constant temperature, the calibration of the tubes, and a number of other details have had to be elaborated more or less anew. All this will be found described in my work "On the Elasticity of Gases." I have published this work only in Russian, not having means sufficient to publish a translation of a work so voluminous, and desiring to conform to the custom existing among *savants* of all countries of describing their labours in their mother-tongue, in order to present to the scientific literature of the country where they live and work a gift in proportion to their powers.

My desire was to investigate the subject in its minutest details in order to eliminate every possibility of doubt as to the causes which determine the deviations observed from the Boyle Mariotte Law. I know that that law is firmly established, and I believe it will remain so. Not less great is the certainty in the mind that rarefied gases approach the perfect state. That certainty I had also on commencing my experiments. It was necessary then to determine as completely as possible all the circumstances on which depend the facts contrary to the opinion generally held. This is why I have modified the apparatus, improved the methods, and employed in this work more than three years without interruption. Now so far as regards low pressures the work is finished, and I have obtained definitely certain proofs of the rigorous accuracy of my first observations.

The experiments which I have made with Kirpitchoff have proved that not only for air, but also for hydrogen, and even for carbonic acid, the deviations are positive when the gas is subjected to a very small pressure; it is found, moreover, that these deviations increase in proportion to the variation from the normal pressure. The same thing has been found in a new series of experiments undertaken by me with M. Hemilian. The experiments are described in tome ii. of my work on the "Elasticity of Gases," which I have just published. A brief extract on this subject is published in the *Ann. de Chimie et de Physique*, October, 1876. I shall quote only the results obtained by us from the experiments made in 1875 and in the beginning of 1876.

Into a new apparatus we have introduced several further improvements, of which the chief are:—(1) The baromanometer, the metre, and the reservoir, containing the gas and the mercury, have been placed in the same bath full of water; (2) We have succeeded in producing a complete vacuum in the barometric chamber; (3) The bath was maintained at an almost uniform temperature by means of an agitator, and the small differences in the temperatures of the various layers have been determined by a differential thermometer; (4) The junction between the air reservoir and the baromanometer has been made, not only without the aid of a tap, but also without the use of mastic.[1] Thus the gas was surrounded only by the glass and the mercury.

We shall confine ourselves to a summary of the results of our experiments, made between 650 and 20 millimetres' pressure, with four gases—H, air, CO, and SO.

1. If, starting with a certain small pressure, we arrive at pressures smaller still, we find for all gases positive deviations, viz., $\frac{d(pv)}{dp} > 0$, the gases, then, are in this case less compressed than Mariotte's Law requires. Similar deviations were also observed for hydrogen by M. Regnault between 1 and 30 atmospheres, and M. Natterer for all gases between 100 and 3,000 atmospheres.

2. Under small pressures and for all gases, the value of the positive deviations, *i.e.*, the numerical quantity (or magnitude) $\frac{d(pv)}{dp}$, increases when the initial pressure diminishes. Thus, for example, for hydrogen at 400 millimetres—

$$\frac{d(pv)}{dp} = +0.000002,$$

and at 120 millimetres—

$$\frac{d(pv)}{dp} = +0.000010$$

3. For gases like CO^2 and SO^2 we find near the atmospheric pressure, negative deviations, *e.g.*, for CO^2, $p_0 = 635$, $p_1 = 200$, $p_0 v_0 = 10{,}000$, $p_1 v_1 = 10{,}029$, but, under less pressures still, the deviations become positive even for CO^2 and SO^2. For example, for CO^2, $p_0 = 190$, $p_1 = 64$, $p_2 = 22$, $p_0 v_0 = 10{,}000$, $p_1 v_1 = 9{,}996$, $p_2 v_2 = 9{,}983$; for SO^2, $p_0 = 190$, $p_1 = 60$, $p_2 = 22$, $p_0 v_0 = 10{,}000$, $p_1 v_1 = 10{,}010$, $p_2 v_2 = 9{,}996$.

4. The existence of positive and negative deviations for the

---

[1] Continued from p. 457.

[1] To attain this end the gas-vessel and the branch of the baromanometer are soldered together by a capillary tube made of a single piece.

same gas, observed by means of the same apparatus, according to the amount of pressure, and the conformity in the various series of experiments, prove that the results obtained do not depend on any constant errors in the methods employed, but that they are really caused by the nature and the essential qualities of the gases investigated.

5. The variations from Mariotte's Law under very weak pressures being very small, it is necessary, in determining them, to make the reading of the pressures, the volumes, and the temperatures (absolute $t = 273°$) with a precision of two-thousandths of these total values; thus, *e.g.*, if $p_0 = 0·200$ m., $p_1 = 0·100$ m., and $v_0 = 2,500$ gr., $v_1 = 5,000$ gr. of mercury ($t = 20$), it will be necessary to determine the pressures with a precision of 0·01 mm., the volumes to 0·1 gr. of mercury, and the temperatures to 0·01 of a degree.

The results will be doubtful if the precision is less.[1] Thus it is found that *under a certain small pressure gases present positive deviations from Mariotte's Law*; even gases like sulphurous acid and carbonic acid, which under high pressures show considerable negative deviations. It is the same with air. M. Regnault commenced his researches with pressures which exceeded that of the atmosphere, and obtained negative deviations.

In 1874 I effected with all the care possible the determination of the deviations for air under pressures of from 650 to 2,000 milimetres, and towards the end of 1875 and in the beginning of 1876, in a special apparatus provided with compound manometers, I repeated the same experiments with M. Bogusski for pressures from 700 to 3,000 millimetres with air, hydrogen, and carbonic acid. These researches proved the rigorous accuracy of M. Regnault's conclusions. Air and carbonic acid were found to be subject under these pressures to negative deviations, greater for carbonic acid than for air; and hydrogen, for these same pressures, was found to present positive deviations. At present we are continuing the same kind of experiments for pressures of more than three metres.

Thus hydrogen, under all pressures, commencing with zero and ending with a pressure infinitely great, presents throughout positive deviations; at no pressure does it follow Boyle's Law rigorously, and it never presents negative deviations. Increased pressures always give a greater volume than what might be expected according to the variation of the pressures. Air under pressures less than 600 millimetres also presents positive deviations; but under pressures greater than that of the atmosphere its deviations become negative, and under pressures which exceed 100 atmospheres its compressibility again becomes positive. Consequently for this gas there are two pressures at which it follows Boyle's Law; the one is very nearly that of the atmosphere, the other lies between 30 and 100 atmospheres. These pressures, under which the changes of the sign of compressibility occur, will be different for carbonic acid; viz., under pressures less than that of the atmosphere the change of sign is found at nearly 200 millimetres, and for higher pressures it commences near that which corresponds to 70 metres of mercury, if we base our researches on this point on the observations of Dr. Andrews on the compressibility of carbonic acid gas for temperatures above 31°. For lower temperatures this point will probably correspond to the passage of carbonic acid into the liquid state. Consequently with a change of temperature the pressure at which the change of sign of compressibility occurs, changes also. For sulphurous acid the sign of compressibility under pressures lower than that of the atmosphere changes at about forty millimetres of pressure. But even this gas, so easily liquefiable, under low pressures, has always a positive compressibility. There is not then, and there cannot be, a gas which is rigorously subject to Mariotte's Law under small pressures.

The idea of an absolute gas belongs, then, to the number of fictions which find no confirmation in facts. We cannot, then, suppose that with the decrease of density or with the increase of the *vis viva* of gaseous molecules, gases approach a state in which they follow Boyle's Law. Then (the density diminishing, the velocity of the molecules increasing, that is to say, the pressure diminishing, the temperature increasing, and the molecular weight diminishing) they all tend towards another state characterised by the expression $\frac{d(pv)}{dp} > 0$; *i.e.*, they are assimilated to solid and liquid bodies, when the condensation reaches its limit. We must believe that there is a limit of condensation and a limit of rarefaction. If we take, in fact, a mass of non-volatile liquid, and if we submit it to pressures infinitely great and infinitely small, we shall see it change volume; but in the two cases, we shall have finite volumes, capable of measurement, and even differing little for one and the same body. It is the same with gases, if we admit that for pressures approaching zero, gases contract according to the same law as that which we can deduce from our compression experiments under pressures less than that of the atmosphere, or as hydrogen contracts. Under great pressures, or under pressures excessively small, every gas resembles a solid or liquid body, and possesses two limits of compressibility. The volumes which correspond to these limits are very different, but there is always reason for believing that they exist.

Without launching into hypotheses to explain these limit volumes (such, *e.g.*, as the supposition that molecules in themselves possess volume), I will confine myself to the question of the matter of celestial space. What is the luminous ether? One of two things—either an elastic independent matter, *sui generis*, or the gas of the atmospheres of celestial bodies, considerably rarefied. In the latter case it is necessary to admit the absence of limits in the atmospheres and a condensation of the ether greater and greater in proportion as we approach a celestial body (sun or planet). There are many arguments for and against both hypotheses. On the one hand, spectrum analysis leads us to conclude that the material of all heavenly bodies is identical; on the other hand, it proves the diversity of the composition of atmospheres. This is why we abstain from solving the question in its essence. But spectrum analysis does not speak less in favour of the former hypothesis, because it shows the diversity of composition of our terrestrial atmosphere from that of many of the other celestial bodies. In the researches on the resistance of celestial matter to the movement of the planets, there appears also to be a confirmation of the former of these two hypotheses, for neither planets nor comets show any diminution in the excentricity of their orbits, which would be an inevitable consequence of motion in a rarefied medium, as has been observed in the case of Encke's comet. Exact investigations on the movement of that comet, repeated in recent times by M. von Asten, the Pulkowa astronomer, show clearly the advances towards the sun at perihelion, although in the beginning M. von Asten had not noticed them. But that comet at perihelion was found only at one-third of the distance which separates the sun from the earth, *i.e.*, it was nearer to the sun than Mercury. It is possible that it passed near to the limits of the solar atmosphere. Faye's comet, as is known, does not present these same diversities, but its perihelic distance is about 1·68, that of Encke's comet being only about 0·33; it exceeds it then so much that their comparison would only serve to confirm the hypothesis of a solar atmosphere. If we admit a limit for the atmospheres, we must expect in gases, for small pressures, exactly that kind of variation from Boyle's Law which I observed in rarefied gases.

To prove that gases under very small pressures, as well as under very considerable pressures, vary from the Boyle-Marriotte Law is by no means the same as to deny the truth of that law; I feel that I ought to state this most explicitly. For a long time the law of gravitation could not be made to accord with the perturbations; latterly these perturbations have proved the best confirmation of the laws of gravitation. In the present case it may be the same. There are three laws for gases: that of Boyle and Marriotte, $pv =$ const.; that of Gay Lussac, $v_t = v_0 (1 + \alpha t)$; and that of Ampère and Gerland $\frac{av}{m} =$ const. (a being the molecular weight, and m the mass). Their *ensemble* is expressed for all gases in general by the equation—

$$apv = 845\,(273 + t)\,m,$$

where a is the atomic weight ($H = 1$), p the pressure in kilograms per square metre, v the volume in cubic metres, m the weight in kilograms, t the centigrade temperature. This is, however, only a first approximation. In the second member of the equation there must be additional terms which express a function of p and of a, very small for the ordinary mean values of p, and which become of a sensible magnitude only when p is very small or very great. To find this function is a question of the future, and demands the labours of a great number of investigators. My aim is to be able to furnish some experimental data which will permit of judging of the form of that function. This work requires many new processes, measuring apparatus of a high degree of precision, many varied arrangements as well as experienced assistants. That idea has secured me the protection of His Imperial Highness the Grand Duke Constantine and the support of the Imperial Russian Technical Society.

---

[1] It is by these causes that the want of conformity in the experiments of Siljeström is sufficiently explained (*Pogg. Ann.*, April and May, 1874; see also the *Bull. de l'Acad. de Sc. de St. Pétersbourg*, t. xix, p. 466, and *Berichte der deutschen chem. Gesell.*, t. viii., p. 1,339; t. viii., pp. 576 and 749), and of M. Amagat (*Comptes Rendus*, April 17, 1876.)

I thus conclude this communication which I have the honour to send you. The researches on the co-efficients of dilatation of gases in their general features confirm the accuracy of the deductions drawn from the observations on compressibility. But that matter is in process of elaboration, and only a part of the researches has been completed. Consequently I abstain from expounding all the details of the subject. I shall only remark that the true coefficient of dilatation of air under constant pressure and with variable volume is found to be greater for pressures near to atmospheric pressure than the number generally accepted, notably from the researches which I have made with M. Kaiander, it is equal to 0·003683 if we take 100° C. as the temperature of boiling water under an atmospheric pressure of 760 mm. in latitude 45°.

If you do not find devoid of interest more ample details on this subject, as also on the determination of the weight of a litre of air, I shall have the greatest pleasure in explaining to the English public through your interesting journal the essential points of the researches made on this subject in my laboratory.

St. Petersburg, January 1 DR MENDELEEF

OUR ASTRONOMICAL COLUMN

BINARY STARS.—From one of the very careful and complete investigations on the orbits of the revolving double stars, by which Dr. Doberck is so greatly contributing to our knowledge of the motions of these interesting objects, we have an orbit of ξ Scorpii which is probably a very near approximation to the true one.

We have called the star by what appears to be its correct designation, ξ Scorpii, but few stars have been subjected to more varied nomenclature than the one in question. In Dr. Doberck's paper, published in No. 2,121 of the *Astronomische Nachrichten*, in all probability through one of the typographical errors which have of late so much disfigured this periodical, the star is styled ζ Libræ. It has been previously very commonly lettered ξ Libræ, and it is 51 Libræ of Flamsteed; Secchi, in *Astron. Nach.*, No. 1,614, calls it ρ′ Libræ, though we are ignorant upon what precedent.

Dr. Doberck's elements are those of a very nearly circular orbit, and it may be remembered that some thirty years since Madler gave elements for circular motion with a period of revolution of about 104 years. In *Astron. Nach.*, No. 1,683, Dr. Thiele gave the results of a very complete discussion of the measures up to 1856, in which he has assumed that Sir W. Herschel's angle on the night of his discovery of the duplicity of the star has been registered correctly, though a doubt has been entertained upon this point. He thus arrives at a highly excentrical elliptic orbit with a period of a little over forty-nine years. It should be remarked that from the near approach of the magnitudes of the components forming the double star ξ Scorpii (it is more correctly a triple star), an error of 180° in the measured angle of position is by no means an improbable one.

Dr. Doberck assumes that Sir W. Herschel's angle of 1782 requires this correction, and deduces an orbit in which the period of revolution is nearly twice that of Thiele, and which therefore approaches the period originally assigned by Madler. His elements are as follow :—

Peri-astron passage 1859·62.

Node ...	12° 15′	Inclination ...	68° 42′
Node to peri-astron on orbit			89° 16′
Eccentricity			0·0768
Semi-axis major			1″·26
Revolution			95·90 years.

A full comparison with the measures up to the present time, appears in the *Astronomische Nachrichten*.

In the same number Dr. Doberck gives first elements of that exceedingly difficult object γ Coronæ Borealis, in which the period of revolution is 95½ years, and the peri-astron passag 1843·7. The distance calculated from this orbit is still unde two-tenths of a second, but it will increase, until towards th end of the first decade of the next century the components according to Dr. Doberck's calculation, will be separated b more than 0″·8.

THE ANNULAR ECLIPSE OF THE SUN, 1737, MARCH 1.—Prof. Grant, in his "History of Physical Astronomy," mention this eclipse as the first annular one of which we have any detaile account. This phase passed over Edinburgh, where it was observed by Maclaurin, the well-known mathematician, by Short the optician, Lord Aberdour, and others. The times wer determined by Maclaurin by a pendulum clock of Graham's and he was also furnished with a meridian instrument by th same maker, with the aid of which the clock was rated by Shor for "a long time before and after the eclipse." The clock use by Lord Aberdour, who was located in Edinburgh Castle, wa compared with Maclaurin's at noon on the day of the eclipse and in addition signals were exchanged between the Castle an Maclaurin's station at the college. Both observers determine the duration of the annular phase to have been 5m. 48s.

The following elements of this eclipse have been deduced fron a similar system of computation as regards the moon's place t that adopted for other eclipses to which reference has been mad from time to time in this column, a system which gives result for the total solar eclipse of 1715 agreeing very closely with th observations of Flamsteed and Halley.

G.M.T. of conjunction in R.A., March 1, at 3h. 1m. 31s.

	°	′	″	
R.A.	342	35	32·0	
Moon's hourly motion in R.A. ...		28	50·9	
Sun's ,, ,, ,, .		2	20·3	
Moon's declination ...	6	44	0·1	S.
Sun's ,, ...	7	24	5·7	S.
Moon's hourly motion in decl. ...		8	49·5	N.
Sun's ,, ,, ,, .		0	57·2	N.
Moon's horizontal parallax		54	19·1	
Sun's ,, ,, ...			9·0	
Moon's true semi-diameter		14	48·0	
Sun's ,, ,, ...		16	7·7	

The equation of time was 12m. 40s. subtractive from mean time The following were points upon the central line by the abov elements :—

Long. 10° 10′ W.	Lat. 54° 53′ N.	Long. 4° 11′ W.	Lat. 56° 35′
,, 7 26 W.	,, 55 42 N.	,, 0 4 W.	,, 57 36

If reduction equations are founded upon a direct calculatio for Edinburgh, there result for any place not far distant :—

$$\cos w = 27{\cdot}6369 - [1{\cdot}59611] \sin l + [1{\cdot}22018] \cos l . \cos (L - 51^\circ\ 1'{\cdot}4)$$
$$t = 2\text{h}\ 13\text{m}.\ 35{\cdot}5\text{s} \mp [2{\cdot}49350] \sin w + [3{\cdot}49325] \sin l - [3{\cdot}89289] \cos l . \cos (L + 147^\circ\ 15'{\cdot}5).$$

where l is the geocentric latitude of the place, L its longitud from Greenwich + if E, − if W, and t is expressed in Gree wich mean time; the upper sign is to be used for beginning annular phase, and the lower for the ending. The quantiti within square brackets are logarithms.

The calculated duration of annularity at Edinburgh 5m. 46·6s., differing only 1·4s. from the observations of Ma laurin and Lord Aberdour, but the middle of this phase is give later by 1m. 51s. At other places mentioned in Maclaurin memoir on this eclipse, published in the *Philosophical Transa tions*, the duration of the annulus was as follows :—At Alnwic 2m. 0s.; at Crosby, near Ayr, 5m. 54s.; at Montrose, 6m. 27s and at St. Andrew's, 6m. 12s. At Aberdeen, which was ve near the central line, the *annulus* was formed at 3h. 43m. c local mean time, and continued 6m. 30s. On the east coast Scotland, where the duration of *annulus* was longest, it did n exceed 6m. 3s. The eclipse is not given annular at Morpet therein agreeing with the observation.

NOTES

THE Swiney Lectures on Geology (free to the public) will be delivered this year at the Royal School of Mines, Jermyn Street, on Monday and Thursday evenings at eight P.M., commencing on Monday, April 9.

As we have already stated, the "Verein fur die deutsche Nordpolarfahrt," of Bremen, has been converted into a Geographical Society (die geographische Gesellschaft in Bremen) with the object of promoting scientific exploring expeditions generally, and of publishing their results. Dr. Finsch, who was sent out by the Verein last year to the mouths of the Obi along with Dr. Brehm and Graf Waldburg-Zeil, is now busily engaged in working out the ethnographical and natural history collections made during the expedition and publishing their results. A paper of Dr. Finsch on the new birds discovered on this occasion has been received by the Zoological Society of London, and will be read at one of their next scientific meetings.

ON Friday, April 13, Mr. W. Spottiswoode will deliver a lecture at the Royal Institution on his great Induction Coil, described in the January number of the *Philosophical Magazine* and in the March number of the *Nineteenth Century*. The lecture will be illustrated with some new experiments on stratified discharges, which a coil of this enormous power has for the first time rendered practicable.

THE Leipsic publisher, Gunther, has issued the first part of a new journal, *Kosmos*, specially devoted to the furtherance of the development doctrine, under the editorship of Caspari, Jager, and Krause, with the assistance of Darwin, Haeckel, and other eminent workers in the Darwinian field. We shall give a detailed notice of the first part in an early number.

PROF. SYLVESTER seems to have become quite naturalised in the United States, if we may judge from the fact that he was one of the speakers at the celebration of Washington's birthday at the Johns Hopkins University, where, as our readers know, he is Professor of Mathematics. Prof. Sylvester spoke of his work and of his satisfaction with his new relations, as also on some points of general interest. He maintains that it is a mistake to divorce teaching and research, illustrating the advantage of their union in his own case by the fact that in the act of teaching, important fields for research have been suggested to him. Recently, for example, at the University in Baltimore, the persistence of a student in his desire to study the new algebra has led Prof. Sylvester into "a research of fascinating interest," from which he hopes for great results. He has reason "to think that the taste for mathematical study, even in its most abstract form, is much more widely diffused than is generally supposed" in the United States. Prof. Sylvester, the *Nation* tells us, spoke at considerable length and with deep feeling on the estrangement between the two great branches of the Anglo-Saxon race caused by the exclusive, ecclesiastical policy of the English Universities in former years. "'Their work it is that a separation deeper and a chasm more difficult to fill up has been created between the two most free and powerful nations in the world—England and America—than any due to political causes, present or past." Why is it, he inquired, that the flower of American youth do not resort for their mental impulse and higher education to Oxford and Cambridge, instead of to Berlin, Leipzig, Jena, or Heidelberg? "It is because there they are welcomed, to whatever religious communion they are attached or unattached, without question and without distinction. It is because there they can rest on the bosom of a common mother, who shows kindness to all and favour to none. . . I have been struck, almost from the first hour of my landing on these shores, by the manifestations I have everywhere witnessed of the close intellectual sympathy, which exists between America and Germany. It is German books that are read, it is German authors who are quoted, German opinion on all matters of science and learning that is appealed to; and as regards community of work and intellectual ties, I do not think it at all extravagant to assert that Germany and America belong to one hemisphere, and we in England to another." If our universities are to blame for this state of things, they have much to answer for; and it is therefore some relief to know that the New York *Nation* accounts for it by the desire of Americans to acquire another language in the country where it is spoken, and to come in contact with a different order of mind, however little superior.

DR. KLEIN, extraordinary professor of mineralogy in the University of Heidelberg, has accepted an ordinary professorship in the University of Göttingen.

THE Clothworkers' and Merchant Taylors' Companies have each contributed one hundred guineas to the fund being raised by the Chemical Society for the promotion of chemical research.

THE trustees of the Johnson Memorial Prize for the encouragement of the study of astronomy and meteorology propose the following subject for an essay, "The History of the Successive Stages of our Knowledge of Nebulæ, Nebulous Stars, and Star clusters, from the Time of Sir William Herschel." The prize is open to all members of the University of Oxford, and consists of a gold medal of the value of ten guineas, together with so much of the dividends for four years on 338*l.* Reduced Annuities as shall remain after the cost of the medal and other expenses have been defrayed. Candidates are to send their essays to the registrar of the University, under a sealed cover marked "Johnson Memorial Prize Essay," on or befor March 31, 1879, each candidate concealing his name, distinguishing his essay by a motto, and sending at the same time his name sealed up under cover with the same motto written upon it.

ONE or more minor scholarships in natural science will be offered by Downing College, Cambridge, during the present year. The scholarships range in value from 40*l.* to 70*l.* per annum, and are tenable for two years, or until the holder is elected to a foundation scholarship. The examination will be held in Downing College on June 5 and the three following days. The subjects of examination will be (1) Chemistry, theoretical and practical; (2) Physics; (3) Comparative Anatomy; and (4) Physiology. All persons are eligible to these scholarships who have not commenced to reside in the University.

ON March 7, at Gjesvar, a Norwegian fishing station, near the North Cape, in 71° 12 N. lat., the most northerly telegraph station on the earth was opened.

THE *Conversazione* of the Quekett Club takes place on the 13th inst., at University College, Gower Street.

THREE electric eels from the River Amazon have this week been added to the Westminster Aquarium. As they require to be kept at a temperature of between 70° and 80° F. it needed some ingenuity to bring them from Liverpool, where they were landed, to London. By placing the vessel containing them on foot-warmers and telegraphing on for changes of foot-warmers at different stations, the water on arriving at Westminster was found to be at 75°. The eels are lodged in a tank kept warm by a steam pipe passing under the shingle, and are at present by the alligators. These, by the by, are waking up wonderfully in activity, and the attendants have now to keep a sharp look-out when cleaning the tank.

WE are enabled to state that the increasing number of demands for space in the Paris International Exhibition has led M. Krantz reluctantly to give up the idea of authorising the construction of the large Giffard Captive Balloon within the precincts of the Exhibition. The construction will take place at all events either on public ground lent by the Government or on some private vacant space at a small distance from the Champ de Mars. The preliminary technical arrangements have been made by M. Giffard. The length of the rope will be about 600 metres. It will be conical; the largest end close to the car will be 8 centimetres diameter, the smallest end only 6. The ascending force, when loaded with ballast, guide ropes, grapnels, and 50 passengers, will be 5 tons. The weight of the cable will be 2¼ tons when fully expended. The ascending force of the hydrogen filling the envelope will be 23 tons. The diameter of the balloon will be 34 metres, the height 50 metres from the lower part of the car to the upper part of the valve, and the engine will be of 200-horse power.

THE supplementary number, 51, of Petermann's *Mittheilungen* contains the second half of the late E. De Pruyssenaere's travels in the region of the White and Blue Nile. This part contains the special scientific results of the accomplished traveller—meteorological observations, barometrical altitude observations, river measurements, astronomical observations, triangulation of a part of the Jezira, besides the southern half of the map, constructed by the editor, Herr Zoeppritz, and a plate of some of the implements, weapons, utensils, ornaments, &c., used by the inhabitants of the region traversed.

AT the meeting of the delegates of the French learned societies to be held at the Sorbonne, as we noticed last week, M. Alluard, the director of the Puy-de-Dôme Observatory, will present a most interesting paper. A self-registering barometer has been kept in constant operation on the top of the Puy-de-Dôme, and another similar instrument was observed at Clermont-Ferrand during the same length of time. The difference of pressure has undergone most remarkable variations, which cannot be accounted for by the Laplace law for determining the altitudes by comparing barometers. The corrections of temperature will be shown to be quite insufficient.

THE Scientific Congress of France, a quite distinct organisation, established by the late M. de Caumont, will hold its forty-third session at Versailles, from May 17 to 27. A number of attractive excursions have been arranged with the help of the municipal authorities, and there will be a floral exhibition.

AT the meeting of the St. Petersburg Society for the Protection of Trade, March 21, the maps prepared last summer by M Orloff during his journey to the Baydaraksky Gulf, were exhibited. The survey and levelling were made from the Irtish, up the Shchuchya River, and along the Baydaraka River to the Baydaraksky Gulf. Both rivers are navigable during the three months—June, July, and August.

A TOMSK telegram received by M. Siderof on March 18, from M. Schwanenberg's expedition, announces the find, on the banks of the Obi, near to the Mariinsky gold-washings, of a well-preserved mammoth with flesh and skin. The definitive excavation of the carcass was stopped until instructions should arrive from St. Petersburg.

DR. J. F. BRANSFORD, surgeon in the United States Navy, has been investigating the antiquities on the island of Omotepe, in Lake Nicaragua, collecting large numbers of vases of various kinds, burial urns, ornaments, and other objects for the National Museum at Washington. Among the more important points substantiated by him was the occurrence on the island of at least three successive and distinct bases of prehistoric civilisation, all of them anterior to the present epoch, these being bounded and defined by successive overflows of lava from the volcano. Very great intervals of time elapsed between the eruptions, as is shown by the accumulations of soil that took place on the fresh surface of the lava from the decomposition of vegetable deposits. No estimate can be made of these eras, but they are believed to carry the period of the earliest overflows back to a very remote antiquity. The objects of these successive layers are very definite and easily recognisable by the practised eye, and highly important deductions in regard to the early civilisation of that region are expected from a critical investigation of the subject. Dr. Bransford has prepared an elaborate report on this subject for presentation to the Navy Department, but, before publishing it, he has obtained permission to revisit the country, and settle some still doubtful points.

A MALVERN correspondent writes that he and many other residents in that part of the country are desirous of having some legislative protection for the *eggs* of such birds as are mentioned in the Wild Birds' Preservation Act. He wishes to know if there is any society for looking to the interests of wild birds; if so he and others will be glad to subscribe. The Woolhope Field Club used to give rewards for the best collection of birds' eggs, but the rule was altered when the mischief of this course as regards ornithology became evident.

THOSE of our readers who were at the Glasgow meeting of the British Association last autumn will, no doubt, remember the interesting collection which was on view in the City Industrial Museum. The Report of the Museum for 1876 has just been issued, and we are pleased to see that under the management of its Curator, Mr. Paton, it is rapidly increasing in size and importance, and we have no doubt that ere long it will become, what so important a city as Glasgow ought to possess, a really valuable industrial collection arranged on a thoroughly scientific plan.

AT a recent meeting of the French Academy M. de Romilly called attention to some remarkable effects obtained by suspension of water sucked up into a bell jar closed below by a tissue with wide meshes; in one arrangement, the net being metallic the suspended water could even be boiled by heat applied below. M. Plateau has just pointed out that he described this phenomenon of suspension in 1867, in treating of the construction of aquatic arachnida.

A propos of the question (which has been disputed) whether toads eat bees, M. Brunet states, in *La Nature*, that going one day into his garden, just before a storm, he found the bees crowding into their hives. About fifty centimetres from the best hive there was a middle-sized toad, which every now and again rose on his fore-legs and made a dart with surprising quickness towards blades of grass. He was found to be devouring bees, which rested on the grass-blades, awaiting their chance to enter the hive. M. Brunet watched till twelve victims had been devoured; he expected the toad's voracity would soon be punished with a sting, but in vain. Objecting to further destruction, he seized the toad by one of his legs and carried him to a bed of cabbage thirty metres off, where he might do real service among the caterpillars, &c. Three days after this, on going out to the hives, he found the same toad (which was easily distinguishable) at its old work. M. Brunet let him swallow only three or four bees, then carried him fifty metres in another direction. Two days later the "wretch" was again found at his post, greedily devouring.

OUR correspondent, "J. H.," in describing the path of the meteor of March 17, as seen by him at Rossall, near Fleetwood, wrote ε Hydræ for α Hydræ. The date of Mr. Ainslie Hollis's letter should have been March 19.

MR. ELLIS asks us to state that in his article on Musical Notation last week, p. 476, col. ii., lines four and five, th readings should be A_1 *fl*, A_2 *rsh*, G_2.

THE additions to the Zoological Society's Gardens during the past week include a Large-eared Brocket (*Cervus auritus*) from South America, presented by Mr. Charles Cooper ; two Common Otters (*Lutra vulgaris*), European, presented by Mr. Augustus B. Foster ; a Vulpine Phalanger (*Phalangista vulpina*) from Australia, presented by Mr. Thos. Welsh ; two Rufous Tinamous (*Rhynchotus rufescens*) from South America, presented by Mr. F. Searle Parker ; eighteen Roach (*Leuciscus rutilus*), six Perch (*Perca fluviatilis*), six Tench (*Tinca vulgaris*), a Bream (*Abromis brama*), a Prussian Carp (*Carassius vulgaris*) from British fresh waters, presented by Mr. J. Smith ; three Fire-tailed Finches (*Erythrura prasina*) from Sumatra, purchased ; a Feline Dourocouli (*Nyctipithecus felinus*), a Kinkajou (*Cercoleptes caudivolvulus*), three Blue-shouldered Tanagers (*Tanagra cyanoptera*), an Adorned Terrapin (*Clemmys ornata*) from South America, deposited ; a Great Kangaroo (*Macropus giganteus*), a Yellow-footed Rock Kangaroo (*Petrogale xanthropus*), a Collared Fruit Bat (*Cynonycterus collaris*), a Black Swan (*Cygnus atratus*) born in the Gardens.

SOCIETIES AND ACADEMIES

LONDON

Royal Society.—March 1.—"Note on the Electrolytic Conduction of some Organic Bodies," by J. H. Gladstone, Ph.D., F.R.S , Fullerian Professor of Chemistry in the Royal Institution, and Alfred Tribe, F.C.S., Lecturer on Chemistry in Dulwich College.

Our results, preliminary as we considered them to be, show that the iodides of ethyl, isobutyl, and amyl, the bromides of ethyl and propylene, the acetate of ethyl, and chloroform are practically non-conductors to a battery-power of 100 cells Grove, and that alcohol is to some extent traversed by the current. They show also that when these liquid non-conductors are mixed with the feeble conductor, alcohol, the conductivity of the mixture is greater than that of alcohol alone, which offers at least a partial clue to the readiness with which such mixtures are decomposed by the copper-zinc couple.

The very considerable development of heat in these liquids, which conduct the electric current with great difficulty, is a circumstance worthy of notice. In these cases it is evident that it does not result from any chemical change, because the decomposition, if anything at all, is utterly insignificant in amount.

"On the Protrusion of Protoplasmic Filaments from the Glandular Hairs of the Common Teasel," by Francis Darwin. Communicated by Charles Darwin, F.R.S.

The following is a summary of the results arrived at by Mr. Darwin :—Certain observations have been made on the protrusion of protoplasmic filaments, from leaf-glands on the teasel ; and the only theory which seems at all capable of connecting these facts is the following. That the glands on the teasel were aboriginally (*i.e.*, in the ancestors of the Dipsacaceæ) mere resin excreting organs. That the protoplasm which comes forth was originally a necessary concomitant of the secreted matters, but that from coming in contact with nitrogenous fluids it became gradually adapted to retain its vitality and to take on itself an absorptive function. And that this power—originally developed in relation to the ammonia in rain and dew—was further developed in relation to the decaying fluid accumulating within the connate leaves of the plant.

March 8.—"On the Structure and Development of Vascular Dentine," by Charles S. Tomes, M.A. Communicated by John Tomes, F.R.S.

March 15.—"On the Density of Solid Mercury," by Prof. J. W. Mallet, University of Virginia. Communicated by Prof. Stokes, Sec. R.S.

The author gets 14·1932 *as the number representing the density of solid mercury at its fusing point as referred to water at 4° C. taken as unity*. This result, which differs considerably from previous figures, he thinks, may be fairly accepted with confidence.

"The Automatic Action of the Sphincter Ani," by W. R. Gowers, M.D., Assistant Physician to University College Hospital. Communicated by J. S. Burdon Sanderson, M.D., F.R.S.

"Description of the Process of Verifying Thermometers at the Kew Observatory," by Francis Galton, F.R.S.

Linnean Society, March 15.—Prof. Allman, president, in the chair.—The Rev. A. Gardner Smith and Mr. A. Y. Stewart were elected Fellows.—The Secretary read a paper on the poisoned spears and arrows of the Samoa Islanders, by the Rev. Thos. Powell. The information thereon had been derived from the son of a native chief. According to his account, the weapons are pointed with human thigh and parietal bones, these being ground to a fine tapering point. A milky juice, the product of several kinds of trees—among others *Callophyllum inophyllum*—is used for dipping the arrow and the spear-heads into, and there is added a substance obtained from wasps' nests, besides some of the fluid of putrid Sea-cucumbers (*Holothuria*). A kind of kiln is then prepared, where the weapons are smoked, after which they are inserted into the dried flower-stalk of a species of *Tacca*, to prevent bad effects from humidity ; lastly, they are bundled together and laid by ready for use. The effects of the poison on the human system—viz., convulsions and tetanus, and the reputed means of cure the author duly mentions. Mr. G. Busk, however, questions the active quality of the said poison ; at least some experiments of his incline him to think that a local irritation may be set up rather than an immediate deadly influence of a virulent vegetable poison, such as is the "Woorali" of South America. On the other hand, Messrs. Nichols and Pratt corroborate Mr. Powell's statements.—Dr. A. Gunther gave a notice of two large extinct lizards formerly inhabiting the Mascarene Islands. The remains of the bones had been partly obtained by Mr. Edward Newton, already well known for his researches on the extinct Mascarene fauna, and partly by Mr. H. H. Slater, Naturalist to the Transit of Venus Expedition. Comparisons have led Dr. Gunther to regard one relatively large animal as most nearly allied to the families of Zonuridæ and Scincidæ. But it differs both from the Glass Snakes and Skinks, hence a new genus has been assigned it and the name *Didosaurus mauritianus* given. The remains of another form from Rodriguez shows it to be allied and indeed identical with the Geckos, close to *G. verus* but specifically distinct, and accordingly named *G. newtonii.*—The second part of contributions to the ornithology of New Guinea, by Mr. R. Bowdler Sharpe, dealt with a collection made by the late Dr. James. This young enthusiastic naturalist was murdered by the natives during an expedition to one of the islands in Hall's Sound, whither he had gone to collect Birds of Paradise. Of fifty-three species obtained only three are new to science, and from this it is inferred that the south-eastern province visited has by no means so rich an avifauna as the northern parts of New Guinea are known to possess. The new species are *Melidora collaris*, *Phonygama jamesii*, and *Tanysiptera microrhyncha*. But a still more interesting night-flying black hawk, *Machaeramphus alcinus*, has turned up in this locality, whose habitat previously was supposed only to be Malacca and Tenasserim. Only four specimens of this rare bird are known to exist.—Samples of supposititious "manna" from Persia, and a bark (Leptospermum ?) from New Zealand, with tonic qualities, were exhibited and remarked on by Mr. Stewart, of the Apothecaries Hall.

Zoological Society, March 20.—Dr. E. Hamilton, vice-president, in the chair.—Mr. Sclater called the attention of the meeting to an article in the *Oriental Sporting Magazine* for May, 1876, by which it appeared that a two-horned rhinoceros had been killed in February, 1876, at a place some twenty miles south of Comillah, in Tipperah. Mr. Sclater stated that this was the third recorded occurrence of a two-horned rhinoceros north of the Bay of Bengal.—Mr. Sclater also called attention to the fact that Mr. W. Jamrach had just imported a young living specimen of the rhinoceros of the Bengal Sunderbunds, which was either *Rh. sondaicus* or a very closely allied form.—Mr. Sclater exhibited a small living Amphisbænian (*Blanus cinereus*), which had been accidentally brought to England in the roots of a hot-house plant from Port St. Mary, Spain.—Messrs. Charles G. Danford and Edward R. Alston read a paper on the mammals of Asia Minor, based principally on collections made by the former in that country. The list included one species of Bat, two of Insectivores, twenty of Carnivores, seven of Ungulates, and fourteen of Rodents. *Spermo philusxanthoprymnus*, Benn., was redescribed, and the name *Mus mystacinus* was proposed for a new species of field-mouse.—Mr. A. G. Butler read a paper on the Myriopoda obtained by the Rev. G. Brown in Duke of York Island. The species sent home were two in number, both of them allied to but distinct from previously described species. Mr. Butler proposed to designate them as *Heterostoma browni* and *Spirobolus cinctipes*.—A communication was read from the Rev. O. P. Cambridge, in which he gave the descriptions of some spiders collected by the Rev. G. Brown in Duke of York Island, New Britain, and New Ireland. Two of these appeared to be undescribed, and were named *Argiope browni* and *Saroles vulpinus*.—Prof. A. H. Garrod read a paper containing notes on the anatomy of the Musk Deer (*Moschus moschiferus*).—A communication was read from Mr. Edward Bartlett, containing remarks on the affinity of *Mesites* and the position which it should occupy in a natural classification. From an examination of structure of the feathers, Mr. Bartlett had come to the conclusion that *Mesites* was an aberrant form of the Ardeine group.—Dr. Günther, F.R.S., read a paper containing an account of the fishes collected by Capt. Feilden during the last Arctic Expedition. Amongst these were several of great interest, especially a new species of Charr, for which the name *Salmo arcturus* was proposed. This Charr was discovered in freshwater lakes of Grinnell-land, and was stated to be the most northern fresh-water fish known to exist.—Mr. Edward Newton, C.M.G., exhibited and read a paper on a collection of birds made in the island Anjuan or Johanna, one of the Comorro group, by Mr. Bewsher, of Mauritius, whereby the number of species now known to have occurred in that island was raised to thirty-five, of which fourteen were first observed there by that gentleman. Five of these, namely, *Zosterops anjuanensis*, *Tchitrea vulpina*, *Ellisia longicaudata*, *Turdus bewsheri*, and *Turtur comorensis*, were described as new.

Meteorological Society, March 21.—Mr. H. S. Eaton, M.A., president, in the chair.—Capt. Fellowes, R.E., George Jinman, Angus Mackintosh, M.D., Robert W. T. Morris, Rev. Edward Vincent Pigott, David S. Skinner, L.R.C.P., and Henry St. John Wood were elected Fellows of the Society.—The following papers were read:—Results of meteorological observations made at Patras, Greece, during 1874 and 1875, by the Rev. Herbert A. Boys. This is in continuation of a former paper read before the Society in 1875. The period embraced in the two papers—January, 1873, to June, 1875—covers a whole winter compressed into about thirty days, a very long and showery spring, an excessively hot summer, a dry winter of extreme cold, a summer of most prolonged drought, a remarkably wet and snowy winter, a very late beginning of hot weather, and the coldest day and night, and the lowest barometer reading for many years.—Contributions to the meteorology of the Pacific—Fiji, by Robert H. Scott, F.R.S. This paper contains a discussion of all published information as to the climate of Fiji which the author has been able to discover.—Local diurnal range, by S. H. Miller, F.R.A.S.—This was followed by another paper on the same subject, by William Marriott, F.M.S., which discussed the questions of whether the tables of corrections for diurnal range, at present used by a large number of observers, are trustworthy, and whether they are applicable to different places in the United Kingdom. The conclusions arrived at were that the present corrections could not be considered as accurate, that no strictly comparable records exist for instituting a satisfactory inquiry, and that it is very undesirable to apply any corrections whatever to the observations to deduce means from them.—Mr. Negretti exhibited several new instruments.

PARIS

Academy of Sciences, March 26.—M. Peligot in the chair.—The following papers were read:—Remarks on the presence of benzine in coal gas, by M. Berthelot. The illuminating portion of the Parisian gas consists mostly of vapour of benzine, forming about 3 per cent. of the whole volume. Fuming nitric acid was employed in the analysis, producing nitrobenzine.—On a recent communication of Mr. Weddell regarding the advantage to be realised in replacing quinine by cinchonidine, by M. Pasteur. Mr. Weddell having stated that cinchonidine was discovered by M. Pasteur, the latter says this is attributing too much to him, and defines his researches on the subject in 1853.—On the digestion of albumen, by M. van Tieghem. The relation of the albumen to the embryo in seeds was studied by two methods—observing isolated albumen subjected to germination and observing the dissolution of albumen during germination, of the entire seed. There are two modes of digestion; the oleaginous and aleuric albumen has an activity of its own, it digests itself, and the embryo only absorbs the products of this interior digestion; it is a "nurse" to it. The amylaceous and cellulosic albumens, on the contrary, are passive; they are digested by the embryo, each in its fashion, and the products of this external digestion are then absorbed by it: they are to it only a nutriment.—On preventive and early trepanation in vitreous fractures complicated by splinters, by M. Sedillot.—Observations of the satellites of Saturn, at the Observatory of Toulouse in 1876, with the large Foucault telescope, by M. Tisserand. These relate to the first five satellites only. From observations of three of them the apparent diameter of Saturn's ring is inferred to be 40″·51.—On a theorem relative to the expansion of vapours without external work, by M. Hirn.—On the theory of plane elastic plates, by M. Levy.—The president of the Vine-growing Society of the Pyrenées Orientales sent a document affirming that it is the American plants that have brought phylloxera into France; all plantation of them is the signal of a fresh invasion.—On the theory of frigorific machines, by M. Terquem.—On the reflection of polarised light, by M. Croullebois. He studies one of the fringes discovered by Airy, and named by M. Billet the *courbe de semelle*; showing what may be inferred from it, as to the physical constitution of a mirror (*i.e.*, its positive, neutral, or negative nature); the value of the angle of maximum polarisation (first constant), and the azimuth of renewed polarisation (second constant).—On the transformation of crystallisable sugar into inactive glucose in raw cane sugars, by M. Gayon. Heat and moisture favour the transformation; there is a real fermentation, with carbonic acid given off. By the mere decrease of crystallisable and increase of uncrystallisable sugar, the yield in refining was diminished by 25 per cent. in one sugar, and 33 per cent. in another.—On the composition of guncotton, by MM. Champion and Pellet. The specimen analysed contained (ashes deducted 1·01 gr. per cent.) free cellulose, 1·00; dinitrocellulose, 6·00; principal nitrated product (by difference), 93·00. Supposing this product pentanitrocellulose, and calculating the constituents on this hypothesis, we have, carbon, 26·54; hydrogen, 2·79; nitrogen, 12·51; oxygen, 58·16; which analysis confirms.—Studies on the series of the quinolines; transformation of leucoline into aniline, by Mr. James Dewar.—On nitrototuquinone and chloranilic acid, by M. Etard.—On the sewage waters of Paris, by M. Lauth. The facts cited prove that the sulphydric putrefaction of such water may be avoided by addition of lime, or (a much more important result) by simple aeration. Putrefaction only occurs when the sewage water is kept out of contact with air. As such conditions probably occur at the bottom of the Seine, the facts related may be utilised for its sanitation.—On the fecundation of the egg in the sea-urchin, by M. Perez. He questions M. Fol's statement that the spermatozoids penetrate into the interior.—Hailstorm at the Cape of Antibes on March 21, by M. Ferrière. The storm came from the depths of the marine horizon; its movement was from west to east, and the hailstones, judging from the orientation of the deposits, must have had a gyratory motion. These facts seem to bear on M. Faye's theory.—Chronic anæmia from stubborn nervous and digestive disorders continuing for five years; transfusion of blood and cure, by M. Oré. Only forty grammes of blood were used. Puncture was made without denudation of the vein. The transfused blood acts by stimulating the organs rendered atonic, and by causing a *proliferation* of new globules.—On the antiseptic properties of bichromate of potash, by M. Laujorrois. The addition of $\frac{1}{1000}$ to ordinary water will render this conservative of all organic products without decomposition, even in free air.

THE ARCTIC BLUE-BOOK

THE admirably illustrated volume which has just appeared in this uninviting form, tells a tale of adventures as interesting and heroic as anything in the long record of Arctic discovery. It throws little light on the question to which public attention has been too much directed this winter—whether any of the misfortunes of the expedition were due to the officers who started the sledge parties without adequate supplies of lime-juice. The report of the Scurvy Committee will appear in a few days. In the mean time it is clear that every pound weight on the sledges was calculated with the utmost care, that wherever anything was to be used in a fluid state an adequate corresponding supply of fuel needed to be carried; that none of the officers, judging from the experience of previous sledge expeditions, seem to have anticipated scurvy; and above all that the work of all the parties on and at the edge of the hitherto untrodden Palæocrystic sea proved so frightfully severe that if lime-juice in abundant rations had been taken the sufferings of the men would probably have been only mitigated It is to the severity of the work, not to the absence of lime-juice, that we believe the terrible outbreaks of scurvy which crippled the sledging parties to have been really due. In Commander Markham's Journal, written on the spot a month out from the ship, he says, "The invalids are not improving, and we are inclined to believe that they are all attacked with scurvy, though *we have not been led to suppose that there is any probability of our being so afflicted and are ignorant of the symptoms.*" Swollen knees and ankles are of frequent occurrence in all Arctic sledging expeditions, and they were prepared to expect as much. Scurvy had scarcely been thought of, and the fact that it had not been thought of by officers whose lives and the lives of their men depended on their forethought, and who had studied the experience of their predecessors with anxious care, is sufficient to show that, *à priori*, there was little or no probability of its appearance. After the experience of Markham's, Aldrich's, and Beaumont's parties, no future travellers over the "Palæocrystic" will [illegible] their lime-juice, but these officers seem all to have been unprepared for scurvy. Aldrich says in his journal, 38th day out,—

> "The men are nearly all suffering a great deal with their unfortunate legs, which appear to get worse every day. This we all feel to be very disappointing, as it affects the journey, and although stiff limbs were expected, everyone thought the stiffness would wear off in time. It seems, however, inclined to hang on, and sets at defiance all the limited medical skill we possess among us, and to scorn succumbing to turpentine liniment, bandages, good 'elbow grease,' &c. With regard to bandages, I am almost afraid to apply them, for some of the limbs are not at all healthy looking; the slightest pressure of the finger leaves a dent which remains a considerable time; and although I have given the most stringent orders about lacing the foot gear on very slackly, I find the loosest moccasin string cuts an ugly, red-looking mark. One or two cannot even bear anyone to lie against them, which makes it excessively inconvenient at night, although everyone is very good tempered, and complaints are reduced to a minimum."

Lieut. Beaumont's party was accompanied by Dr. Coppinger till May 4, and Beaumont says,—

> "It was at the end of this journey, May 6, that J. Hand, A.B., one of my sledge crew, told me in answer to my inquiry as to why he was walking lame, that his legs were becoming *very* stiff, he had spoken to Dr. Coppinger about them, but attributing the stiffness and soreness then to several falls that he had had, he did not think much of it, before that officer's departure; now, however, there was pain as well as stiffness, and both were increasing. I directed him to use liniment before he turned in, which he afterwards said made him better."

This was the first beginning of scurvy, but even a medical officer attached to the expedition had obviously supposed it the mere common swollen leg and ankle of ordinary Arctic sledging. Beaumont goes on —

> "On coming into camp I examined Hand's legs, and found the thighs discoloured in patches, and from his description of the stiffness and pain I suspected scurvy. *I had no reason to expect it, indeed I had never thought of it*, but the striking resemblance of the symptoms to the ones described in the voyage of the *Fox*, as being those of Lieut. Hobson, who suffered severely from scurvy, suggested it to my mind, and my suspicions were confirmed by Gray, the captain of my sledge, an ice quartermaster, who, in his whaling experience, has seen much of it. He, however, led me to believe, at the same time, that it would probably wear off, saying that many of the men in whale ships who have it lying ''twixt the flesh and the bone all the winter,' as he expressed it, wear it off by the regular exercise and work of their occupation when the spring comes, it was a good sign, he said, that it should come to the surface. Thus, from the 7th until the 10th I waited, hoping that his words might prove true. I was very reluctant to order Lieut Rawson to return, it was like sending back half the party, it would be, I felt, a great disappointment to him to turn back then, and his advice and assistance would be a very great loss to me, but the indications of the disease and their aggravated nature became too plain to be misunderstood—sore and inflamed gums, loss of appetite, &c., all pointed too clearly to scurvy, so on May 10 it was arranged that Lieut Rawson, with his party, should take Hand back, deciding, on his arrival at Repulse Harbour, whether to cross over to the *Alert* or go on to Polaris Bay. I at the same time called upon the remainder of my men to say honestly if they suspected themselves to be suffering from the same disease, or could detect any of its symptoms, as in that case it would be better for the party to advance reduced in numbers than to be charged with the care of sick men. I did this because two of them had complained of stiff legs after the hard work on the snow slopes, but they all declared themselves to be now perfectly well, and most anxious to go on."

So much for the scurvy question The Blue-Book makes it manifest that neither the commanders of the sledge parties nor Captains Nares and Stephenson, nor Dr. Coppinger suspected that the sledge parties would be in danger of that terrible disease.

The most interesting part of the story is told in the daily journals kept by Markham, Aldrich, and Beaumont. No reader of these simple and modest records will doubt that "the ancient spirit is not dead" which has carried the Union Jack in triumph over every ocean, and planted it wherever honour and danger were most surely to be found.

Markham and Aldrich left the *Alert* on April 3, tramunication was read from the Rev. O. P. Cambridge, in which he gave the descriptions of some spiders collected by the Rev. G. Brown in Duke of York Island, New Britain, and New Ireland. Two of these appeared to be undescribed, and were named *Argiope browni* and *Sarotes vulpinus*.—Prof. A. H. Garrod read a paper containing notes on the anatomy of the Musk Deer (*Moschus moschiferus*).—A communication was read from Mr. Edward Bartlett, containing remarks on the affinity of *Mesites* and the position which it should occupy in a natural classification. From an examination of structure of the feathers, Mr. Bartlett had come to the conclusion that *Mesites* was an aberrant form of the Ardeine group.—Dr. Gunther, F.R.S., read a paper containing an account of the fishes collected by Capt. Feilden during the last Arctic Expedition. Amongst these were several of great interest, especially a new species of Charr, for which the name *Salmo arcturus* was proposed. This Charr was discovered in freshwater lakes of Grinnell-land, and was stated to be the most northern fresh-water fish known to exist.—Mr. Edward Newton, C.M.G., exhibited and read a paper on a collection of birds made in the island Anjuan or Johanna, one of the Comorro group, by Mr. Bewsher, of Mauritius, whereby the number of species now known to have occurred in that island was raised to thirty-five, of which fourteen were first observed there by that gentleman. Five of these, namely, *Zosterops anjuanensis*, *Tchitrea vulpina*, *Ellisia longicaudata*, *Turdus bewsheri*, and *Turtur comorensis*, were described as new.

Meteorological Society, March 21.—Mr. H. S. Eaton, M.A., president, in the chair.—Capt. Fellowes, R.E., George Inman, Angus Mackintosh, M.D., Robert W. T. Morris, Rev. Edward Vincent Pigott, David S. Skinner, L.R.C.P., and Henry St. John Wood were elected Fellows of the Society.—The following papers were read:—Results of meteorological observations made at Patras, Greece, during 1874 and 1875, by the Rev. Herbert A. Boys. This is in continuation of a former paper read before the Society in 1875. The period embraced in the two papers—January, 1873, to June, 1875—covers a whole winter compressed into about thirty days, a very long and showery spring, an excessively hot summer, a dry winter of extreme cold, a summer of most prolonged drought, a remarkably wet and snowy winter, a very late beginning of hot weather, and the coldest day and night, and the lowest barometer reading for many years.—Contributions to the meteorology of the Pacific—Fiji, by Robert H. Scott, F.R.S. This paper contains a discussion of all published information as to the climate of Fiji which the author has been able to discover.—Local diurnal range, by S. H. THE ARCTIC BLUE-BOOK

THE admirably illustrated volume which has just appeared in this uninviting form, tells a tale of adventures as interesting and heroic as anything in the long record of Arctic discovery. It throws little light on the question to which public attention has been too much directed this winter—whether any of the misfortunes of the expedition were due to the officers who started the sledge parties without adequate supplies of lime-juice. The report of the Scurvy Committee will appear in a few days. In the mean time it is clear that every pound weight on the sledges was calculated with the utmost care; that wherever anything was to be used in a fluid state an adequate corresponding supply of fuel needed to be carried; that none of the officers, judging from the experience of previous sledge expeditions, seem to have anticipated scurvy; and above all that the work of all the parties on and at the edge of the hitherto untrodden Palæocrystic sea proved so frightfully severe that if lime-juice in abundant rations had been taken the sufferings of the men would probably have been only mitigated. It is to the severity of the work, not to the absence of lime-juice, that we believe the terrible outbreaks of scurvy which crippled the sledging parties to have been really due. In Commander Markham's Journal, written on the spot a month out from the ship, he says, "The invalids are not improving, and we are inclined to believe that they are all attacked with scurvy, though *we have not been led to suppose that there is any probability of our being so afflicted and are ignorant of the symptoms.*" Swollen knees and ankles are of frequent occurrence in all Arctic sledging expeditions, and they were prepared to expect as much. Scurvy had scarcely been thought of, and the fact that it had not been thought of by officers whose lives and the lives of their men depended on their forethought, and who had studied the experience of their predecessors with anxious care, is sufficient to show that, *à priori*, there was little or no probability of its appearance. After the experience of Markham's, Aldrich's, and Beaumont's parties, no future travellers over the "Palæocrystic" will omit their lime-juice, but these officers seem all to have been unprepared for scurvy. Aldrich says in his journal, 38th day out:—

> "The men are nearly all suffering a great deal with their unfortunate legs, which appear to get worse every day. This we all feel to be very disappointing, as it affects the journey, and although stiff limbs were expected, everyone thought the stiffness would wear off in time. It seems, however, inclined to hang on, and sets at defiance all the limited medical skill we possess among us, and to scorn succumbing to turpentine liniment, bandages, good 'elbow grease,' &c. With regard to bandages, I am almost afraid to apply them, for some of the limbs are not at all healthy looking; the slightest pressure of the finger leaves a dent which remains a considerable time; and although I have given the most stringent orders about lacing the foot gear on very slackly, I find the loosest moccasin string cuts an ugly, red-looking mark. One or two cannot even bear anyone to lie against them, which makes it excessively inconvenient at night, although everyone is very good tempered, and complaints are reduced to a minimum."

Lieut. Beaumont's party was accompanied by Dr. Coppinger till May 4, and Beaumont says:—

> "It was at the end of this journey, May 6, that J. Hand, A.B., one of my sledge crew, told me in answer to my inquiry as to why he was walking lame, that his legs were becoming *very* stiff, he had spoken to Dr. Coppinger about them, but attributing the stiffness and soreness then to several falls that he had had, he did not think much of it, before that officer's departure; now, however, there was pain as well as stiffness, and both were increasing. I directed him to use liniment before he turned in, which he afterwards said made him better."

This was the first beginning of scurvy, but even a medical officer attached to the expedition had obviously supposed it the mere common swollen leg and ankle of ordinary Arctic sledging. Beaumont goes on:—

> "On coming into camp I examined Hand's legs, and found the thighs discoloured in patches, and from his description of the stiffness and pain I suspected scurvy. *I had no reason to expect it, indeed I had never thought of it*, but the striking resemblance of the symptoms to the ones described in the voyage of the *Fox*, as being those of Lieut. Hobson, who suffered severely from scurvy, suggested it to my mind, and my suspicions were confirmed by Gray, the captain of my sledge, an ice quartermaster, who, in his whaling experience, has seen much of it. He, however, led me to believe, at the same time, that it would probably wear off, saying that many of the men in whale ships who have it lying ''twixt the flesh and the bone all the winter,' as he expressed it, wear it off by the regular exercise and work of their occupation when the spring comes; it was a good sign, he said, that it should come to the surface. Thus, from the 7th until the 10th I waited, hoping that his words might prove true. I was very reluctant to order Lieut. Rawson to return, it was like sending back half the party; it would be, I felt, a great disappointment to him to turn back then, and his advice and assistance would be a very great loss to me, but the indications of the disease and their aggravated nature became too plain to be misunderstood—sore and inflamed gums, loss of appetite, &c., all pointed too clearly to scurvy; so on May 10 it was arranged that Lieut. Rawson, with his party, should take Hand back, deciding, on his arrival at Repulse Harbour, whether to cross over to the *Alert* or go on to Polaris Bay. I at the same time called upon the remainder of my men to say honestly if they suspected themselves to be suffering from the same disease, or could detect any of its symptoms, as in that case it would be better for the party to advance reduced in numbers than to be charged with the care of sick men. I did this because two of them had complained of stiff legs after the hard work on the snow slopes, but they all declared themselves to be now perfectly well, and most anxious to go on."

So much for the scurvy question. The Blue-Book makes it manifest that neither the commanders of the sledge parties nor Captains Nares and Stephenson, nor Dr. Coppinger suspected that the sledge parties would be in danger of that terrible disease.

The most interesting part of the story is told in the daily journals kept by Markham, Aldrich, and Beaumont. No reader of these simple and modest records will doubt that "the ancient spirit is not dead" which has carried the Union Jack in triumph over every ocean, and planted it wherever honour and danger were most surely to be found.

Markham and Aldrich left the *Alert* on April 3, the velling in company to Cape Joseph Henry—latitude 82'50. From that point Markham struck straight north on April 11, with fifteen men and three sledges, weighing in all 6,079 lbs., or 405 lbs.—3⅝ cwts.—per man. They carried two ice-boats with them, the first of which, weighing 740 lbs., had to be abandoned on April 19, while the second, weighing 440 lbs., their only chance of safety if the ice should break up, had to be abandoned on May 27, while they were still seven miles or so from the nearest land. The ice on the surface of the floes was covered generally with snow some three feet deep, and the men sank in it beyond their knees. If the Palæocrystic sea had been a decently level plain covered with loose powdery snow, the work to get to the pole would have been hard enough. The party found it much such a place as South Kensington might be after an earthquake had toppled half the houses into ruin. There was seldom a floe or flat ice-surface of any extent—rarely as much as a mile in any direction—never more than a mile and three-quarters. "For the last ten or fifteen days of our outward journey," says Markham, "floes were few and far between, and it might almost be said that our road lay entirely through hummocks and deep snow-drifts." A hummock is a huge mass of ice-blocks piled up like builder's rubbish. The highest mass measured was 43 feet 2 inches, but many were observed which exceeded that height, and were estimated as between 50 and 60 feet. On the heavier floes were high hillocks apparently formed by snow drift, the accumulation probably of years, resembling diminutive snow mountains, and varying from 20 to over 50 feet in height. It was across this sort of material that the party had to drag themselves to the pole. They found that they could scarcely ever get along without "double banking." They had two sledge crews for three sledges, and they had calculated to pull the heavy sledge by the whole fifteen men, and to return for the lighter sledges which were to come up together, each dragged by its seven or eight men. Thus three miles of ground would have had to be traversed for every mile made good. In fact even the smaller sledges needed almost always the whole fifteen men, and after the larger ice-boat was abandoned on April 19th, there was little difference of weight between them. Thus each mile in advance cost five miles walking, three of them full loaded, two through the snow and without the steadying support of the drag-ropes. The back journeys were found almost as fatiguing as the others. From April 16th (Cape Joseph Henry) to May 12th, the most strenuous efforts carried them from 82.49½ to 83.20.26, *i.e.* 31 minutes northing, or about thirty-six English miles in twenty-six days, an average of 1⅜ miles a-day advanced, and of seven miles walked. The advance was soon impeded by the illness of the men. It is on the 14th—eleven days from the ship, three days from the depot and last land at Cape Joseph Henry—that we first find the ominous entry, "pain in his ankle and knee, both of which exhibited slight symptoms of puffiness." On the 16th the patient had to be put on one of the sledges, so that already there were only fourteen men at the drag-ropes and 160lbs. more to drag. "On the 17th another man cannot drag but is just able to hobble after us," carrying, that is to say, his own weight, but only for half the day. On the 19th both had to be carried, and another man fell out from the drag-ropes. Although they dropped their ice-boat, 740 lbs. weight, on the 19th, on the 25th a fourth man is reported weak. A fifth man "can scarcely walk" on May 2nd, and on May 3rd all five are "utterly helpless and therefore useless." On May 4th "more of the men are complaining of stiffness and pain in their legs, which we fear are only the premonitory symptoms." Here is a glimpse of the party on May 6th:—

"The sick men are invariably the cause of great delay in starting, as they are perfectly helpless, being even unable to dress or undress without assistance. We appear to have arrived at a perfect barrier of hummocks and portions of floes, all broken and squeezed up and covered with deep snow. It is possible we may be able to penetrate these obstacles, eventually reaching larger and more level floes, on which we may be able to make more rapid progress. We ascended one large hummock, from the summit of which the prospect was anything but encouraging—nothing but one vast illimitable sea of hummocks. The height of this hummock was ascertained by means of a lead line, and was found to be from its summit to the surface of the snow at its base 43 feet 3 inches. It did not appear to be a floe-berg, but a mass of hummocks squeezed up and cemented together by several layers of snow, making it resemble one huge solid piece. The travelling has been exceedingly heavy, and with the weights on the sledges augmented, the deep snow, and a third of our band *hors de combat*, it is next to impossible to advance many feet without resorting to 'standing pulls,' or the endless 'one, two, three, haul.'"

On the 7th they had to "advance with one sledge, *unload it*, return with it empty, and then bring on the gear and invalids." On the 8th "the interior of our tents have more the appearance of hospitals than the habitations of strong working men. In addition to the cripples, four men are suffering from snow blindness." It is in this condition that they struggle through the sea of hummocks.

"The hummocks around us are of different heights and bulk, varying from small fragments of ice to huge piles over 40 feet high. Some of these larger ones are simply masses of squeezed-up ice, whilst others of great magnitude, but perhaps not quite so high, are the regular floe-bergs. Between these hummocks, and consequently along the only road that is practicable for our sledges, the snow has accumulated in drifts to a great depth, and these forming into ridges render the travelling all the more difficult. Some of the tops of these ridges are frozen hard, and it is no uncommon occurrence to step from deep snow through which we are floundering up to our waists, on to a hard frozen piece, and *vice versâ*. Occasionally these ridges are only partially frozen, sufficiently only to deceive one, which makes it exceedingly disagreeable and laborious to get through."

On May 10, "with five out of our little force totally prostrate, four others exhibiting decided symptoms of the same complaint," Commander Markham sees that it would be "folly to persist pushing on" They have been forty days out and are only provisioned for thirty more. On the 12th those left decently strong go out in the morning for their farthest north—1¼ miles out from the camp, 399½ from the pole. There they sang the "Union Jack of Old England," the "Grand Palæocrystic Sledging Chorus," winding up, like loyal subjects, with "God save the Queen." When they got back to the sledge they broached a magnum of whisky sent for the purpose by a genial and henceforth famous ecclesiastical potentate, "the Dean of Dundee," smoked a single cigar apiece, presented them *ad hoc* before leaving the ship, and consumed the solitary hare they had shot on the way out. The story of their return journey is intensely interesting. On June 7, when they had still forty miles to go, and doubtless were near the end of their provisions, Lieut. Parr—whose untiring energy and admirable "road-making" made him the very perfection of companions for Commander Markham—started alone on a desperate walk to the ship for assistance. They had only *eleven good legs out of thirty-four in the party*, and "even some of these are shaky," says Markham on May 25. Fortunately two of them, both excellent, remained to Parr a fortnight later. The first death of the party happened next day, but the day after, June 9, late in the evening, relief came. Parr's wonderful walk—far more memorable than Weston's or O'Leary's—probably saved the lives of one or two men of the gallant party which has come nearest of any human being, possibly nearest of any living creature, to the solitude of the North Pole.

Space alone prevents us dwelling on the equally interesting work done by Aldrich on the northern shore of the American continent, and by Beaumont on North Greenland. The names of Markham, Aldrich, Beaumont, Parr, and Sir George Nares, have been added definitively to the long list of our Arctic heroes. Few things have been finer in seamanship than Sir George Nares' passage up Smith's Sound and Robeson Channel into the Palæocrystic sea and home again. The skill with which he devised and combined the exploring parties and prepared everything so that the utmost was accomplished which it was possible for brave men to accomplish without useless sacrifice of human life, has scarcely yet received sufficient acknowledgment either from his country or from the public.

ANTHRACEN

Anthracen; its Constitution, Properties, Manufacture, and Derivatives, including Artificial Alizarin, Anthrapurpurin, &c., with their Applications in Dyeing and Printing. By G. Auerbach. Translated and edited by William Crookes, F.R.S. (London: Longmans, Green, and Co., 1877.)

FROM the extent to which the anthracene and artificial alizarin industries have grown within the last few years, and the interest taken in them in England, it has been deemed advisable to bring forward an English edition of Auerbach's text-book on the above subject. This work has been carried out by Mr. W. Crookes, from a revised manuscript supplied by the author.

In the author's preface to this volume we are told that since the production of the first German edition four years ago, from the amount of new facts recently brought to light, it has been found necessary to make various additions, so as to render the treatise complete up to the present date. The arrangement of the earlier edition has been to a certain extent adhered to, but made rather more systematic, placing certain of the compounds in groups to admit of easy reference.

At the commencement a short acccount of anthracene is given, and reference made to the first investigations of the body, by Dumas and Laurent in 1832, and the later discoveries of Fritzsche, Anderson, Berthelot, Graebe, and Liebermann, with some remarks on the views entertained by these two latter chemists, with regard to the constitution of anthracene and its derivatives. After describing the physical properties of this body, and the different modes in which it may be formed, a full description is entered into of its manufacture on a large scale, from coal tar, according to the results obtained by E. Kopp, who has made a careful study of the preparation of anthracene from soft pitch. A description is also given of the furnace best adapted for the distillation of the pitch, and the different methods for purifying the crude anthracene by extraction with heavy naphtha, and sublimation.

In treating of the methods for the valuation of crude anthracene, the older processes in which it may be extracted by means of alcohol or carbon disulphide are mentioned, from their having to a certain extent an historical interest, but which have been superseded by the method of Luck, in which greater accuracy is obtained. This latter method depends on the conversion of anthracene into the theoretical quantity of anthraquinon when dissolved in glacial acetic acid and boiled with chromic acid. A full description is given of the hydrides of anthracene, and its chlorine and bromine derivatives. In the description of anthraquinon, before entering upon its properties and manufacture, the various methods in which it may be synthetically formed are discussed, among others, the method of Bayer and Caro, by means of which the anthraquinon derivatives may be formed from phthalic acid and phenolene; the discovery of which method has added much to a clearer conception of the nature of anthraquinon.

The latter half of the volume deals with the history and preparation of natural and artificial alizarin, and the consideration of its derivatives. In describing the different processes for the preparation of artificial alizarin, mention is made of the improvement on former methods introduced by Graebe, Liebermann, and Caro, in which they produce it from monosulphanthraquinonate of soda; the advantage claimed by these over the other methods being the direct conversion of anthracene into bisulphanthracenic acid, and its transformation into bisulphanthraquinonic acid by cheap oxidising agents.

Anthraflavic acid, chrysammic acid, purpurin and their derivatives receive full consideration, and an appendix is attached containing some practical receipts for dyeing with purpurin and artificial alizarin.

The volume concludes with a most valuable bibliography embracing a list of the substances treated of throughout the work arranged in alphabetical order, with the names of the authors who have written on that particular branch of the subject, and with exact reference to the journals in which the researches have been published. As papers on the different subjects mentioned in the volume are scattered over many different periodicals, the completeness with which this bibliography has been arranged will prove a most valuable assistance to those who wish to consult the original memoirs.

We observe that throughout the edition Mr. Crookes has retained the German mode of writing anthracene without the final "e"; this may be unimportant, but it is not the method usually adopted in English text-books. There is a slight mistake at the top of page 157 in the use of the term "ferrous" instead of "ferric." This is doubtless a slip, but in the particular reaction described is of some importance.

We feel sure that Mr. Crookes will receive the thanks of those interested in this subject in England for the care and completeness with which he has arranged and carried out the text-book.

OUR BOOK SHELF

Half-Hours among some English Antiquities. By Llewellynn Jewitt, F.S.A., &c. (London: Hardwicke and Bogue, 1877.)

THIS ought to be an extremely useful little manual to those who desire to obtain a knowledge of the various classes of antiquities to be found in England, both prehistoric and historic. Mr. Jewitt writes with full knowledge and in a manner that cannot fail to secure the attention of the reader. He theorises very little, confining himself mainly to a statement of facts in reference to the various objects included under the name of antiquities. He speaks of barrows, stone-circles, cromlechs, flint and stone implements, bronze instruments, Roman remains of various kinds, ancient pottery, arms and armour, sepulchral slabs and brasses, coins, church bells, glass, tiles, tapestry, personal ornaments. Thus, it will be seen, Mr. Jewitt's programme is extensive and varied, and although much cannot be said in the space at his command, his little work will prove a very useful introduction to works of a more special kind. Not its least valuable features are the illustrations—upwards of 300—which accompany the text.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts No notice is taken of anonymous communications*]

Centralism in Spectroscopy

IN NATURE, vol. xv. p. 489, there are some remarkable counter-assertions by Mr. Christie to certain of my matter-of-fact statements on your p. 449, of which the most pressing for me to notice is the paragraph wherein he declares that "the Edinburgh Observatory has, for the last *four* years, possessed *three* spectroscopes which are almost precisely identical with those used with such effect by Dr. Huggins."

I beg to say that the above is not the case, and for this, amongst other reasons, viz., that though three spectroscopes are there in part, they belong solely as yet to H M. Office of Works in London, which office, moreover, decided long since to return all of them to their maker, in lieu of *one* new spectroscope. And Mr. Christie must have known of this perfectly well when he wrote the above paragraph, for the carpenters of the department, who fetched away, about nine months ago, the one and only collimator to all those three partial spectroscopes, in order to send it back to its maker, spoke, as a matter of notoriety, of Mr. Christie himself being the adviser of H.M. Office of Works in that transaction, as well as the designer of the one new spectroscope ordered by the London office to take the place of the former three, but not received here yet.

With regard to the other new, and far more important, *Greenwich* spectroscope, of which Mr. Christie both chides me for not waiting for the full account to appear, as he now intimates, in a forthcoming number of the *Proceedings* of the Royal Society, and also challenges me to discuss its principles with him at once, I beg to say that my former remarks had reference solely to the official *codex* of last year's work at the Royal Observatory, Greenwich, as published by the Royal Astronomical Society in their last Anniversary Report, at p. 162, where all the world both may, and I suppose was intended to, see it, and where Mr. Christie's name appears no more than it did in my letter And as in that letter (at your page 450) I ventured to assign the *next* anniversary meeting of the same society as the limit of time within which the full practical value of the said new Greenwich spectroscope will have been arrived at, I do *not* think we can do better than wait for that time to arrive.

15, Royal Terrace, Edinburgh, April 6 PIAZZI SMYTH

Parhelia and Paraselenæ seen on March 20, 1877, and again on March 21, 1877, at Highfield House Observatory

PERHAPS this phenomenon is the most remarkable of the many somewhat similar ones that it has been my good fortune to witness during the last forty years, the chief features being brilliancy and persistency

FIG 1 represents the appearance at 8 A.M.: an ordinary halo of 22½° radius, with an elongated mock sun at the apex. This lasted till 9 30 A M, when, in addition to the halo, $\alpha\,\beta$, and the mock sun, γ, there was a second circle, $\delta\,\epsilon$, of 45 radius, also having the true sun for its centre, an inverted portion of a third circle, $\eta\,\theta$, of 22½ radius having its centre 45° above the true sun; also a portion of a fourth circle, $\iota\,\kappa$, of 90° radius, whose centre was 90° below the sun The mock sun, γ, was very bright and prismatic, as also was the circle, $\alpha\,\beta$ The other rings were colourless.

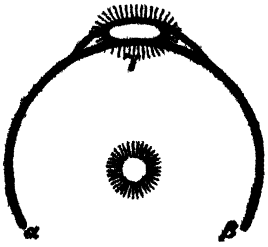

FIG 1 8 A M

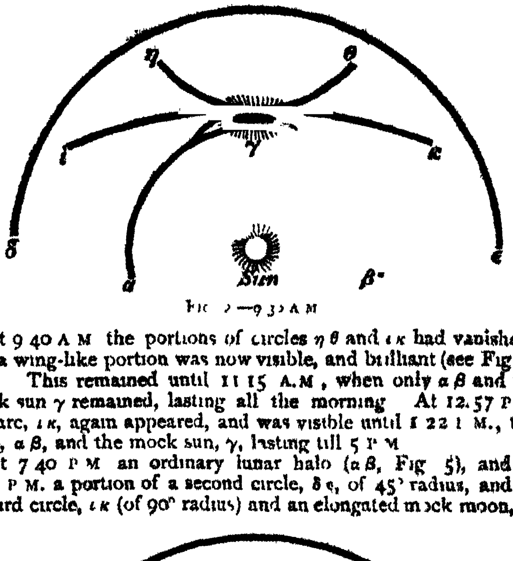

FIG 2—9 30 A M

At 9 40 A M the portions of circles $\eta\,\theta$ and $\iota\,\kappa$ had vanished, but a wing-like portion was now visible, and brilliant (see Fig 3, $\lambda\,\omega$) This remained until 11 15 A.M., when only $\alpha\,\beta$ and the mock sun γ remained, lasting all the morning At 12.57 P M the arc, $\iota\,\kappa$, again appeared, and was visible until 1 22 P M., the halo, $\alpha\,\beta$, and the mock sun, γ, lasting till 5 P M

At 7 40 P M an ordinary lunar halo ($\alpha\,\beta$, Fig 5), and at 8 25 P M. a portion of a second circle, $\delta\,\epsilon$, of 45° radius, and of a third circle, $\iota\,\kappa$ (of 90° radius) and an elongated mock moon, γ, were very apparent. At 8.31 the ordinary lunar halo alone remained. At 9.10 a portion of a circle, $u\,a$, not quite 90° radius, appeared (see Fig. 6), but this did not touch the circle $\alpha\,\beta$, but was 10° above it. At 9.15 P.M. this also vanished, but the lunar halo remained as long as the moon was above the horizon.

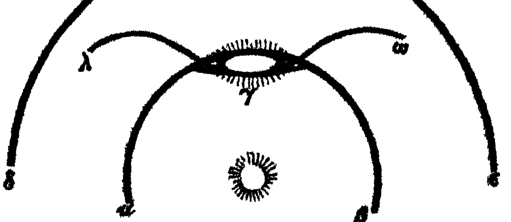

FIG. 3.

On March 21, at 8 A.M., there was a solar halo and mock sun exactly like the one seen at 8 A.M., March 20 (see

Fig. 1), and this lasted all day, with the addition at 4 P.M. till 5 40 P.M. of the arc $\iota\kappa$ (being the exact copy of Fig. 4 of March 20), at 6 P.M. there was the ordinary circle $\alpha\beta$, the mock sun γ, and an inverted portion $\eta\theta$ (Fig 2) At 6 10 only the ordinary halo remained.

From 8 P.M. till 9 40 P.M. (21st) there was a lunar halo with an elongated mock moon; so that a similar condition of the atmosphere prevailed for thirty-eight hours

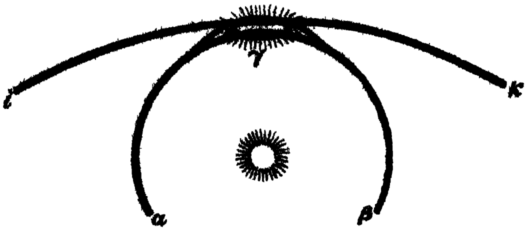

Fig 4

Whenever the circles were brilliant, they were formed in a very thin haze-like cloud, through which the sun or moon (in either case) shone brightly

The weather was cold with thick ice in the morning

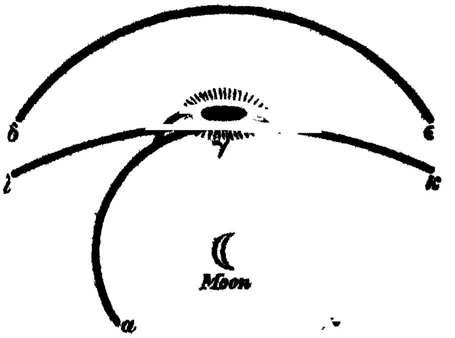

Fig 5

At 8 A.M. on the 20th the sky was scattered over with thin woolly cirri, indistinct in outline, and dirty-white in colour, with here and there a small prominent white portion (the sky resembling a sea with a few white wave-crests here and there) These clouds moved in a south current, but at 9 A.M. the clouds were again floating in a north-east current.

The wind on the 20th was north-east, and on the 21st north.

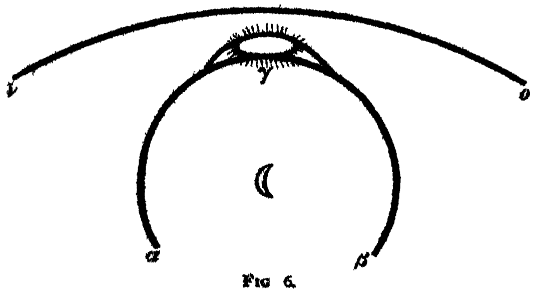

Fig 6.

Temperature on 20th	Dry bulb.	Wet bulb	Temperature on 21st.	Dry bulb	Wet bulb
8 A.M.	32°·3	31°·0	8 A.M.	35°·0	32°·7
1 P.M.	41·9	34·0	1 P.M.	42·1	34·0
6 P.M.	37·5	34·0	6 P.M.	39·7	33·6
11 P.M.	32·8	31·7	11 P.M.	30·0	28·3

March 22, solar halo and lunar halo.

" 27, " "
" 28, solar halo.
" 30, lunar halo.

E. J. LOWE

Owens College

It seems probable that the claims of Owens College to be constituted into a university and degree-giving body for the north of England, will soon be brought before the public in a more definite shape than that of newspaper correspondence. There are one or two considerations affecting the question, which do not seem to me to have been brought forward by any of those who have entered into the discussion, and I shall esteem it a favour if you will allow me briefly to notice these.

I may premise that no word in this letter is intended to derogate from any claims that Owens College may advance on the ground of past or prospective services to education in the district of England to which its efforts must be principally, though not entirely, confined. It is almost impossible to over-rate those claims, but when they are so put forward as to imply that Owens College is the only possible centre for giving degrees in the north of England, the dwellers on the banks of the Tyne, the Wear, and the Tees, are apt to feel that too little account is made both of the necessities and of the actual educational resources of their own part of the "north of England"

In the first place, a careful study of Bradshaw makes it clear that, for the counties of Durham and Northumberland, and even the north-east portion of Yorkshire, a university examination or college course is at least as accessible in London as at Manchester, so that for these counties the benefits of Owens College, whether as college or university, are practically on a par with those of University College, London, and the degree examinations of the University of London.

Secondly, it is a fact, although apparently unknown to the majority of those who have written on this question, that there already exists in the north of England—at Durham—a university with a Royal Charter for giving degrees in all faculties, and whose conditions for giving those degrees combine in an admirable manner the modern spirit with the strictness of the old requirements.

This university was originally founded by the liberality of the Cathedral authorities, who, with a spirit worthy of imitation elsewhere, set apart certain of their own funds for the purpose of giving a liberal education in arts and theology to students who for various reasons could not avail themselves of the advantages of Oxford and Cambridge As always happens in such cases, benefactions of scholarships and fellowships have accrued which have considerably increased the funds available for educational purposes

Nor have these funds been restricted, as many might expect, looking at the source from which they come, to sectarian purposes. While most of the colleges at Oxford and Cambridge were still compelling Jews and Nonconformists to attend religious services to which they objected, the regulations of the University of Durham anticipated the Universities' Tests Act by granting exemption in such cases, and during the last six years more than a thousand pounds a year of the university funds has been set aside for the purposes of the Science Faculty of the university which has its local habitation in Newcastle

I may add that the Senate and Convocation of the university have in late years adopted a most liberal view in regard to the admission of students of other colleges than those at Durham and Newcastle to the degrees which they give, and I have personally little doubt that they would consider with favour any scheme for extending the area over which their degrees are available.

The question of the desirability of multiplying the number of centres for giving degrees is a wide one, into which I have no desire to enter. My only wish is that in any consideration of the question of establishing a new centre, *all* the facts regarding its sphere of action and the centres which already exist within what is claimed as that sphere should be known.

W STEADMAN ALDIS

College of Physical Science, Newcastle-on-Tyne, March 24

The Suspected Intra-Mercurial Planet, Occultation of Kappa Geminorum

MARCH 21 was fine here, but with frequent clouds. I had several observations of the sun from 9 o'clock to 12, Dublin mean time, and then at 12.35, 1 35, 2 0, and 3 50, after which the sun become permanently clouded for the remainder of the day The only object remarked was a small spot with a double nucleus near the western limb followed by a few very small spots.

March 22 was finer, and I observed at 8 30, 9.12, 10.20, 10.50, 11.25, 12 38, 1.35, 1.50, 2 55, 4 25, 5 8, and 5.33. The small spots of the previous day had completely disappeared, and broad bright lacunæ occupied their place. The large spot at the last observation had so closely approached the edge that it was scarcely, if at all, visible, and the entire disc might then be said to appear free from spots of any kind. On March 23 the sun remained altogether clouded. At night, however, the sky cleared, and I had a good view of the occultation of Kappa Geminorum. The disappearance was, as usual, instantaneous, but immediately after it a delicate ray seemed to shoot out from the place of the star in a direction perpendicular to the edge of the moon, and the appearance lasted about eight seconds.

Milbrook, Tuam, March 24 J. BIRMINGHAM

α Centauri

AT the meeting of the Royal Astronomical Society December 8, 1876, Mr. Marth asked for measures of this binary.

As the star never reaches more than 11° above my horizon, the definition must always be imperfect; but the following measures taken on the morning of February 22 appear consistent, and may be useful until better results are obtained from the southern hemisphere :—

Epoch 1877·14.	Distance.	Position.
1	3″·4	64°·0
2	3·1	64·5
3	3·1	64·3
4	3·7	64·7
Mean	3·3	64·4

The component stars are of about the first and second magnitudes, and their colour is yellow. Power employed, 240; definition very bad. MAXWELL HALL

Jamaica

The Boomerang

WILL you allow me to add my experience of the use of this weapon to that furnished by your other correspondents? My experience is mainly confined to the natives about the Condamine and its affluents, where I was frequently in company with natives for about a year. They had two weapons—one large, for war, the other small, for game. I should think the weapon is seldom thrown in war, since most of their contests (such as they are) take place in scrubb or forest, where it could not be used to advantage; but I have seen a native frightfully cut in the abdomen, and was told by a native that he had been struck by a boomerang thrown by the hostile party. I have seen a few of these contests, but never saw the boomerang used in any way. The "waddys" were thrown freely, the spear seldom. The game boomerang is thrown among flights of ducks, and also parrots when congregated on the trees and gathering nectar from their flowers, and with marked effect. This I have seen several times. There are two ways of throwing the weapon, which, as I could throw it well at one time, I will endeavour to describe. It is grasped quite at the end by the right hand and raised above the head, the elbow being bent, the weapon assuming a position with its convex edge downwards on a nearly horizontal line at right angles to the intended line of flight. The arm is brought swiftly round from left to right, becoming gradually extended until it reaches a line directly in front of the face, when the weapon is delivered from the now straight arm, with the concave edge towards the line of flight. This is the method of throwing into the air. No dependence can be placed on the return of the weapon within a circle of twenty yards, though it sometimes returns dangerously near the thrower. If it meets with an obstacle it is either stopped and falls dead to the earth, or its course is changed. In either case its peculiar motion is destroyed, as must be obvious. In the other method of throwing the weapon is held in the same way, but delivered nearly on line with the hip, and made to strike the earth about ten yards in front of the thrower, pitching, I believe (though it is not easy to observe), on one of its horns. Thence it ricochets and flies straight away for perhaps seventy or eighty yards, keeping a position of about four feet from the earth, and gradually rising until it is spent. It returns very little if at all. In this way only can it be used for war, since in the other it begins to mount at once, and would soon be above the enemy's head. The weapon is made of various woods, a piece with a slight elbow being selected. It is hardened by baking. The right form is arrived at by trial, as I have seen during the process of manufacture. Those sold to Europeans are the failures. I had to pay a good price for the two I brought home, but they were excellent specimens.

The natives drive ducks. A flight is marked down on a small creek; men are then posted along the bank, others drive the birds towards them, and the boomerangs are thrown as they pass. I do not recollect having seen the weapon used for ground game. These are surrounded and killed with spears and sticks. ARTHUR NICOLS

Is Meteorology a Science?

THE recent article in NATURE on the Treasury Blue Book relating to meteorology brings into unpleasant prominence the opinion of the eminent astronomer, Sir G. Airy, that meteorology is not a science; and the evidence of the eminent physicist, Sir William Thomson, to the same effect; while a celebrated philosopher in the columns of the *Fortnightly Review* has not long since described meteorology as "a formless registry of facts."

But surely these eminent authorities have hardly realised the great change which has come over the whole aspect of meteorology since the introduction of synoptic charts?

Synoptic meteorology shows that the world is, broadly speaking, covered with shifting cyclones and anti-cyclones, which have each, subject to local, diurnal, and other variations, a characteristic weather, and physical appearance, and one great problem of meteorology is to explain the observed weather over any area, at any instant, by defining the position of these cyclones and anti-cyclones. It is in fact analogous to that branch of geology which explains the scenery and contours of any country by the position of areas of upheaval, crumbling, and subsequent denudation.

But there is another problem for the meteorologist to solve, viz., Given the position of the cyclones and anti-cyclones at any instant, to determine their future course and changes; and this can even now be done in certain cases. As if the geologist were asked what the future course of the present state of the earth's surface will be, where fresh upheavals or crumblings will occur, and what the corresponding changes in scenery will be? In this case the position of the meteorologist is far in advance of the geologist.

But still another reproach is cast upon meteorology—that the knowledge requisite to issue forecasts cannot be expressed in mathematical formulæ or in simple maxims. Here, too, the analogy of geology may show that neither formulæ nor maxims are necessary to make a science. Just as a number of skilled geologists, from long experience, agree as to the structure of a complicated piece of country, so will a number of meteorologists agree as to the probable course of any series of cyclones or anti-cyclones.

The limits of a letter do not permit me to show why mean values, or harmonic series can never much advance meteorology as a science, if any better argument were needed than their failure after a trial of forty years.

But I think we are justified in saying that, since the introduction of synoptic methods, meteorology is as much a science as geology; that both are pure observational sciences, and that their methods have much in common, while in some points meteorology is even the further advanced of the two.

21, Chapel Street, S.W. RALPH ABERCROMBY

Atmospheric Currents

I HOPE you will permit me to reply to Mr. Clement Ley's letter on atmospheric currents in NATURE, vol. xv. p. 450.

It is certain that the earth's rotation cannot originate any current, but modifies them when originated.

We are agreed as to the cause of the trade-winds. The controversy is as to the questions, Why the trade-winds do not extend to the poles? What is the cause of the counter-trades or west winds between the trade-wind regions and the poles? and what is the cause of the polar depression of the barometer?

The polar depression of the barometer is due to the centrifugal force of the vortex which is constituted by the counter-trades as they circulate round the pole from east to west. There is a depression at the centre of every vortex, as any one may see in a wash-basin.

The counter-trades are "the reaction of the trade-winds." The laws of motion make it impossible for the winds to have any effect in either accelerating or retarding the earth's rotation—supposing, what we are safe in taking as proved, that they originate exclusively as the effect of solar heat. The effect of the trade-winds alone, blowing from east to west, would be to retard the earth's rotation, but this is exactly balanced by the counter-trades of the circumpolar vortexes, blowing from west to east.

I cannot agree with Mr. Clement Ley when he says that it involves a fallacy to explain the mean winds, or great currents, on one principle, and the actual winds, or temporary currents, on another. If the great currents were much feebler in proportion to the temporary currents than they are, the mean prevalence of east winds in the tropics, and of west winds in the higher latitudes, would be discernible only as a residual fact when a number of anemometric observations made at various places were completely discussed. JOSEPH JOHN MURPHY

The Germ Theory

YOUR number for March 22 contains a review of my work on the Germ Theory of Disease, which, in some points, conveys so erroneous an impression of my exact position that I must ask you to allow me space for a few remarks regarding it.

Adverse criticism is what the author of such a book as mine expects, and, to some extent, desires.

A fair representation of his views and arguments, is what every author may insist on as a right.

It is the misleading manner in which my position is stated in your review that has induced me to pen this note.

To one or two of your statements I would refer in illustration of what I complain.

After referring to my expressed belief that contagia are living organised particles—an opinion held by many eminent physicians and men of science—your reviewer says: "If, however, the particles in sheep-pox, small pox, and vaccine be the infecting matter, they are easily seen by the microscope, and ought, therefore, to be found in the blood, but such is not the case." This, the old and stock argument against the germ theory, is specially dealt with by me on two different occasions—at p. 25, *et seq.*, and at p. 204, *et seq.* If it was worth your reviewer's while to raise this old objection to the germ theory, it was equally worth his while to make some reference to my explanation of the fact on which it rests. This he has not done—a manifest unfairness.

A little further on the review says: "Increased elimination of urea is explained thus: *The increased consumption of liquor sanguinis by the contagium particles leads to increased formation of retrogressive albumen and of urea.* It seems by this that contagium particles have livers and kidneys."

The part which I put in italics is put in your review within inverted commas, conveying thereby the impression that it is a correct quotation from my book. It is far from being so. As given by you, it is a misquoted short passage, separated from its context, and altered to suit the purpose of your review.

The chapter on increased elimination of urea is perfectly clear and intelligible to any ordinary mind, and contains nothing which justifies your reviewer in attributing to me, as he has done, the absurd belief that contagia are possessed of livers and kidneys. Neither is he justified in using the words "eat" and "drink" to express the action of a minute organism on its environment. Such phraseology can serve only to mislead those who are ignorant of the mode in which these organisms grow; and is quite inapplicable to any nutritive process which goes on in such organisms as I have described contagia to be.

Your reviewer quotes my statement that "if we were to bleed, to purge, to give antimony to, or even simply to withhold food and water from all the cases of typhus and enteric fever which occur, there can be no doubt that we should find the mortality from these diseases greatly increased;" and remarks on this, "Dr. Maclagan is right here, for by *simply withholding food and water* there can be no doubt that he would greatly increase the mortality by starving his patients to death." Your reviewer seems to be unaware that I refer in these remarks to a mode of treating fever which at one time did prevail.

To one other point I would refer in illustration of your reviewer's inaccuracy.

He says "the heat of specific fevers is partly ascribed to the propagation of the contagium causing increased consumption of tissue. But increase of living matter causes the disappearance of heat, not its production."

Even according to this, your reviewer's own somewhat awkward statement of the matter, the increased heat is attributed by me to increased consumption of tissue, indirectly brought about by the propagation of the contagium. Nowhere do I say that increase of living matter causes production of heat; and nowhere does your reviewer attribute such a statement to me. Quite the contrary. I distinctly say that the increased production of heat results from increased disintegration of the tissues; and your reviewer distinctly attributes this saying to me. What, then, is the meaning of the latter part of the sentence just quoted? It bears but one interpretation. Your reviewer attaches to the first half of the quotation a meaning the reverse of that which it conveys. While saying that I ascribe the increased heat to increased consumption of tissue, he seems to think that he is saying something quite different, and pens his criticism accordingly. If he thus misunderstands his own statements, I need, perhaps, scarcely be surprised at his sometimes misinterpreting mine. I do object, however, to such misinterpretations and inaccuracies appearing in so influential a journal as NATURE.

Dundee T. MACLAGAN

SEXUALITY IN PLANTS[1]

THE concluding part of the tenth volume of Pringsheim's *Jahrbücher* contains three papers, one of them by Dr. Arnold Dodel, of Zurich, being of the highest importance. This paper occupies the greater part of the present Heft, and is illustrated by eight coloured plates. The title is "*Ulothrix zonata*, its Sexual and Non-Sexual Reproduction, a Contribution to the Knowledge of the Lower Limit of Sexuality in Plants." The anatomy and life-history of the Ulothrix is exhaustively treated, the whole paper being a model of careful and accurate research, as well as a valuable contribution to our knowledge of the lower plants. The paper is divided into sections, of which the following is a short summary. The results given are those obtained during fourteen months' consecutive observation of the plant. The genus Ulothrix has been divided into many species, but Dodel shows that *U. zonata* is so variable in its different stages that most of the so-called species must be reduced to one. The alternation of generations is very remarkable and divisible into four stages. During the progress of the alternation of generation three distinct forms are to be distinguished, two being *filamentous* generations, and the third a zygospore generation. The filamentous generations are invariably produced non-sexually and reproduce themselves repeatedly, forming, in fact, the plant known to systematic botanists as *Ulothrix zonata*. The third generation, the zygospore, was unknown till discovered by Dodel. In the long series of filamentous generations two distinct forms are to be distinguished. The first is produced non-sexually and is the autumn or winter generation. It develops non-sexual macrozoospores and quickly spreads the species in a given locality. The second is a sexual stage developing microzoospores. It arises from the non-sexual macrozoospore, and gives rise to the microzoospores which by conjugation form the third generation, the zygospore or zoozygospore.

The production of the microzoospore-forming generation terminates the series of filamentous generations. This stage is found in spring and summer, and by giving rise to the zygospores which by remaining in a state of rest for some months during the hot dry summer weather, reproduce the plant in the autumn. During the hot weather the filamentous generations more or less completely disappear. The zygospore generation, although a product of gamogenesis, is itself non-sexual.

Ulothrix zonata exhibits polymorphism in a remarkable degree, hence many forms looked upon as distinct species must be suppressed. This opens up a wide question in regard to other algæ, and shows how essential it is to obtain an accurate knowledge of the life history of all forms.

The cells of Ulothrix give rise to a variable number of zoospores. A mother cell may form 1, 2, 4, 8, 16, or 32 zoospores, there being no obvious distinctions between the sexual and non-sexual zoospores. On the one side is the large macrozoospore with four cilia, and then there is every gradation down to the smallest microzoospore which conjugates, and which is furnished with only two cilia. The only distinction between the macro- and microzoospores seems to be that the former have four cilia, the latter only two. When the microzoospores fail to conjugate they may develop non-sexually just like the macrozoospores. This is a fact of the highest importance. In this plant, belonging to the lowest group in which sexual reproduction occurs, the sexual and non-sexual zoospores are hardly to be distinguished, and if by any chance union of the sexual zoospores does not take place, the zoospore behaves like a macrozoospore and develops non-sexually.

---

[1] Jahrbücher für wissenschaftliche Botanik. Herausgegeben von Dr. N. Pringsheim. Zehnter Band, Viertes Heft. Leipzig. Engelmann, 1876.

After remaining in a state of rest, sometimes for nearly twelve months, the contents of the zygospore break up into zoospores, from which arise the filamentous stage of Ulothrix.

In Ulothrix the conjugating cells are generally morphologically and physiologically identical, but sometimes larger zoospores conjugate with smaller, a difference in sex being here indicated. In other cases the microzoospores which have not conjugated germinate and give rise to individuals capable of reproducing. The study of the formation and subsequent development of the zygospore shows that the product of conjugation is to be considered as a new sexually-produced generation. It is a unicellular plantlet, with a root-like process and a slowly-growing plant-body which performs the function of assimilation. It in fact represents the embryo and the sporophore of the Pteridophytes. The root-end of the plantlet is formed by the union of the germinal spots of the conjugating microzoospores, while the assimilating plant-body represents the united chlorophyll-bearing parts of the zoospore.

The Ulothrix is thus one of the Zygosporeæ, and is probably related to Hydrodictyon, but it shows certain affinities to Sphæroplea, the lowest of the Oosporeæ.

As this part concludes the tenth volume of this serial, a most useful table of contents and special index of names of plants and details treated of in all the papers in the ten volumes has been added by Herr Zopf. This enables the student at once to refer to any given plant, or even to the part of it described in the various papers.

W. R. McNab

THE ROYAL NAVAL COLLEGE, GREENWICH

ON February 1, 1873, the Royal Naval College was opened at Greenwich, "for the purpose of providing for the education of naval officers of all ranks above that of midshipman in all branches of theoretical and scientific study bearing upon their profession." The first annual report on the Royal Naval College thus established has been recently presented to both Houses of Parliament.

When the College was established it was determined by the Admiralty to bring together in it all the necessary means both for the higher education of naval officers and also of others connected with the navy. During the session which terminated last year four captains, four commanders, ninety-three lieutenants, and eight navigating-lieutenants joined the college as students, but of these only one captain, thirty-three lieutenants, and three navigating-lieutenants went through the whole nine months' course, although one captain, two commanders, fifty lieutenants, and three navigating-lieutenants underwent the final examination. Besides these officers, who may all be regarded as being purely voluntary students, there was also a large number of others studying at the college, with a view to passing certain examinations, which would qualify them either for promotion or advancement or for appointment to some special branch or department of the service.

Finally, ten private students are reported as having passed through a course of instruction, nine of the number being foreign officers, a fact which testifies to the estimation in which the college is held abroad.

With regard to the subjects of study we find that, besides the course of mathematics, which is compulsory for all students, systematic courses of instruction, extending over the entire session, are given in physics, chemistry, steam, navigation, and nautical astronomy, marine surveying, permanent and field fortification, military surveying and drawing, military history, foreign languages—namely, French, German, and Spanish—and in freehand drawing. Special courses of lectures are also given on various subjects, among which the principal seem to be the Structural Arrangements of Men-of-War, International Law, Naval History, and Practical Ship-building.

TYPICAL LAWS OF HEREDITY[1]

II.

FIRST let me point out a fact which Quetelet and al writers who have followed in his paths have unaccountably overlooked, and which has an intimate bearing on our work to-night. It is that, although characteristics o plants and animals conform to the law, the reason of their doing so is as yet totally unexplained. The essence of the law is that differences should be wholly due to the collective actions of a host of independent *petty* influences in various combinations, as was represented by the teeth o the harrow, among which the pellets tumbled in various ways. Now the processes of heredity that limit the number of the children of one class such as giants that diminish their resemblance to their fathers, and kil many of them, are not petty influences, but very important ones. Any selective tendency is ruin to the law of deviation, yet among the processes of heredity there i the large influence of natural selection. The conclusion is of the greatest importance to our problem. It is, that the processes of heredity must work harmoniously with the law of deviation, and be themselves in some sense conformable to it. Each of the processes must show this conformity separately, quite irrespectively of the rest. I is not an admissible hypothesis that any two or more o them, such as reversion and natural selection, should follow laws so exactly inverse to one another that the one should reform what the other had deformed, because characteristics, in which the relative importance of the various processes is very different, are none the less capable o conforming closely to the typical condition.

When the idea first occurred to me, it became evident that the problem might be solved by the aid of a very moderate amount of experiment. The properties of the law of deviation are not numerous and they are very peculiar. All, therefore, that was needed from experiment was suggestion. I did not want proof, because the theoretical exigencies of the problem would afford that What I wanted was to be started in the right direction.

I will now allude to my experiments. I cast about fo some time to find a population possessed of some measurable characteristic that conformed fairly well to the law and that was suitable for investigation. I determined t take seeds and their weights, and after many preparatory inquiries, fixed upon those of sweet-peas. They were particularly well suited to my purposes; they do no cross-fertilise, which is a very exceptional condition; they are hardy, prolific, of a convenient size to handle, and their weight does not alter when the air is damp or dry The little pea at the end of the pod, so characteristic o ordinary peas, is absent in sweet peas. I weighed seeds individually, by thousands, and treated them as a census officer would treat a large population. Then I selected with great pains several sets for planting. Each set contained seven little packets, and in each packet were ten seeds, precisely of the same weight. Number one of the packets contained giant seeds, all as nearly as might be of $+3°$ of deviation. Number seven contained very small seeds, all of – 3° of deviation. The intermediate packets corresponded severally to the intermediate degrees ± 2° ± 1° and 0°. As the seeds are too small to exhibit, I have cut out discs of paper in strict proportion to their sizes, and strips in strict proportion to their weights, and have hung below them the foliage produced by one complete set. Many friends and acquaintances each undertook the planting and culture of a complete set, so that I had simultaneous experiments going on in various parts of the United Kingdom. Two proved failures, but the final result was this: that I obtained the more or less complete produce of seven sets, that is of 7 × 7 × 10, or 490 carefully weighed seeds.

---

[1] Lecture delivered at the Royal Institution, Friday evening, February 9, by Francis Galton, F.R.S. Continued from p. 493.

It would be wholly out of place if I were to enter into the details of the experiments themselves, the numerous little difficulties and imperfections in them, or how I balanced doubtful cases, how I divided returns into groups, to see if they confirmed one another, or how I conducted any other of the well-known statistical operations. Suffice it to say that I took immense pains, which if I had understood the general conditions of the problem as clearly as I do now, I should not perhaps have cared to bestow. The results were most satisfactory. They gave me two data, which were all that I required in order to understand the simplest form of descent, and so I got at the heart of the problem at once.

Simple descent means this. The parentage must be single, as in the case of the sweet peas which were not cross-fertilised, and the rate of production and the incidence of natural selection must both be independent of the characteristic. The processes concerned in simple descent are those of Family Variability and Reversion. It is well to define these words clearly. By family variability is meant the departure of the children of the same or similarly descended families from the ideal mean type of all of them. Reversion is the tendency of that ideal mean type to depart from the parent type, "reverting" towards what may be roughly and perhaps fairly described as the average ancestral type. If family variability had been the only process in simple descent, the dispersion of the race would indefinitely increase, with the number of the generations, but reversion checks this increase, and brings it to a standstill, under conditions which will now be explained.

On weighing and sorting large samples of the produce of each of the seven different classes of the peas, I found in every case the law of deviation to prevail, and in every case the value of 1° of deviation to be the same. I was certainly astonished to find the family variability of the produce of the little seeds to be equal to that of the big ones, but so it was, and I thankfully accept the fact, for if it had been otherwise I cannot imagine, from theoretical considerations, how the problem could be solved.

The next great fact was that Reversion followed the simplest possible law; for the proportion was constant between the deviation of the mean weight of the produce generally and the deviation of the parent seed, reckoning in every case from one standard point. In a typical case, that standard must be the mean of the race, otherwise the deviation would become unsymmetrical, and cease to conform to the law.

I have adjusted an apparatus (Fig. 1) to exhibit the action of these two processes. We may consider them to act not simultaneously but in succession, and it is purely a matter of convenience which of the two we suppose to act the first. I suppose first Reversion then Family Variability. That is to say, I suppose the parent first to revert and then to tend to breed his like. So there are three stages: (1) the population of parents, (2) that of reverted parents, (3) that of their offspring. In arranging the apparatus I have supposed the population to continue uniform in numbers. This is a matter of no theoretical concern, as the whole of this memoir relates to the distinguishing peculiarities of samples irrespectively of the absolute number of individuals in those samples. The apparatus consists of a row of vertical compartments, with trap-doors below them, to hold pellets which serve as representatives of a population of seeds. I will begin with showing how it expresses Reversion. In the upper stage of the apparatus the number of pellets in each compartment represents the relative number in a *population* of seeds, whose weight deviates from the average, within the limits expressed by the distances of the sides of that compartment from the middle point. The correct shape of the heap has been ensured by my having cut a slit of the proper curvature in the board that forms the back of the apparatus. As it is glazed in front I have only to pour pellets in from above until they reach the level of the slit. Such overplus as may have been poured in will run through the slit, to waste, at the back. The pellets to the right of the heap represent the heaviest seeds, those to the left the lightest. I shall shortly open the trap-door on which the few representatives of the giant seeds rest. They will run downwards through an inclined shoot, and fall into another compartment nearer the centre than before. I shall repeat the process on a second compartment in the upper stage, and successively on all the others. Every shoot converges towards one standard point in the middle vertical line; thus the present shape of the heap of pellets is more contracted in width than it was before, and is of course more humped up in the middle. We need not regard the humping up; what we have to observe is that each degree of deviation is simultaneously lessened. The effect is as though the curve of the first heap had been copied on a stretched sheet of india-rubber that was subsequently released. It is obvious from this that the process of reversion cooperates with the general law of deviation. Fig. 6 shows the principle of the process of reversion clearly.

I have now to exhibit the effects of variability among members of the same family. It will be recollected that the produce of peas of the same class deviated normally on either side of their own mean weight; that is to say, I must make the pellets which were in each of the upper compartments to deviate on either side of the compartment in which they now lie, which corresponds to that of the medium weight of their produce. I open the trap-door below one of the compartments in the second stage, the pellets run downwards through the harrow, dispersing as they run, and form a little heap in the lowest compartments, the centre of which heap lies vertically below the trap-door through which they fell. This is the contribution to the succeeding generation of all the individuals belonging to the compartment in the upper stage from which they came. They first reverted and then dispersed. I open another trap door, and a similar process is gone through; a few extreme pellets in this case add themselves to the first formed heap. Again, I continue the process; heap adds itself to heap, and when all the pellets have fallen through, we see that the aggregate contributions bear an exact resemblance to the heap from which we originally started. A simple formula (see Appendix) expresses the conditions of equilibrium. I attended to these, when I cut out the slit in the back board of the upper compartment, by which the shape of the original heap was regulated. Thus it follows from the formula that if deviation after reversion was to deviation before reversion as 4 to 5, and if 1° of family variability was six units, then the value of 1° in the population must be ten units.

It is easy to prove that the bottom heap is strictly a curve of deviation, and that its scale tends invariably to become the same as that of the upper one. It will be recollected that I showed that every variety of curve of deviation was producible by variations in the length of the harrow, and that if the pellets were intercepted at successive stages of their descent they would form a succession of curves of increasing scales of deviation. The curve in the second stage may therefore be looked upon as one of these intercepts; all that it receives in sinking to the third stage being an additional dose of dispersion.

As regards the precise scale of deviation that characterises each population, let us trace, in imagination, the history of the descendants of a single medium-sized seed. In the first generation the differences are merely those due to family variability; in the second generation the tendency to wider dispersion is somewhat restrained by the effect of reversion; in the third, the dispersion again increases, but is more largely restrained, and the same process continues in successive generations, until the step-by-step progress of dispersion has been overtaken and exactly checked by the growing antagonism of reversion. Reversion acts precisely after the law of an elastic spring, as was well shown by the illustration of the india-rubber sheet. Its tendency to recoil increases the more it is stretched, hence equilibrium must at length ensue between reversion and family variability, and therefore the scale of deviation of the lower heap must after many generations always become identical with that of the upper one.

We have now surmounted the greatest difficulty of our problem; what remains will be shortly disposed of. This refers to sexual selection, productiveness, and natural selection. Let us henceforth suppose the heights and every other characteristic of all members of a population to be reduced to a uniform adult male standard, so that we may treat it as a single group. Suppose, for example, a female whose height was equal to the average female height $+ 3^\circ$ of female deviation, the equivalent in terms of male stature is the average male height $+ 3^\circ$ of male deviation. Hence the female in question must be registered not in the feet and inches of her actual height, but in those of the equivalent male stature.

On this supposition we may take the numerical mean of the stature of each couple as the equivalent of a single parent, so that a male parent plant having 1° deviation and a female parent plant having 2° of deviation, would together rank as a single fertilised plant $0 + 1\frac{1}{2}^\circ$.

In order that the law of sexual selection should co-operate with the conditions of a typical population, it is necessary that selection should be *nil*, that is, that there should not be the least tendency for tall men to marry tall women rather than short ones. Each strictly typical quality taken by itself must go for nothing in sexual selection. Under these circumstances one of the best known properties of the law of deviation (technically called that of "two fallible measures") shows that the population of sums of couples would conform truly to the law, and the value of 1° would be that of the original population multiplied by $\sqrt{2}$. Consequently the population of *means of couples* would equally conform to the law, but in this case the 1° of original deviation would have to be divided by $\sqrt{2}$, the deviations of means of couples being half that of sums of couples.

The two remaining processes are productiveness and survival. Physiologically they are alike, and it is reasonable to expect the same general law to govern both. Natural selection is measured by the percentage of survival among individuals born with like characteristics. Productiveness is measured by the average number of children from all parents who have like characteristics, but it may physiologically be looked upon as the percentage of survival of a vast and unknown number of possible embryos, producible by such parents. The number being unknown creates no difficulty if they may be considered to be, on the average, the same in every class. Experiment could tell me little about either natural selection or productiveness. What I have to say is based on plain theory. I can explain this best by the process of natural selection. In each species, the height, &c., the most favoured by natural selection, is the one in which the demerits of excess or deficiency are most frequently balanced. It is therefore not unreasonable to look at nature as a marksman, her aim being subject to the same law of deviation as that which causes the shot on a target to be dispersed on either side of the point aimed at. It would not be difficult, but it would be tedious, to justify the analogy; however, it is unnecessary to do so, as I propose to base the analogy on the exigences of the typical formula, no other supposition being capable of fulfilling its requirements. Suppose for a moment that nature aims, as a marksman, at the medium class, on purpose to destroy and not to save it. Let a block of stone (Fig. 4) represent a rampart, and let a gun be directed at a vertical line on its side on purpose to breach it: the shots would fall with the greatest frequency in the neighbourhood of the vertical line, and their marks would diminish in frequency as the distance increased, in conformity with the law of deviation. Each shot batters away a bit of stone, and the shape of the breach would be such that its horizontal outline will be the well-known curve. This would be the action of nature were she to aim at the destruction of medium sizes. Her action as preserver of them is the exact converse, and would be represented by a cast that filled the gap and exactly replaced the material that had been battered away. The percentage of thickness of wall that had been destroyed at each degree of deviation is represented by the ordinate of the curve, therefore the percentage of survival is also an ordinate of the same curve of deviation. Its scale has a special value in each instance, subject to the general condition in every typical case, that its 0° shall correspond to the 0° of deviation of height, or whatever the characteristic may be.

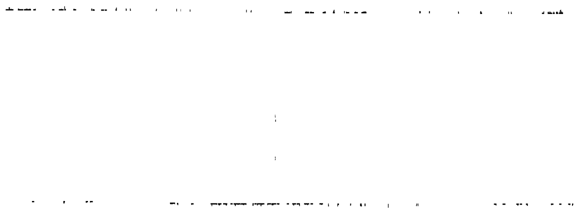

FIG. 4.

In Fig. 5 the thickness of wall that has been destroyed at each degree of deviation is represented by the corresponding ordinate of the horizontal outline of the portion which remains. Similarly, in the case of an original population, in which each class was equally numerous, the amount of survivors at each degree of deviation is also represented by the corresponding ordinate of this or a similar curve.

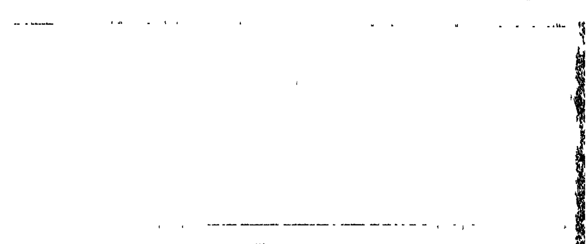

FIG. 5.

But in the original population at which we are supposing nature to aim the representatives of each class are not equally numerous, but are arranged according to the law of deviation; the middle class being most numerous, while the extreme classes are but scantily represented. The ordinate of the above-mentioned outline will in this case represent, not the *absolute number*, but the *percentage* of survivors at each degree of deviation.

(*To be continued.*)

ON THE SIMPLEST CONTINUOUS MANIFOLDNESS OF TWO DIMENSIONS AND OF FINITE EXTENT[1]

ONE of the most remarkable speculations of the present century is the speculation that the axioms of geometry may be only approximately true, and that the actual properties of space may be somewhat different from those which we are in the habit of ascribing to it. It was Lobatchewsky who first worked out the conception of a space in which some of the ordinary laws of geometry should no longer hold good. Among the axioms which lie at the foundation of the Euclidian scheme, he assumed all to be true except the one which relates to parallel straight lines. An equivalent form of this axiom, and the one now generally employed in works on geometry, is the statement that it is impossible to draw more than one straight line parallel to a given straight line through a given point outside it. In other words, if we take a fixed straight line, A B, prolonged infinitely in both directions, and a fixed point, P, outside it; then, if a second straight line, also infinitely prolonged in both directions, be made to rotate about P, there is *only one* position in which it will not intersect A B. Now Lobatchewsky made the supposition that this axiom should be untrue, and that there should be a finite angle through which the rotating line might be turned, without ever intersecting the fixed straight line, A B. And in following out the consequences of this assumption he was never brought into collision with any of the other axioms, but was able to construct a perfectly self-consistent scheme of propositions, all of them valid as analytical conceptions, but all of them perfectly incapable of being realised in thought.

Many of the results he arrived at were very curious; such as, for instance, that the three angles of a triangle would not be together equal to two right angles, but would be together less than two right angles by a quantity proportional to the area of the triangle. If we were to increase the sides of such a triangle, keeping them always in the same proportion, the angles would become continually smaller and smaller, until at last the three sides would cease to form a triangle, because they would never meet at all.

There are many other assumptions, at variance with the axioms of Euclid, which may be made respecting distance-relations, and which yield self-consistent schemes of propositions differing widely from the propositions of geometry. We see, therefore, that geometry is only a particular branch of a more general science, and that the conception of space is a particular variety of a wider and more general conception. This wider conception, of which time and space are particular varieties, it has been proposed to denote by the term *manifoldness*. Whenever a general notion is susceptible of a variety of specialisations, the aggregate of all such specialisations is called a manifoldness. Thus space is the aggregate of all *points*, and each point is a specialisation of the general notion of *position*. In the same way time is the aggregate of all *instants*, and each instant is a specialisation of the general notion of *position in time*. Space and time are, in fact, of all manifoldnesses, the ones with which we are by far the most frequently concerned.

Now there is an important feature in which these two manifoldnesses agree. They are both of them of such a nature that no limit can be conceived to their divisibility. However near together two points in space may be, we can always conceive the existence of intermediate points. And the same thing holds in regard to time. Mathematicians express this fact by saying that space and time are *continuous* manifoldnesses. But there is another feature, equally important with the foregoing, in regard to which space and time are strikingly contrasted. If we wish to travel away from any particular instant in time, there are only two directions in which we can set out. We must either ascend or descend the stream. But from a point in space we can set out in an infinite number of directions. This difference is expressed by saying that time is a manifoldness of *one dimension*, and that space is a manifoldness of *more than one dimension*. An aggregate of points in which we could only travel backwards or forwards would be, *not* solid space, but a *line*. A line, therefore, is a manifoldness of one dimension. A *surface*, again, may be regarded as an aggregate of lines; and it is an aggregate of such a nature, that if we wish to travel away from a particular line, there are only two directions in which we can set out. It is therefore a line-aggregate of one dimension. Considered as a point-aggregate it has two dimensions, and accordingly it is a manifoldness of two dimensions. In the same way it will be seen that solid space is a manifoldness of three dimensions.

I have endeavoured by these remarks to explain what is meant when we speak of a continuous manifoldness of two dimensions. It is the object of this paper to communicate some results I have arrived at respecting the properties of the simplest of such manifoldnesses which has a finite extent. The existence of the particular manifoldness I shall endeavour to describe has been referred to in a remarkable lecture by Prof. Clifford on "The Postulates of the Science of Space," but, so far as I am aware, its properties have not hitherto been worked out in detail.

The simplest of all doubly-extended continuous manifoldnesses is the *plane*. But it is not a manifoldness of finite extent. It reaches to infinity in every direction, and its area is greater than any assignable area. It is therefore not the manifoldness of which we are in search. Now the circumstance in which the plane differs from those doubly-extended manifoldnesses which are next to it in order of simplicity, is the possibility that figures constructed in it may be magnified or diminished to any extent without alteration of shape; in other words, that figures which can be constructed in it at all can be constructed to any scale. That this property is not possessed by curved surfaces, may be seen by considering the case of a spherical triangle. If the sides of a triangle constructed on a given sphere be all of them increased or diminished in the same proportion, the shape of the triangle will not remain the same. Now it has been found by Prof. Riemann that this property of the plane is equivalent to the following two axioms:—(1) That two geodesic lines which diverge from a point will never intersect again, or, as Euclid puts it, that two straight lines cannot inclose a space; and (2) that two geodesic lines which do not intersect will make equal angles with every other geodesic line. The second is precisely equivalent to Euclid's twelfth axiom. Deny the first of these axioms, and you have a manifoldness of uniform positive curvature; deny the second, and you have one of uniform negative curvature. The plane lies midway between the two, and its curvature is zero at every point.

Let us consider, then, the case of a doubly-extended manifoldness, of which the curvature is uniform and positive. The first of the before-mentioned two axioms is no longer true. Geodesic lines diverging from a point do not continue to diverge for ever. They meet again and inclose a space. The first question which presents itself is with reference to the situation of the point towards which they ultimately converge. In the case of a spherical surface they will converge towards a point which is separated from the starting-point by half the length of a geodesic line. And this is the only case we are able to conceive. The surface of a sphere is the only doubly extended manifoldness of uniform positive curvature which geometry recognises, and it is the only one which we can figure to ourselves in thought. It is not, however, the *simplest* of such manifoldnesses. To obtain the simplest case we must suppose that the point towards which two geodesic lines converge is separated from their starting-point, not by *half*, but by the *entire* length of a geodesic line; or, what amounts to the same thing, that it *coincides* with the starting-point. It is true that we are utterly unable to figure to ourselves a surface in which two geodesic lines shall have only one point of intersection, and shall yet inclose a space. But we are perfectly at liberty to reason about such a surface, because there is nothing self-contradictory in the definition of it, and because, therefore, the analytical conception of it is perfectly valid. It is the simplest continuous manifoldness of two dimensions, and of finite extent, and those few properties of it which I have worked out appear to me to be very beautiful. In order to make my observations more intelligible, I shall for the future speak of it as a surface, and its geodesic lines I shall speak of as straight lines. I have the highest authority for using this nomenclature, and though it will impart to my theorems a very paradoxical sound, it is calculated, I think, to give a juster idea of their meaning, than if I were to use the more accurate, but less familiar terms.

---

[1] Read before the London Mathematical Society, December 14, 1876

Assuming, then, as the fundamental properties of our surface, that every straight line is of finite extent (in other words, that a point moving along it will arrive at the position from which it started after travelling a finite distance), and that two straight lines cannot have two points in common, the first corollary I propose to establish is that all straight lines in the surface are of equal extent.

Let A, B, be two straight lines in the given surface. If possible, let A be greater than B. From A cut off a portion equal to B. Let P, Q, be the extreme points of this segment, and let R be any point in B Apply the line A to the line B in such a manner that the point P falls on the point R, then, since in a surface of uniform curvature equal lengths of geodesic lines may be made to coincide, the segment PQ will coincide with the entire straight line B. Hence Q will fall upon R. But P coincides with R, and P and Q do not coincide with one another, since PQ is less than the entire straight line A; therefore Q cannot coincide with R. Hence A cannot be greater than B.

The straight lines here spoken of are, of course, not *terminated* straight lines. What the proposition asserts is that the *entire* length of all straight lines in the given surface is the same. The corresponding proposition in spherical geometry is that all great circles of a given sphere are equal.

There are a great many other analogies between the imaginary surface here treated of and the surface of a sphere. Its straight lines, though they are like the straight lines of a plane in the circumstance that any two of them have only one point of intersection, are in many other respects analogous to great circles. In any of its straight lines, for instance, each point has a corresponding point which is *opposite* to it, and farther from it than any other point in the line. For if by setting out from a point and travelling a finite distance in a particular direction we get back to the starting-point, there must be a point half way on our journey which is farther from the starting-point than any other point in the line, and which may very appropriately be called its opposite point. It is an obvious corollary that the distance between any two points will be the same as the distance between their opposite points.

Let us now consider the case of a number of straight lines radiating from a centre. In each of them there will be a point which is opposite to that centre. And it will be a separate point for every separate straight line. For no two straight lines can have two points in common, and since these radiating lines have a common centre of radiation, they can have no other point in common. Hence, if we suppose one of these lines to rotate about the centre, the point opposite to the centre will describe a continuous line, and one which finally returns into itself. It is the locus of all points in the surface opposite to the centre of radiation. What now is the character of this locus? In the first place it is a line which is of the same shape all along, and of which all equal segments therefore can be made to coincide. For any two positions of the rotating line which contain a given angle may be placed upon any other two positions which contain an equal angle. Then, since the length of all straight lines in the surface is the same, the opposite points will coincide, and by parity of reasoning all intermediate points of the locus. But, in the second place, the locus is also of the same shape on both sides. For each point in it may be approached from the centre of radiation in two different ways, and it is at the same distance from that centre, whether it be approached in the one way or the other. Any particular segment, in fact, of the locus has its extreme points joined to the centre of radiation by lines which are of equal length, and which include an equal angle—lines, therefore, which may be made to coincide. Since this is the case for any segment whatever, and for every subdivision of a segment, all the points of a segment will still remain on it if the segment be turned round and applied to itself. Hence the locus is of the same shape, whether viewed from the one side or from the other. But since it is also of the same shape all along, it satisfies Leibnitz's definition of a straight line, and it is, in fact, a geodesic line of the surface.

Hence we have this second proposition—that all points in the surface opposite to a given point lie in a straight line.

From the method of its construction, this straight line is farther from the given point than any other line in the surface. Travelling from the given point as a centre, in whatever direction we might set out, we should, after completing half our journey, arrive at this farthest straight line, we should cross it at right angles, and we should then keep getting nearer and nearer to our starting-point, until we finally reached it from the opposite side.

Each separate point in the surface, moreover, has a separate farthest line. For if any two points be taken, the points opposite to them on the straight line which joins them will be distinct. Hence their farthest lines will cut this joining line in two separate points. They must, therefore, be two *separate* lines, for the same straight line cannot cut another straight line in two separate points. In a similar manner it may be shown that each straight line in the surface has a separate farthest point. Hence there exists a reciprocal relation between the points and straight lines of the surface, a relation which we may express by saying that every point in the surface has a *polar*, and that every straight line in the surface has a *pole*. It is then easy to show that when a point is made to move along a straight line its polar will turn about a point, and that when a straight line is made to turn about a point, its pole will move along a straight line.

It is interesting to compare these propositions with the corresponding ones in spherical geometry. There, too, each point has a farthest geodesic line; that is to say, a geodesic line which is farther from it than any other geodesic line on the sphere. But each geodesic line has *two* farthest points or poles, instead of having only one. Hence there is not that perfect reciprocity of relationship between points and geodesic lines which exists in the surface we have been examining; and this is one of the many ways in which the sphere shows itself to be inferior to that surface in simplicity.

The most astounding fact I have elicited in connection with this surface is one which comes out in the theory of the circle. Defining a circle as the locus of points equidistant from a given point, we shall find that it assumes a very extraordinary shape when its radius is at all nearly equal to half the entire length of a straight line. For let us again figure to ourselves a number of straight lines radiating from a point. Let l be the total length of each straight line. Then the supposition we have to make is that the radius of our circle shall be nearly equal to $\frac{l}{2}$. Let us suppose it equal to $\frac{l}{2} - m$, where m is small as compared with l. Each of the radiating lines will cut the circle in two points, and each of these points will be at a distance from O equal to $\frac{l}{2} - m$ or $\frac{l}{2} + m$, according as the distance is measured in the one direction or the other. And their distance from each other will be equal to $2m$, that is to say, it will be comparatively small. But each point on the polar of O will be at a distance from O equal to $\frac{l}{2}$. Hence each point on the circle will be at a distance from this polar equal to m. Moreover, every point at a distance of m from the polar will be a point on the circle, because it will be at a distance of $\frac{l}{2} - m$ from O. But the locus of points at a distance of m from the straight line, A B, will consist of two branches, C D and E F, one on either side of A B, and at the same distance from it along their whole length. It is true that these branches form in reality a single continuous line. A point travelling along from C to D, and further in the same direction, would ultimately appear at E, travel along to F, and then, after a further journey, reappear at the point C. But this does not alter the fact that when a small portion only of this line is contemplated, it presents the appearance of two straight lines, each of them parallel to, and equidistant from, A B.

In the limiting case, where the radius becomes equal to $\frac{l}{2}$, C D and E F both of them coincide with A B. The circle merges into a straight line, and becomes, in fact, the polar of its own centre. It is not, indeed, quite accurate to say that it merges into a straight line, for it reduces itself rather to two coincident straight lines, and its equation in co-ordinate geometry would be one of the second degree.

In regard to the surface here treated of, it is easy to see that, as with the sphere, the smaller the portion of it we bring under our consideration, the more nearly its properties approach to those of the plane. Indeed, if we consider an area that is very small as compared with the total area of the surface, its properties will not differ sensibly from those of the plane. And on this ground it has been argued that the universe may in reality be of finite extent, and that each of its geodesic lines may return into itself, provided only that its total magnitude be very great as compared with any magnitude which we can bring under our observation.

In conclusion, I cannot do better than quote the passage in which Prof. Clifford explains what must be the constitution of space if this hypothesis should be true. "In this case," he says, "the universe, as known, is again a valid conception, for the extent of space is a finite number of cubic miles. And this comes about in a curious way. If you were to start in any direction whatever and move in that direction in a perfect straight line according to the definition of Leibnitz, after travelling a most prodigious distance, to which the parallactic unit—200,000 times the diameter of the earth's orbit—would be only a few steps you would arrive at—this place. Only, if you had started upwards, you would appear from below. Now one of two things would be true. Either when you had got half way on your journey you came to a place that is opposite to this, and which you must have gone through, whatever direction you started in, or else all paths you could have taken diverge entirely from each other till they meet again at this place. In the former case every two straight lines in a plane meet in two points, in the latter they meet only in one. Upon this supposition of a positive curvature the whole of geometry is far more complete and interesting; the principle of duality, instead of half breaking down over metric relations, applies to all propositions without exception. In fact I do not mind confessing that I personally have often found relief from the dreary infinities of homaloidal space in the consoling hope that, after all, this other may be the true state of things."

F. W. FRANKLAND

HYDROGRAPHY OF WEST CENTRAL AFRICA

MR. STANLEY'S second letter in last Thursday's *Telegraph* contains important information on the district between Tanganyika and the Albert and Victoria Nyanza—information complementary to that given in his former letters, which we embodied in a map, vol. xiv. p. 374. He has, in fact, discovered another "source" of the Nile, and one evidently of great length and volume—the Kagera—which he has gallantly named the Alexandra Nile. This river issues from a large lake, Akanyaru or Alexandra Nyanza, in two branches and flows north, uniting under 1° S. lat., and flowing east to the Victoria Nyanza. Mr. Stanley was only able to see the Alexandra Nyanza from a distance, but it is evidently of considerable size, and receives a river at its west end, the Upper Alexandra Nile, which probably comes from a considerable distance. Mr. Stanley believes that the Alexandra Nyanza has a marshy connection with Kivu Lake on the south, from which issues the Rusizi, an affluent of the Tanganyika. If then these various connections are ultimately verified, the problem of African hydrography becomes more complicated than ever. The Rusizi will connect the Nile system with Tanganyika, and very shortly, at least, Mr. Stanley believes, the Lukuga will carry the water of the latter to the west—to the Congo, say some. Meantime Mr. Stanley is probably at or has already left Nyangwe. After deciding this question of the connection of Albert and Tanganyika Lakes from that side, he will probably devote himself to the task of tracing down the Lualaba, which, according to Cameron, should bring him into early communication with Dr. Nachtigal, who is to trace up the Congo.

It may not be uninstructive to point out what is the present state of the problem which these two explorers have set themselves to solve. Our principal scientific authorities on the Congo are still Capt. Tuckey and Prof. Smith, who in 1816 ascended about 200 miles up the river, and who have left us a record yet deserving of study. They left England at a time when the outlet of Mungo Park's Niger was a subject of speculation, and amongst the theories then started, the Congo, as an outlet, held a high place. The same notions of the magnitude of this river obtained then, and Capt. Tuckey and his civilian scientific staff started with the idea that they would be able to navigate it for hundreds of miles. They had, however, only been in the river some four or five days when Prof. Smith makes this entry in his diary :—"The channel is very narrow and the current never more than three knots . . . everthing yet seems to indicate that the descriptions of the great breadth of the river, the length of its course, &c., have been exaggerated." Again, twelve days afterwards, when they had got considerably further up the river, he writes, "The whole appearance of the river, its numerous sandbanks, low shore, inconsiderable current, narrow channel, seem but little to justify its extravagant fame. Its sources cannot be further inland than those of the Senegal and Gambia." Capt. Tuckey, who ties himself very rigidly to a statement of facts, ventures to say that at Fathomless Point the true mouth of the river "is not three miles in breadth ; and allowing the mean depth to be forty fathoms and the mean velocity of the stream four and-a-half miles an hour, it will be evident that the calculated volume of water carried to the sea has been greatly exaggerated." The mean velocity of the current higher up the river than the true mouth appears to be about two miles, and Tuckey remarks that they found no difficulty in rowing the gigs to the foot of Casan Yellala *against the current*.

These falls or rapids (Yellala) deserve some notice. They extend continuously for about twenty miles along the river, and are very much like the rapids on the Somerset Nile between Foweira and Magungo, where Col. Gordon reports a fall of 700 feet in a space of ten or fifteen miles. On August 14, 1816, Prof. Smith says, "We discovered the celebrated fall of Yellala, at a distance of about a mile and a half. But how much were we disappointed in our expectations on seeing a pond of water only with a small fall of a few hundred yards." They had been led to expect a second Niagara, and instead of that, found a rapid having a perpendicular fall of thirty feet in a slope of 300 yards formed of a descending bed of mica slate. The width of the river is very various, sometimes expanding to half a mile. It is compared by Tuckey to Loch Tay and by Smith to the Drammen, in Norway, at the bridge. Sometimes it contracts to 100 yards ; in one place it is reduced to fifty yards in breadth, but at this point the stream rushes through at the rate of eight miles an hour. The rapid and considerable rise of the water during the rainy season is largely accounted for by the fact that "the hills do not absorb any of the water that falls, the whole of which is carried direct to the river by gullies and ravines, with which the hills are furrowed all over." These hills are composed entirely of slate, with masses of quartz and syenite, and their extreme barrenness forms one of the most striking features of the country.

It would appear from Capt. Tuckey's and Prof. Smith's reports that the farthest point they reached on the river was at least 1,000 feet above the sea, and as this point is about 800 miles in a direct line from Nyangwe, which Cameron has fixed at 1,400 feet, the connection between the Congo and Lualaba on the question of level alone seems very doubtful.

The Casai and Kwango are doubtless the chief affluents of the Congo ; it may have tributaries from the north and north-west behind the coast ranges, but these will be of secondary importance. As soon as we get east of the Congo water-parting, we begin to descend to the great valley of the Lualaba, Livingstone's "central line of drainage." This river occupies the centre of a saucer-like depression, one lip being probably the Congo water-parting, the other the Bambarre, or perhaps Kabogo Mountains to the west of Tanganyika. The fall of this depression is from south to north ; commencing at the Katanga copper mines of the Pombeiros, it runs to Lake Kassali 1,750 feet, to Nyangwe 1,400 feet ; thence to the "Unvisited Lake" of Livingstone, the "Great Lake" of Poncet, or the "Sankorra" of Cameron, probably also the "Liba" of the Benin slaves, and so on by the Shari to Lake Chad, 830 feet.

From these statements, then, it will be seen that the solution of the hydrographical problem of Western Central Africa is difficult to arrive at on the data we at present possess, and that to advocate any special theory may be rash. The Congo theory is a fascinating one, but the levels seem against it. However, with two such men as Nachtigal and Stanley in the field, the solution of this problem, as of others almost equally interesting, will soon be discovered.

THE LONDON INDUSTRIAL UNIVERSITY

WE give below a series of extracts from an admirable letter addressed by Major Donnelly, the chief of the scientific staff of the Science and Art Department, to Sir Sydney Waterlow, with reference to the proposed Industrial University to be established by the City Guilds in London :—

London, March 14, 1877

DEAR SIR SYDNEY WATERLOW,—In reply to your request, I am happy to place at your service such suggestions, with regard to the proposed "City Guilds' Industrial University," as my experience in connection with the Science and Art Department enables me to offer. . . .

Under anything like a broad view of the subject it would be difficult to say what branch of learning should be omitted in an Industrial University. But if we confine ourselves to what is practicable with the probable means immediately at command, and if we look to commence by supplying that of which there is the greatest want, we shall, I think, have no hesitation—considering the relative facilities for obtaining instruction in the different branches of knowledge—in deciding that science as now understood, and particularly Applied Science, has the first call on our attention.

. . . The Industrial University might be *commenced* by establishing professorships with the necessary laboratories, tutorial staff, &c., in the following branches of Science and Art :—

Mathematics (Pure and Applied and Practical Geometry).
Chemistry.
Physics (Heat, Light, Magnetism, and Electricity).
Mechanics (Practical Mechanics, Machinery, and Machine Drawing).
Engineering and Building Construction ; and in

Applied Art (Modelling, Designing, Enamelling, Repoussé work, Wood Carving, &c.).

As the teaching would be specially directed to the industrial applications of science it is needless to say that considerable subdivision would be required in the subjects named. . . .

. . . It is of great importance that the professors should be not only teachers, but investigators, constantly endeavouring to enlarge the field of accurate knowledge, and scientific procedure, in our industries. To appreciate how much may be effected in this way we have only to consider the millions saved to France by Pasteur's researches on the disease of the silkworm, or the knowledge obtained by his inquiry on fermentation.

. . . The time of the professors may be much economised by making it no part of their duty to commence their courses with the elements of general science. It is quite unnecessary that they should do so. This teaching may be obtained at other places, with which the Industrial University would be only needlessly interfering if it gave elementary instruction. It should, on the contrary, be its object to supplement and specialise the knowledge obtainable in ordinary science classes from which the students should be drawn; and they should be expected to have acquired sufficient general knowledge of science before entering the classes and laboratories of the University to be able to follow its courses with advantage.

A leading feature of the University should be evening courses—not merely popular lectures—for the use of those whose circumstances in life have rendered it necessary that they should commence the practical work of life early. By circumstances in life I do not refer solely to poverty. There are many occupations that it is advisable, if not necessary, to enter upon early. For instance, it is of the utmost importance for a mechanical engineer to be a good practical workman. To do this he must join the workshop when young. And the lad who enters when he is thirteen has an advantage which might not be expected. Mr. Phythian, the Master of the Oldham School of Science and Art established by the Messrs Platt, informs me that to the lads who come into the workshop at this age the evening intellectual work is no effort; it is a relaxation and recreation. To the apprentices who enter at eighteen it is almost an impossibility. They are so exhausted by their day's labour that they cannot pay attention.

It is agreed on all hands that if the teaching of science is to be of any use it must be essentially practical—that is to say, the teaching of the laboratory. And no pains should be spared to make the laboratories perfect and readily available. By them the University may supply a great want.

It is perhaps necessary to guard against the idea that the University is to teach any trade or business. There could be no greater mistake than for it to attempt to do so. The purely technical knowledge of a trade must be learnt by practising it. The teaching of a public institution can with advantage only extend as far as the special application of various branches of abstract science to the different arts. It is no doubt difficult to define how far the teaching of applied science may go without trenching on the workshop. But in practice the limits are readily found. This difficulty will be still less felt in an institution drawing its pupils from among those actually engaged in trade, who will know what they can acquire in the University, and what they can better learn directly in business. The programme of examinations in technology by the Society of Arts will give many suggestions on this subject.

I have no doubt that the Society of Arts would be willing to transfer the whole or a part of their system of examinations in technology to such a body as the City Guilds, who, with far larger funds at their disposal, may give it a development which the Society of Arts can never obtain for it. By employing local agencies and taking advantage of the machinery of the Science and Art Department, these examinations are held throughout the country. And by availing itself of this and similar organisations, the Central University might be brought *en rapport* with [illegible] part of England, Scotland, and Ireland.

. . . Through the action of the Government, stimulating local effort, the country is being rapidly covered by a network of Science and Art schools and classes, where the working classes—whose interests and advances the City Guilds are, I understand, especially anxious to promote by the Industrial University—have opportunities of obtaining that elementary instruction in Science and in Art which must be the basis of any sound technical education. There are now 1,750 separate schools or classes in the country in connection with and receiving aid through the Science and Art Department.

It is therefore unnecessary to consider the question of the creation of any organisation for giving instruction in elementary general science or art. What are wanted are a stimulus to increase the number of students, the development of systematic courses of instruction onwards and upwards from the elementary school, and means to enable poor, but clever and industrious, youths to pursue such courses. The award of small scholarships or bursaries in competition which would support the holders while carrying forward their studies in a higher school—the retention of the bursary being contingent on a definite course of instruction being pursued satisfactorily—is therefore, I believe, the most effective means the Guilds can adopt to aid technical instruction.

. . . It is very necessary to bear clearly in mind in what directions the University must look for its pupils. Broadly speaking, these will I believe be:—

1. The holders of Bursaries and Scholarships.

2. Young men whose means enable them to carry on their education beyond the school age, and who can attend an institution in London more conveniently than elsewhere.

3. A limited number of students of the same class who are attracted by the goodness of the instruction and its appropriateness to their future pursuits. I say a limited number, because, however good the instruction, it will take years to divert the class of students from the channels which time has consecrated.

4. Evening students—men who are engaged during the day.

It would be useless to expect many students from classes 2 and 3 at first. . . .

The real point seems to me to make a beginning. Get a good site—by a 'good site I mean a site in an accessible position, sufficiently large to allow of expansion as the University grows—build chemical and physical laboratories, and lecture rooms, and some mathematical class rooms, on a portion of the site. If these are well managed, and are in a prominent position, such as that suggested on the Embankment, where they cannot but be seen—it is difficult to make anything known in London—surely there must be many rich men in the city besides the city companies who will seize the opportunity, by adding to the endowment or the buildings, of perpetuating their memories as munificent patrons of what will eventually be a credit to the country.

. . . It always seems to be forgotten that the population of London is as large as that of Scotland; and that if its provision for instruction were tenfold what it is, it would not be proportionately larger than that of the Canton of Zurich.

Any plan you commence upon must be much modified as the institution is expanded and developed. To succeed, the University must be built up by slow degrees and adapted, with the experience you gain from day to day, to meet the wants and circumstances of the time. That it will be a success, and a great success, if taken heartily in hand by the City of London, there can be no doubt.

Believe me,
Yours very faithfully,
J. F. D. DONNELLY

OUR ASTRONOMICAL COLUMN

THE OPPOSITION OF MARS IN 1892.—Early in August, 1892, the planet Mars will come into opposition at a distance sensibly the same as in September of the present year, when it is proposed to make a serious attempt to determine the solar parallax by observations of this planet, a method which has not hitherto been applied under such advantageous circumstances as are now possible, but which is calculated to furnish the sun's distance from the earth with a degree of precision comparable with that to be attained by the observation of a transit of Venus, and with far less trouble and expense. It will not perhaps be without interest at the present moment, when the attention of astronomers is particularly directed to the efficient observation of Mars near the opposition in September next, if we present an ephemeris for the opposition of 1892, the only one of the present century yet to come, which can be to all intents and purposes as favourable as that of 1877. The ephemeris is founded upon the tables of M. Leverrier, which have been applied with sufficient accuracy for the object in view. The positions are for mean noon at Paris.

1892	App. R.A. of Mars. h. m. s.	App. Decl. of Mars. ° ′ ″	Log distance from Earth.
July 23	21 18 47·4	— 22 25 24	9·59247
„ 25	— 17 5·9	22 38 27	9·58837
„ 27	— 15 16·0	22 51 22	9·58489
„ 29	— 13 19·0	23 4 0	9·58201
„ 31	— 11 16·4	23 16 13	9·57975
Aug. 2	— 9 9·3	23 27 51	9·57812
„ 4	— 6 59·4	23 38 47	9·57714
„ 6	— 4 48·1	23 48 55	9·57678
„ 8	— 2 36·8	23 58 7	9·57705
„ 10	21 0 27·1	24 6 18	9·57796
„ 12	20 58 20·4	24 13 23	9·57951
„ 14	— 56 18·0	24 19 18	9·58166
„ 16	20 54 21·4	— 24 23 59	9·58443

The opposition will take place on August 4, and Mars will be in perigee on August 6 at a distance of 0·3774. The distance in perigee in the present year will be 0·3767.

THE COMET 1873 II. (TEMPEL, JULY 3).—This very interesting comet of short period will return to perihelion in 1878. The elements which rest upon the widest extent of observation are those of Mr. W. E. Plummer; in his orbit the period of revolution is 1850·25 days, or 5·066 years, and the perihelion passage in 1873 having taken place June 25·38, G.M.T., the comet, neglecting the effect of perturbations which in the present revolution is not likely to be material, will be again due in perihelion about 1878, July 19·5. Probably geocentric places derived from Mr. Plummer's orbit, with this date for perihelion passage, will give a sufficient idea of the circumstances of the next appearance, and a few positions so derived are accordingly subjoined:—

At 12h	R.A. °	N.P D.	Distance from earth
June 29	322·5	97·4	0·437
July 9	328·7	100·7	0·400
„ 19	334·7	104·9	0·377
„ 29	340·0	109·8	0·369
Aug. 8	344·3	114·6	0·375
„ 18	347·4	118·8	0·397

The comet, therefore, appears under conditions nearly as favourable as possible for observations, the least distance of its orbit from that of the earth being 0·33, at a greater radius-vector. In aphelion the comet is distant from the sun 4·555, and its distance from the orbit of the planet Jupiter at this point (which is that of nearest approach) is 0·736. Four days after perihelion passage the comet approaches the orbit of Mars within 0·05, all these distances being expressed in parts of the earth's mean distance from the sun.

There does not appear to have been any observation of this comet previous to 1873, notwithstanding its short period. It could neither have been the object seen on one morning only in October 1846 by Hind, nor that observed by Goldschmidt on May 16, 1855, which was at first mistaken for the short-period comet of De Vico (1844 I).

In addition to the comet in question, Tempel is also the discoverer of comet 1866 I, associated with the great November meteor-shower, and comet 1867 II, which was re-observed in 1873, after its orbit had undergone considerable change from a near encounter with Jupiter about the preceding aphelion passage.

NEW COMET.—Prof. Winnecke, the director of the Imperial Observatory at Strasburg, announces his discovery of "a fine bright comet, with nucleus and trace of a tail," early on the morning of April 6. The following position depends upon observations with an annular micrometer on a 3½ feet telescope, the comet being inconveniently situated for the larger instrument.

April 5 at 15h. 53m. 39s. mean time at Strasburg, Right Ascension 22h. 7m. 49·44s., Declination + 14° 54′ 15·4″. The diurnal motion in R.A. is rather less than 1m., and that in Decl. about 1½°, both increasing.

The dearth of comets which had prevailed since December 1874, appears to have terminated, and we must soon hear of the re-discovery of the one which bears the name of D'Arrest, and has been so elaborately calculated by M. Leveau.

[Since the above was in type the following elements, calculated by Herr Hartwig, have been received from Prof. Winnecke:—Perihelion passage, April 18·1741, Berlin time, longitude of perihelion, 251° 59′ 57″; ascending node, 317° 51′ 18″; inclination, 56° 42′ 42″; logarithm of perihelion distance, 9·96767, motion retrograde. By these elements the comet at midnight on April 25, in R.A. 22h. 39m. and N.P.D. 42°·7, will have twice the theoretical intensity of light that it had on the date of discovery.]

CHEMICAL NOTES

THE NEW METALS ILMENIUM AND NEPTUNIUM.—About thirty years ago R. Hermann announced the discovery of a new metal, ilmenium, accompanying tantalum and niobium in various minerals, and closely allied to them in its general characters. Several years later he relinquished his claims to the discovery, in consequence of researches by Marignac in the same field leading to entirely different results. Later investigations have, however, strengthened his belief in the existence of ilmenium, and in the February number of Kolbe's *Journal fur praktische Chemie* he not only brings forward results tending to establish the individual character of ilmenium, but describes a new metal, *neptunium*, belonging to the same group, and occurring in tantalite from Haddam, Connecticut. As the quantities obtained are small, the characteristic reactions limited, and as the spectral properties cannot be made use of, chemists will naturally reserve their opinion till confirmatory observations have been made by some other well-known investigator. The following are the essential results obtained by Hermann. The mineral was found to consist of equal portions of columbite ($ROMe_2O_3$) and ferroilmenite ($RO2MeO_3$). By fusion with potassium bisulphate the hydrates of the metallic oxides were separated out in the following proportions:—

Ta_2O_3	32·39
Nb_4O_7	36·79
Il_4O_7	24·52
Np_4O_7	6·30
	100·00

The hydrates can be changed into double fluorides, and from the greater solubility of potassium-neptunium fluoride, it may be obtained free from tantalum and ilmenium salts but retaining a small quantity of the niobium salt; these, however, on being changed into niobate and neptunate of sodium may be separated on account of the greater solubility of the latter. By fusion of the neptunate of sodium with potassium bisulphate and treatment with water, the hydrate of neptunic acid was obtained in a pure condition. Neptunium may be distinguished from niobium and ilmenium by its having, along with tantalum, the property of forming an amorphous insoluble precipitate on the addition of caustic soda to the boiling solution of the fluoride; the other two form crystalline and easily soluble compounds. The very soluble character of neptunium-potassium fluoride as compared with the corresponding tantalum salt serves to distinguish it from that metal. The reactions with phosphorus salts in the inner part of the bunsen flame are the following:—tantalic acid, colourless; niobic acid, blue; ilmenic acid, brown; neptunic acid, wine yellow. Addition of tincture of galls to solutions of the sodium salts gives characteristically-coloured precipitates. The atomic weight of neptunium, determined from the double salt $4KFl + Np_2Fl_7 . 2H_2O$, was found to be 118. Hermann has also obtained ilmenium in the form of a black powder by heating potassium-ilmenium fluoride with potassium chloride and potassium.

ABSORPTION OF HYDROGEN BY ORGANIC SUBSTANCES UNDER THE INFLUENCE OF THE SILENT DISCHARGE.—M. Berthelot has recently found that under the effect of the discharge, benzene absorbs about two atoms of hydrogen, yielding a polymeride of C_6H_8, a resinous substance with an irritating smell. On heating, benzene first distils over; then a liquid, soluble in strong nitric and sulphuric acid, finally leaving carbon containing a little hydrogen. Oil of turpentine absorbs about 2·5 atoms of hydrogen, yielding resinous products. Pure carbon does not combine with hydrogen under the influence of the discharge, and a mixture of hydrogen with acetylene behaves much in the same way as pure acetylene. A mixture of hydrogen and carbon monoxide yields the solid body observed by Brodie and Thénard, $5CO + 3H_2 = CO_2 + C_4H_6O_3$, a trace of acetylene being formed.

PHOSPHORUS PENTAFLUORIDE.—Professor Thorpe has lately described this body (Liebig, *Ann.* clxxxii.), which he prepares by the gradual addition of phosphorus pentachloride to arsenic trifluoride. Phosphorus pentafluoride is a colourless gas, with a pungent and extremely irritating odour; it reacts upon water, forming phosphoric and hydrofluoric acids. The density with regard to hydrogen was found to be 63·23 (theory requiring 63); under the pressure of twelve atmospheres at 7° it exhibits no marked deviation from Boyle's law; it does not seem to be affected by the passage through it of electric sparks either when pure or when mixed with hydrogen or oxygen. With dry ammonia it forms the compound $2PF_5 5(NH_3)$.

MOLECULAR VOLUMES OF SULPHATES AND SELENATES.—An account of investigations on this subject has lately been published by Otto Petterson (*Deut. chem. Ges. Ber.*, ix. 1559), in which he finds that, in the series of sulphates and selenates of potassium, ammonium, rhubidium, and cæsium the molecular volume of the compound is regularly increased by 6·6 when the group SO_4 is exchanged for the group SeO_4; also, that the substitution of a molecule of ammonium, rubidium, or cæsium for a molecule of potassium produces an increase in volume of 9, 8, and 23 respectively in the selenates as well as in the sulphates. He has also examined the double sulphates and selenates of cobalt, nickel, and copper with potassium, in which results are found tending to confirm the hypothesis that in double salts the components are unaltered; this is more marked in the case of the selenates, in which the volumes of the double salts are equal to the sums of the volumes of their components. The author disagrees with Favre and Valson in their conclusions that double salts cannot exist in solution, and are formed at the moment of crystallisation; he believes on the contrary that as no contraction takes place on crystallisation these salts may be held to exist in the same condition in solution as after crystallisation; the double salt of thallium is, however, an exception. In the case of the alums also when obtained in an anhydrous condition the volume of the salt exactly equals the volumes of its components.

CONTRIBUTIONS TO THE THEORY OF LUMINOUS FLAMES.—A continuation of experiments on the above subject is given by K. Heumann (*Liebig's Ann.*, clxxxiii.), in which he finds that carbonaceous matter will give luminous or non-luminous flames, according as the temperature of the flame is high or low; diluting the gaseous combustible with indifferent gases also requires a higher temperature to cause a separation of the carbon, and thus produce luminosity. Reduction of temperature in a flame prevents either partially or entirely the formation of carbon, consequently the author thinks that the deposition of carbon on cold surfaces in a flame is not the consequence of cooling, as a deposition may be formed on red-hot surfaces, but burns away in contact with air. In burners of different materials, those of iron were found to prevent the luminosity of the lower part of the flame to a greater extent than those of steatite, also when the burner is heated, a greater amount of light is produced, the consumption of the combustible remaining the same. Herr Heumann thinks that by heating the burner the luminosity is increased, and extends to a greater extent over the lower part of the flame.

NOTES

WE are informed that H.M. Government has just been pleased to sanction the necessary expenditure to replace the important deep-soil thermometers of the Royal Observatory, Edinburgh, which were so cruelly broken by a madman last September. The estimate has been prepared by Messrs. Adie and Son, Princes Street, Edinburgh, and is understood to include everything that can conduce to scientific accuracy.

PROF. J. DEWAR, F.R.S.E., Jacksonian Professor of Natural Experimental Philosophy in the University of Cambridge, has been elected Fullerian Professor of Chemistry to the Royal Institution in the room of Dr. Gladstone, resigned.

DR. COLAN, the senior medical officer of the recent Arctic Expedition, has been promoted to be Deputy Inspector-General of Hospitals.

DR. W. B. CARPENTER, C.B., commenced, on Monday evening, at the School of Mines, Jermyn Street, a free course of lectures on geology, which he is delivering as Swiney Professor.

AT the meeting of the French Geographical Society on April 4 it was announced that the great gold medal of the Society had been awarded to Commander Cameron in recognition of his services in the cause of geographical science.

THE estimate for "Education, science, and art in Great Britain amounted in 1853–4 to 578,000*l.*; this year the estimate was 3,546,000*l.*" "In 1835 the Government paid for public education a sum of 26,750*l.*, but in 1875–6 the amount had increased to 3,972,008*l.*"

AMONG the fifty-seven candidates for admission into the Royal Society are two clergymen of the Church of England, one Wesleyan minister, one peer, one foreign baron, one baronet, eleven M.D.s, &c.

THE late Mr. J. C. Tufnell has bequeathed to University College, Gower Street, 5,000*l.* to be used in establishing two scholarships, one in general chemistry and the other in analytical and practical chemistry.

THE Rev. E. Ledger, Gresham Professor of Astronomy, will deliver a course of Lectures on the Telescope, in the theatre of Gresham College, on the evenings of April 17, 18, 19, 20. The electric light will be used to illustrate the lectures.

LIEBIG is to have another monument. A few weeks ago we noted the "inauguration" of one at Darmstadt. Subscriptions are now being collected for the purpose of raising a statue to him in Munich. About 7,000*l.* has already been contributed.

MR. H. W. S. WORSLEY-BENISON, F.L.S., has been appointed Lecturer on Botany at Westminster Hospital.

THE services of Mr. W. Saville Kent, F.L.S., F.Z.S., have been engaged temporarily to superintend and place in thorough order the "Fish House" at the Zoological Society's Gardens, Regent's Park. A considerable number of marine fish and other specimens of interest have been imported to the tanks during the past week.

TWO views have been offered as to the mode of action of the gas in the radiometer. One attributes the motion to reaction of gas particles getting heated on the vanes, then dancing off; the other to air currents which are directed towards the plate in consequence of heated air rising from it. M. Neesen has endeavoured (*Pogg. Ann.*) to decide between these views. If the second view is correct, he argued, the wall of the vessel, by becoming also heated, must also acquire influence through rise of heated air from it as from the vanes. If the rotation be merely a phenomenon of reaction there is no reason to suppose such an influence of the fixed wall. Now by giving the radiometer an eccentric position within the glass vessel such an influence of the walls should be readily recognised. He describes a number of experiments made in this way, and which he regards as supporting the second view.

IN an article contributed to *Poggendorff's Annalen*, M. Zollner is led to take the following positions in reference to the radiometer. The explanation of radiometric motions based on the principles of the mechanical theory of gases, makes suppositions about the relation of the mean lengths of path of the gas molecules to the dimensions of the vessel which are not realised in fact. This explanation further leaves out of consideration, without sufficient ground, the simultaneous existence of mercury vapours whose molecules have a more than seven times greater mass and a much smaller mean length of path than the molecules of the gas acting according to the mechanical theory of gases. Hence we are not warranted in regarding the radiometric motions discovered by Crookes as an empirical confirmation of the mechanical theory of gases.

BERLIN dealers in delicacies have recently received from the south, and especially from Upper Italy, immense quantities of edible birds which have been captured there in their flight northwards. Unfortunately there were not only snipe, fieldfare, and larks, or so-called "delicacies" among the birds sent, but also singing birds, that are never eaten in Germany, such as goldfinch, thrush, and nightingales. The animals were caught on their migratory flight by means of nets, or surprised during the night and indiscriminately killed. A new indication of the importance of an international law for bird protection!

AN exhibition of objects relative to pre-historic archæology will be opened shortly in Moscow, and promises to be very interesting.

AN elaborate volume just published by the Federal Statistical Bureau of Switzerland, gives the number of scientific societies in the country in 1875 as 46, with 54,955 members. The societies for educational purposes numbered 816, with 54,424 members.

THE municipal authorities of Berne have set aside the sum of 14,000*l.* for the foundation of a Museum of Natural History in that city.

ASSOCIATIONS and Committees are being formed in most of the large towns of the Netherlands with the object of "fitting out a suitable vessel for Nova Zembla and other stations of interest in the Arctic regions." The avowed aim of the expedition is not the discovery of the Pole, but the erection of some unpretentious granite monuments to the memory of the glorious discoveries of the earlier Dutch navigators. About the end of the seventeenth century, "in the name and on behalf of the honourable Council of the renowned City of Amsterdam," Willem Barends set out on his third voyage, which ended in the explorer's wintering on Nova Zembla, whence he never returned. It is, above all, the memory of Barends which the Dutch are about to honour. The costs of the expedition are to be defrayed by voluntary subscriptions, and the vessel will, in all probability, be commanded by a Dutch lieutenant who has taken part in three Arctic expeditions under the British flag.

THE Committee of the German African Society has issued an appeal for help towards the establishment of a series of permanent stations in Africa, so as gradually to narrow the area of the unknown country, to serve as centres of culture, and to be depots for information and for trade with the natives. The effort would be in sympathy with that of the International Congress at Brussels, and the appeal is made specially to Germany to maintain the exceptionally high place she has taken in the scientific discovery of Central Africa.

GEOGRAPHICAL students will be glad to learn that an index to Petermann's *Mittheilungen aus Justus Perther's geographischer Anstalt über Wichtige neue Erforschungen auf dem Gesammtgebiete der Geographie* has been published for the period between and including the years 1865 to 1874. The value of this is greatly increased by the publication therewith of index maps, which show at a single glance those parts of the world of which maps have been published in the *Mittheilungen* during the period in question, with references to the places where they have appeared.

GEN. UCHATIUS bases his invention of the steel bronze, or more correctly, hard bronze, cannons, now introduced into the Austrian service, on the observation, that all metals (with exception of lead and zinc) have their elasticity increased, when they have undergone a continuous weighting above their first limit of elasticity. In the first February number of *Dingler's polytechnisches Journal*, M. Uchatius gives, in reply to the objections of some technologists, the results of further experiments, which appear to show that even homogeneous bronze is capable of a great increase of its elasticity through simple stretching, without condensation. It is only a stretching of the metals above their limit of elasticity, whereby the molecules, brought to a state of flow, glide over each other, and assume a wholly new position more favourable to resistance, that causes the increase of elasticity. A simple condensation produces merely an increase of the absolute solidity and diminution of the tenacity, but no real increase of elasticity. The limit of elasticity may be raised nearly to the breaking consistence, so that in many cases it is six and seven times the original. Mere stretching for a short time is of little use; the tension must act a considerable time. It is also well to apply a gradually increasing weight.

A SINGULAR fact with reference to the production of heat is described by M. Olivier (*Comptes Rendus*). A square bar of steel 15 mm. in width and 70 to 80 ctm. long is seized with the two hands, placed, one at one end, the other in the middle of the bar. The other end is pressed against an emery grind-stone rotating rapidly. In a few minutes the rubbed end is considerably heated. The band at the middle has no sensation of heat, but that at the extremity is strongly heated, so that it has to be taken from the bar. Thus, in certain cases, heat appears not to be propagated in metals from one part to that next it.

IN the year 1824 M. Wohler made the observation that palladium, whether in the form of sponge or of polished sheet, has the property of becoming sooty in a spirit flame, and gradually coated with a thick layer of carbon. A piece of spongy palladium will thus be enlarged to several times its original volume. The same phenomenon occurs if the metal is made to glow in a coal-gas flame. If the deposited carbon be burnt, there remains always a fine skeleton of palladium, which is then found to be penetrated with the carbon and quite brittle. By more recent experiments M. Wöhler convinced himself that the phenomenon is not due to a special affinity of palladium for carbon. He is rather of opinion that the strong absorption power of this metal for hydrogen is the reason why ethylene gas and the gases of the spirit flame, which themselves are not absorbed by palladium, are decomposed under the influence of this metal, as the experiments show, with separation of carbon.

LED by speculative considerations regarding the formation of the earth, M. Sacher, of Salzburg, made experiments a short time ago on the solidification of balls of spermaceti floating freely in a liquid, and he has more recently experimented on the propagation of heat in unequally dense liquids. In a beaker glass, 16 ctm. high, he put five layers of alcohol varying in density from 0·98 to 0·82, and each 3 ctm. thickness. Three thermometers were placed with their bulbs in the first, third, and fifth layers respectively, and the vessel was slowly heated from below. In another similar vessel containing liquid all of the same density, the three thermometers showed nearly the same temperature;

but in the stratified liquid marked differences appeared between the layers on readings being taken every five minutes. Thus in ten minutes the readings were 31° (below), 18·5° (middle), 18° (top); after twenty minutes, 44°, 19·5°, 18°; after fifty-five minutes, 77°, 40°, 21°. The numbers prove, then, that in liquids of decreasing density heat is distributed very slowly from below upwards. Experiments in cooling led to a similar result.

PROF. QUINCKE, of Heidelberg, has long experimented as to whether gases can penetrate through the pores of glass. A pressure of forty to one hundred and twenty atmospheres is found to be incapable of forcing a perceptible quantity of carbonic acid or hydrogen gas through a glass wall 1·5 mm. thickness, during a period of seventeen years. No loss of weight was perceptible. M. Quincke, however, will not draw the inference that the molecules of hydrogen and carbonic acid have larger dimensions than the molecules or pores of the glass. The distance at which the molecular forces of the glass act on the gas-particles is of course greater than the dimensions of the molecules themselves. The pore walls of the glass may get coated with an "absorbed" gas layer, which itself becomes immovable through the nearness of the solid substance, and hinders the passage of gas particles from the interior of the glass tube into the outer air. Perhaps, too, there may be dropable liquid in the pores of the glass, preventing outflow of the gas. A similar objection applies (according to M. Quincke) to M. Traube's method of determining the size of the molecules of a substance from the possibility of passing through a so-called "precipitate-membrane."

A DROUGHT in excess of any that have occurred during the last fourteen years, as regards long continuance and severity, has prevailed for some months in Victoria and parts of Australia adjoining. It terminated about February 12, and from that date to the 22nd of the same month, when the mail left, heavy thunderstorms and rainfall had prevailed, and cooler weather set in. The reports from Deniliquin and other places in the interior state that not a blade of grass was to be seen on the plains, and cattle were dying in thousands.

THE Russian Naval Department proposes to send a ship this summer to the mouths of the Obi and Jenissei to make a thorough maritime survey of both gulfs.

THE *Western Review of Science and Industry* is the title of a new monthly devoted to various departments of science, and published in Kansas City, Mo.

IN view of the promising future of the African continent M. Bernardin, of Ghent, has done a good service by publishing a *brochure* (compiled from the works of various travellers), on the commercial products of Central Africa. An excellent map of Petermann's, showing the standpoint reached by exploration up to September, 1876, is included in the pamphlet.

THE death is announced of Prof. P. Panceri, the eminent Italian anatomist. He died suddenly whilst lecturing in the University at Naples.

THE additions to the Zoological Society's Gardens during the past week include a Common Wolf (*Canis lupus*) European, presented by Mr. J. A. Parlet; a Ceylon Fish Owl (*Ketupa ceylonensis*) from Ceylon, presented by Capt. B. B. Turner; a Vulpine Phalanger (*Phalangista vulpina*) from Australia, presented by Mr. W. Bazeley; two Sykes's Hemipodes (*Turnix sykesii*), a Rain Quail (*Coturnix coromandelica*), an Asiatic Quail (*Perdicula asiatica*) from India, three Chinese Quails (*Coturnix chinensis*) from China, presented by Mrs. Wood Mason; an Entellus Monkey (*Semnopithecus entellus*) from India, received in exchange; a Collared Fruit Bat (*Cynonycteris collaris*) born in the Gardens.

SOCIETIES AND ACADEMIES

LONDON

Chemical Society, April 5.—Prof. Odling, F.R.S., in the chair.—A lecture on the discrimination of crystals by their optical characters was delivered by Prof. N. S. Maskelyne, F.R.S. After a few general remarks on the use, to the chemist, of the methods employed by crystallographers, the lecturer proceeded to consider the methods of determining the symmetry of crystals by their optical characters. The origin and meaning of various terms used in crystallography were explained and illustrated by models, &c.; the lecturer then threw on the screen, by means of a polarising apparatus and the electric light, the beautiful coloured effects produced by crystals of cerussite, barytes, borax, &c., the effect of heat in altering the position of the optical axes of a crystal of gypsum being especially beautiful. In conclusion, the lecturer pointed out the ready means, which the examination of the optical characters of a crystal under the polarising microscope often afforded to the chemist, of acquiring a great deal of information in a very short time, and expressed a belief, that if chemists would work up suitable groups of crystals for examination by the crystallographer, very important knowledge as to the functions of various groups of molecules in a crystal would be gained.

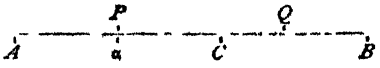
Anthropological Institute, March 27.—Col. A. Lane Fox, F.R.S., V.P., in the chair.—Capt. W. Samuells, of the Bengal Staff Corps, was elected a member.—An account of some Kitchen Middens near Ventnor, by Mr. Hodder M. Westropp was read by the director. A corn-crusher, of Scandinavian appearance, was found in one of them, and in another higher up in the cliff, there was discovered a small cinerary urn of unusual shape encircled with a pattern of coralline sea-weed.—Messrs. W. Power and E. Laws communicated a short paper on a Kitchen Midden near Tenby; Dr. Crockley Clapham a paper on the brain-weights of the Chinese and Pelew Islanders; and Mr. James Shaw some notes on right-handedness and improved instinct in animals during the human period. Dr. Clapham found that the weight of the brain both of the Chinese and the Islanders was above the average, but they presented certain peculiarities in their convolutions, The skulls of the Pelew Islanders were markedly dolichocephalic. The size of the brain of the Chinese and the Islanders was in no wise an index of the intelligence possessed by them.

MANCHESTER

Literary and Philosophical Society, February 6.—E. W. Binney, F.R.S., president, in the chair.—Notice of the Junior Literary and Philosophical Society of Manchester, 1806-1807, by W. E. A. Axon, M.R.S.L.—On compound combinations, by Prof. Cayley, F.R.S., &c.—On ternary differential equations, by Robert Rawson.—On the powerful oxidising action of animal charcoal upon organic matters as shown by the analysis of the drainage from a large heap of a mixture of night-soil and animal charcoal, by William Thomson, F.R.S. Edin.—A plea for the word "Anglo-Saxon," by Rooke Pennington, LL.B., F.G.S.

CAMBRIDGE

Philosophical Society, March 12.—Prof. Cayley, vice-president, in the chair.—Prof. Clerk Maxwell communicated to the Society a paradox in the theory of attraction.



Let the line AB be divided in any given point C, and let

$$PC^{-1} - AC^{-1} = CQ^{-1} - CB^{-1}$$

be the condition of correspondence of two points P and Q, in the segments AC, CB respectively, then if P and Q vary simultaneously, still remaining correspondent,

$$PC^{-2}d(PC) = CQ^{-2}d(CQ),$$

or the corresponding elements are to each other as the squares of their distances from C. If we now suppose that AB is a material line of uniform density, the law of attraction being the inverse square of the distance, the attractions of corresponding elements on the point C will be equal and opposite. But every element of AC has a corresponding element in CB, and hence we might conclude that the attraction of AC on C is equal and opposite to that of CB on C, which is evidently not the case, unless $AC = CB$. The paradox is explained by considering that all that we have proved is that the attraction of AP on C is equal and opposite to that of QB on C, and this however near to C the corresponding points *P* and *Q* are taken, and this is strictly true. But however near to *C* the corresponding points are taken, the attractions of *PC* and of *CQ* are both infinite, but differ by a constant quantity, namely the attraction of *Aa* on *C*, where *aC* is taken equal to *CB*.—Prof. Clerk Maxwell also made a communication on double and triple integration by summation.—Mr. J. W. L. Glaisher gave a preliminary account of the results of an enumeration of the primes in Burckhardt's tables (1 to 3,000,000).

Paris

Academy of Sciences, April 2.—M. Peligot in the chair.—The following papers were read:—Isoperimetric triangles having one side of constant length and satisfying three other conditions, by M. Chasles.—On a theorem relative to expansion of vapours without external work (continued), by M. Hirn.—Report on a new work of M. Bertin, following his note on rolling. This work gives an account of M. Bertin's double oscillograph, which records each instant the inclinations of the ship in the direction of the rolling and the inclination of the part of the wave which carries the ship; also observations with it from the war-ship *Crocodile.* Though the indications are only approximate, they are thought of considerable interest. Admiral Paris called to mind an instrument devised by his son in 1867, for tracing waves.—Experimental researches on natural sulphides, by M. Meunier. It is a general fact that natural sulphides brought into the presence of suitable metallic solutions cause reduction in the free state of the dissolved metal. The experimental facts given seem to have a bearing on the *mineralogical associations* so frequent in metalliferous veins. If a vein of galena receive the infiltrations of sea-water (which always contains silver), all the silver will be held and concentrated by the sulphide. Now native silver exists in a certain number of galenas, and we may suppose it has been thus introduced.—New nebulæ discovered and observed at the Observatory of Marseilles, by M. Stephan. Thirty in number.—On the approximation of a class of transcendants which comprise, as a particular case, hyperelliptic integrals, by M. Laguerre.—On the paraboloid of eight straight lines, by M. Mannheim.—On the theory of frigorific machines, by M. Terquem. Even under the best conditions, frigorific air-machines cannot successfully compete with machines having volatile liquid, (1) because of the large size necessary, (2) the passive resistances due to this, and the use of two pumping bodies; and (3) the want of adaptability to produce different degrees of refrigeration. Their advantages are the production of lower temperatures, simplicity, and the use of a safe and cheap agent.—Researches on the metallic reflection of obscure and polarised calorific rays, by M. Mouton.—On the sulphide of manganese, by MM. De Clermont and Guiot. They produce the green sulphide in new cases, and by reactions in which its formation was said never to have been observed. Thus M. Muck says it is impossible to transform manganous carbonate into green sulphide; but the authors effect this by heating in free air, with ebullition, carbonate of manganese, precipitated with some sulphydrate of ammonia. They find the rose sulphide dried at 105° contains 9 per cent. of water (green sulphide at 105° is anhydrous). The rose sulphide is much more soluble in chlorhydrate of ammonia. These sulphides are thought isomeric modifications of one and the same body, more or less hydrated.—Reply to remarks of M. Chevreul concerning the phosphorescence of organic bodies, by M. Radziszewski. He adduces some facts showing that in phosphorescence the slowness of the reaction is an essential condition, though to define the maximum and minimum limits would be difficult at present.—Two cases of aneurism of the bend of the elbow treated successfully with the antiseptic ligature of catgut, by M. Boeckel.—On some abnormal fecundations in star fish, by M. Fol.—On the distribution of carbonic acid of the blood between the red corpuscles and the serum, by M. Fredericq. It is generally said that all or nearly all the carbonic acid held in the blood is in the serum (or plasma) in the state of combination or solution. Examining venous horse-blood, the author found the red corpuscles capable of absorbing a considerable quantity of CO_2, though always less than that taken by an equal volume of serum (about a half less). Passing a current of CO_2 through the blood, the excess seemed to be distributed equally between the corpuscles and the serum. While blood can be almost directly deprived of its gases by vacuum and heat; it is quite otherwise with serum, which, after such treatment, will give a fresh liberation of CO_2, when treated with phosphoric acid newly boiled. This invalidates some of MM. Mathieu and Urbain's results.—On the *rôle* of stomates and cuticular respiration, by M. Barthélemy. He thinks M. Merget's recent experiments overlook the most important factor in the case, viz., the living being submitted to experiment, the leaves having been detached from the plant and submitted to various vapours.—Observations of globular lightning formed and bursting without sound above a layer of clouds, by M. Blanc. The apparent diameter of the balls at 18 k. distance was 1°; they were reddish or yellow, but always white on bursting; they went horizontally, and looked like immense soap bubbles.

Vienna

Imperial Academy of Sciences, March 1.—The following among other papers were read:—Main outlines of a theory of the sense of temperature, by M. Herzog.—Researches on the Tunicata of the Adriatic and the Mediterranean, by M. Heller. The freely-moving Salpæ and Salpæ-like Ascidians, which are numerous in the Mediterranean, are almost wholly wanting in the Adriatic.—On normal hexylic alcohol and normal œnanthylic acid, by M. Janecek.—Researches on the extension of the tonic vascular nerve-centres in the spinal cord of the dog, by M. Stricker.—The development of the antheridium of *Anthoceros*, by M. Waldner.—On Ranvier's representation of bone-structure, with remarks on the use of a Nicol in microscopic researches, by M. Ebner.—On metanitro- and metamido-benzacetylic acid; on the action of animal charcoal on salts; on solution of sulphur in acetic acid; and on demonstration of fuchsine in wine, by Dr. Liebermann. Fuchsine solutions give very characteristic absorption bands, in the spectrum, between yellow and green. Fuchsine may be detected even with a dilution of 1 : 500,000.—Note on molecular transformations, by M. v. Sonstorff. Iodine crystals kept eight years in a glass vessel were found to grow by volatilisation and subsequent condensation. Amorphous phosphorus passed, in part, into the crystalline state.—On the origin of the zodiacal light, by M. Noe.—Behaviour of calcium-phosphate towards sugar solutions, by M. Krasan.—On new Rudista from the Bohemian chalk formation, by M. Teller.—On the Sarmatian deposits between the Danube and the Timok, by M. Toula.—Researches on the etiology of Pelorian flower-forms, by M. Peyritsch.—On a new method of determining the internal resistance of galvanic batteries, by M. Fleischl. The two like poles of two equal elements (of the kind to be measured) are connected, and the resistance of this currentless combination is then compared with a known resistance.—On the geological character of the Isthmus of Suez; the pliocene formations of Zante and Corfu, the nature of the Sarmatian formation and its analogies in the present and in earlier geological epochs, by M. Fuchs. The fauna of the Red Sea and Mediterranean are very different, but they appear to have been so also before the isthmus arose.

AGRICULTURE IN THE UNITED STATES

Report of the Commissioners of Agriculture of the United States of America for the Year 1875. (Washington, Government Printing Office.)

THE first impression that strikes us upon taking up this substantial volume is closely allied to envy. Here is a fund of valuable and condensed information relating to every point connected with the development of the soil's resources, a record of original work and of experience at home, and abounding in suggestions from the practices of other countries. It is true we have to some extent, in the excellent transactions of our great agricultural societies, a means of presenting a digest of agricultural progress. But these are, and must to some extent be, written in popular style, whereas the Report before us, while deeply interesting, is essentially business-like and proportionally more useful to those whom it concerns.

It may be thought by many that a new country, of boundless extent like America, can scarcely have advanced to a stage in agricultural progress demanding the assistance of science; that the breaking up of virgin tracts by adventurous settlers is scarcely an occupation to elicit sympathy on the part of the workers in microscopic examinations and chemical analyses. Such is, however, not the case. "Farmers and planters," we are told, "now realise that there is something else in this important work beyond the mere drudgery of sowing, reaping, and curing;" and again, "the general awakening of interest in agricultural subjects has induced a considerable correspondence with the botanical division," as well as with the chemical and other departments.

The Report of the Commissioners includes those of the statistician, the entomologist, and the chemist; and besides these departments, details are given of the labours of the Horticultural, Botanical, Seed, and Microscopic Sections. The report of the statistician reveals the immense extent of cultivated land in the United States. Close upon 45,000,000 acres of maize, producing 1,321,000,000 bushels of corn account for the cheap rate at which this commodity has recently been offered in this country. The vast area of 26,381,512 acres of wheat producing, in 1875, 292,000,000 bushels, also throws light upon some of the difficulties of competition which now perplex the English wheat-grower. Here is a supply of wheat capable of feeding 53,000,000 human beings for one year, and, to put it in another light, grown upon eight times the area devoted to this purpose in Great Britain. The total population of the States is 38,115,641, so that they not only are able to feed themselves, but to export a sufficient amount to maintain the population of Great Britain nearly half a year.

The report of the Entomologist upon *Heteroptera* or "plant-bugs," contains a large number of illustrations and short descriptions of many species, some of which are injurious, while others, owing to their carnivorous tendencies, are beneficial. This information is followed with practical directions for coping with insect pests, which, if not novel, are at least useful. In the chemical section the effect produced by various mineral substances upon growing vegetables when added to the soil have been demonstrated by Mr. Abram McMurtrie. The deleterious effect of arsenical compounds has been tested upon plants grown in pots, and the results are vividly brought before the reader by illustrations showing the comparative sizes attained by the plants experimented on. The agriculturist is not as interested in substances detrimental to plant life as in those which produce an opposite effect. The lesson taught by such experiments is, however, exceedingly useful, for there is, no doubt, great room for experiments upon growing plants so placed that the surrounding conditions of soil, air, and water may be regulated with a special purpose in view.

A considerable section in the middle of the volume is occupied with an account of the sheep exhibited in the Vienna Exhibition of 1873. The information is no doubt highly useful, as it gives the American reader a graphic idea of the various breeds of English and Continental races of sheep. The ample details regarding the Merino sheep are chiefly taken without acknowledgment from a report contributed by Prof. Wrightson to the Journal of the English Agricultural Society, and are therefore familiar to English readers.

After 150 pages upon "Statistics of Forestry" and varieties of fruit, there is an interesting account of the method of curing forage by *ensilage*. This process consists in burying green fodder in pits (*silos*) or trenches, and covering it with earth. The process is applied to green maize, rye, rye-grass, rape, red clover, and autumnal vetches. It is impossible in a short notice like the present, to give a description of the method pursued, but there is no doubt that it is practicable. M. Crevat, after several years' trial, has settled upon pits of the following dimensions. Depth 7·55 feet, length 28·25 feet at the surface of the ground, sloping down to 24·28 feet on the bottom; breadth 8·53 feet at the top, and 6·56 feet at the bottom. Each pit has a capacity of about 1,412¾ cubic feet, and appears capable of holding about 10½ tons of green fodder. There appear to be many modifications of the process, some farmers partially drying the fodder before pitting it, while others prefer pitting it fresh. Contrary as this may appear to our usual system of carefully drying hay before carting it, the general adoption of this method of storing fodder in many continental countries proves that green fodder may be preserved if firmly trodden down so as to exclude the air. The same plan succeeds admirably with sugar-beet pulp which may be kept in pits for any length of time. English farmers preserve brewers' grains by trampling them firmly into large vats, and, at the same time, sprinkling salt among them. Salt is also frequently employed in the process of *ensilage*, or making sour hay, but as often the process is completed without its assistance. The report of the Commissioner certainly throws light upon the subject, which we think deserves the attention of English agriculturists, and especially of colonists.

The general interest in scientific agriculture is remarkably evinced in America by the large number of agricultural colleges. There are no fewer than thirty-nine agricultural and mechanical colleges attended by 3,703 students and taught by 463 professors. When it is remembered that the total population of the States is only fractionally larger than our own, the fact of the existence of nearly 4,000 agricultural students is somewhat startling. In this country we have one agricultural college supported by less than 100 students. Yet we are the possessors of the most extensive colonies in the world, far exceeding, in extent, even the vast area of the United States. It may well be difficult for English agriculturists to compete with foreign rivals if the meagre number of agricultural students in England compared with America may be taken as in any degree a gauge by which interest in scientific progress may be measured.

CUMMING'S THEORY OF ELECTRICITY

An Introduction to the Theory of Electricity. By Linnæus Cumming, M.A. (London: Macmillan and Co., 1876.)

MR. CUMMING deserves our thanks for having made an effort to introduce into elementary teaching the advances in the treatment of electricity made chiefly by the labours of Green, Thomson, and Clerk-Maxwell. Mr. Cumming possesses all the qualifications necessary for such a task. He evidently has a full knowledge of the subject, and seems to possess, in addition, experience as a teacher. He has had, no doubt, great difficulties to encounter. These difficulties are not alone due to the limitations as to the mathematicial knowledge of his readers, which Mr. Cumming has justly imposed on himself. The books and papers out of which Mr. Cumming had to take his material, were written from various points of view, and they were chiefly addressed by scientific men to scientific men. It was natural that the same words should not be always used exactly in the same sense, the great object being that men already possessing a knowledge of the subject should understand each other. It is only when the knowledge of a certain subject is comparatively advanced that the terms settle down into a definite meaning. A text book, on the other hand, is addressed to students who at the most have only a slight acquaintance with the subject, and it should not only teach that particular subject, but also scientific method, and scientific reasoning. It is, therefore, of primary importance that the precise meaning of the term should be scrupulously adhered to. Even a good definition does not always ensure this, for there is often a metaphysical colouring which does not come out in the definition, but which we soon discover in the way a term is used. We take one example. The word potential is defined by Sir Wm. Thomson thus:—

"The potential at a point is the work which would be done on a unit of positive electricity by the electric forces if it were placed at that point without disturbing the electric distribution, and carried from that point to an infinite distance."

Nothing could be more precise than this, yet the word potential will call forth different associations in different minds, and this will greatly influence the way in which the word is used. Some writers will attach no meaning to the potential at a point, except in so far as they can imagine an electrified particle to be placed at that point, to others the expression will convey a perfectly definite meaning, defining the state of the medium at that point, irrespective of any electrified particle which might be placed there. It will generally be soon found out in what sense the writer uses the word.

The passage in Mr. Cumming's book which has suggested these remarks, is contained in Prop. 8, p. 203. The proposition runs thus:—

"In computing the potential of any closed circuit, we may substitute for it any closed circuit which is obtained by projecting the given circuit by means of lines of force."

The expression potential of a circuit may perhaps have sometimes been used for the induction or number of lines of force through a circuit; yet we imagine the term suggests rather the idea of action at a distance, and would be analogous to substituting in electro statics the expression "potential *of* a point" for that generally used—"potential *at* a point." Mr. Cumming has so consistently adopted the views and language of Faraday and Clerk-Maxwell, that we have been struck rather unpleasantly by the passage. This is, perhaps, only a matter of detail, and we may here remark that Mr. Cumming might with advantage have bestowed more care on the wording of his propositions. On p. 40, for instance, an experimental law is given, and two exceptions are added. With very little trouble the law might have been worded so as to admit of no exceptions. Other examples might be given.

There is one feature in the book about which we should like to make a few remarks. An occasional allusion to hypothetical matters cannot of course be altogether avoided, yet we think that in books like Mr. Cumming's, which are intended to give an outline of what is known, and not of what is unknown, of the subject, such allusions should be reduced to a minimum.

On p. 119 five propositions are given on molecules and atoms, which are not alluded to throughout the book except in the following passage:—

"From the last statement it can be easily seen that when the molecules of two different solids impinge on each other, as at the surface of contact, they cannot accommodate themselves to each other's motion, but constrain each other, this constraint producing a loss of energy. If, however, the two solids are of the same kind and at the same temperature, the molecules on each side of the surface of contact are swinging in exactly the same manner, and can easily accommodate themselves to each other's motion without more constraint than exists in the solid part of either body. It is this loss of energy owing to the unsymmetrical swinging of the molecules at the surface of contact which reappears as difference of potential between the two solids, or as the energy of electrical separation.

"The opposed electricities so separated will, for the most part, be heaped up on either side of the plane of separation by a Leyden jar action."

In the same chapter Mr. Cumming gives his opinion on the theory of the voltaic cell and electrolysis in general. We are told how we might imagine the atoms and molecules to be placed; we are told about polarisation; but Faraday's laws are not even alluded to.

It would, of course, be an advantage to science if Mr. Cumming were to take an active part in the theoretical and experimental investigation of the subject; yet we doubt whether a text-book on the theory of electricity is the best place to bring his views forward, especially if they are in contradiction to the best experiments we have on the subject (Sir William Thomson's). A teacher ought to be spared as much as possible from having to tell his students that he does not agree with the writer of a text-book.

The parts of Mr. Cumming's book which we have ventured to criticise refer chiefly to matters of taste. There is no doubt that in the hands of a good teacher the book will prove very useful. We hope that it will have a wide circulation, and that a second edition will soon enable Mr. Cumming to introduce such improvements as on a reperusal of his own book may occur to him.

ARTHUR SCHUSTER

OUR BOOK SHELF

Proceedings of the London Mathematical Society, vol. vii. November, 1875, to November, 1876. (London: Messrs. Hodgson and Son, Gough Square.)

IN the present volume we have about thirty communications made by eighteen writers. Prof. Cayley writes on Three-bar Motion (treating the matter in a different way from that in which it is handled in this same volume by Mr. S. Roberts, the priority of whose results is conceded by Mr. Cayley) on the Bicursal Sextic; Prof. H. J. S. Smith contributes short papers on the value of a certain Arithmetical Determinant and a Note on the Theory of the Pellian Equation; Lord Rayleigh has a note on the Approximate Solution of certain Potential Problems; Mr. Spottiswoode writes on Determinants of Alternate Numbers, working out some suggestions of Prof. Clifford. This last-named gentleman contributes the transformation of Elliptic Functions with a Note, and Free Motion under no Forces of a Rigid System in an *n*-fold Homaloid.

In Analysis, there are further papers by Mr. J. W. L. Glaisher on an Elliptic Function Identity, and the Summation of the Geometrical Series of the *n*th Order as a Definite Integral; Prof. Lloyd Tanner on the Solution of Certain Partial Differential Equations of the Second Order (two papers); Mr. J. Hammond on the Relation between Bernouilli's Numbers and the Binomial Coefficients, and on the Mean of the Products of the Different Terms of a Series; Mr. T. Muir on the Transformation of Gauss's Hypergeometric Series into a Continued Fraction; Mr. S. Roberts a Further Note on the Motion of a Plane under Certain Conditions; Mr. Hewitt on a Theorem of Eisenstein's.

Under the heading of Geometry we may class Prof. Rudolf Sturm's paper on Correlative Pencils; Mr. A. B. Kempe's General Method of describing Plane Curves of the *n*th Degree by Linkwork; Prof. Wolstenholme's Loci Connected with the Rectangular Hyperbola.

There are a few shorter communications. We have said enough to give our mathematical readers an idea of the range of subjects treated in this volume. The names of the authors are a sufficient guarantee that the subjects are ably treated and brought down to the latest accepted results.

A Primer of Chemistry, including Analysis. By Arthur Vacher. (London: J. and A. Churchill, 1877.)

THIS little book attempts to present within the limits of a hundred pages "a general view of the elements of inorganic chemistry." It embodies the experience gained by the author during ten years in which he has been engaged in teaching the subject, and the result is that many points are treated in somewhat novel fashion. The subject is considered as fully as could be expected within the narrow limits mentioned, and the amount of information conveyed is really considerable and generally accurate.

The first sixty-seven pages contain chapters on "Experiments with some of the Elements," "The Use of Symbols" in formulæ, equations, and calculations, "Experiments with some Compounds," "Weights and Measures," "Classification of Compounds," and "List of Substances." The remaining thirty pages or so are devoted to Qualitative Analysis.

Perhaps the greatest novelty introduced is the use of the term *unit* instead of atomic or combining weight, so as to avoid using the terms *atom* and *molecule*, which the author thinks are "unsuitable for ordinary use among beginners;" and of *antimetal* instead of *radicle* (which latter by the way he incorrectly writes "radical"). It may be questioned whether the use of the term "unit" may not interfere with the conception of the meanings to be attached to "atom" and "molecule," which the pupil must gain afterwards. "Antimetal" is objectionable since all radicles are not antimetals; ammonium, for example, is a radicle which plays the part of a metal. Clearly the term is intended as equivalent to "acid radicle," or acid minus its basic hydrogen; it is never used in any other sense in the book, and its use with this restricted meaning may be advantageous, or at least free from objection.

Several items may be pointed out as requiring alteration or improvement; notably the following: that "a *compound*[1] is any substance which is not an element" (p. 11); that chlorine has a "*pale green* colour" (pp. 6 and 61); that oxygen is *insoluble* in water (pp. 39 and 56); and that $KMnO_4$ gives a *red* solution (p. 64). In working with test-tubes the student is several times directed to add "half an inch" of acid or water as the case may be. Of course it is evident what is meant, but test-tubes are of various sizes, and a large excess of acid or other liquid would be used if the directions were followed exactly with large tubes. On p. 77, "take the charcoal quickly to your nose" is another rather curious direction.

The analytical part of the book is the best; the tables throughout being reliable. The detection and separation of cobalt and nickel (Table III., p. 95) might be effected more quickly and easily by other methods than that given; and on p. 87, NO_3 as well as CrO_4 and Fe''' should be mentioned as decomposing H_2S. If these and several other minor improvements be made the "primer" will not be without value in imparting the rudiments of education in chemistry; and in these days when elementary text-books are becoming so numerous, may fairly count on being appreciated as it deserves by the class of students for whom it is intended.

W. H. W.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*]

Hibernation of Birds

IN NATURE (vol. xv., p. 465) there is a review of "Palmén on the Migration of Birds," and in the course of it the reviewer takes occasion to refer to what he calls the "hibernation mania" as one that is now and again revived, in spite of the fact that the migration of birds is fully proved, and that no evidence at first hand has ever been produced in favour of the supposition that birds ever lie dormant.

Having frequently heard my brother-in-law, Sir John McNeill, relate a circumstance which occurred to himself proving that swallows do occasionally lie dormant, I wrote to him asking him for the particulars. I now inclose his reply, which perhaps you will publish, as it may possibly elicit other evidence on the same matter.

Gilbert White's conviction that swallows do occasionally lie dormant in this country, was mainly founded on the fact that instances are not uncommon of swallows appearing suddenly during warm sunny days in winter, and again disappearing on the return of cold. This fact it is certainly very difficult to account for on any other supposition. ARGYLL

---

[1] A *chemical* compound being meant as is evident from the context.

Argyll Lodge, Kensington, April 11

"In your letter received last night you tell me of an article in NATURE the author of which seems to deny that swallows ever hibernate, and asserts that no one has yet testified to the fact from his own personal observation. That, however, is a mistake, for I have stated and I now repeat that I have seen swallows in large numbers hibernating. The circumstances were these:—

"About twenty-five miles south of Teheran, the capital of Persia, there is a village called Kenara-gird near which is a stream of brackish water running in a deep bed with nearly perpendicular banks some forty or fifty feet high. Being largely impregnated with salt this stream is rarely if ever frozen, and in frosty weather is resorted to by flights of wild ducks. During a frost of unusual severity I went from Teheran to Kenara-gird, accompanied by Sir Henry Rawlinson, for the purpose of duck-shooting, the severity of the frost promising good sport. Having slept at the village we next morning followed the downward course of the stream along the north bank, and had proceeded about a mile, I should think, when we came to a place where there had quite recently been a small land-slip. The brink of the bank to the extent of perhaps twenty feet in length, and ten or twelve broad in the middle, tapering off to each end, had slipped, but had not fallen down the bank. Between this detached portion and the perpendicular face about ten feet high, from which it had broken off, we saw, to our great surprise, a number of swallows, not less, I am sure, than twenty or thirty, lying, as I at first supposed, dead, but on taking up one of them I found that it was alive but dormant; it was warm and its breathing was quite perceptible. I examined a considerable number, and found that they were all alive and breathing, but none of them gave any sign of consciousness. My attention was then attracted to the perpendicular face on our left, from which the slip had broken off, and which was perforated by a vast number of holes each about the size of a rat-hole On looking into such of these as I was tall enough to see into, I found in all of them swallows in the same dormant state. I was able with finger and thumb to pull out swallows from several of these holes, and in each case found that the hole which penetrated horizontally a considerable way into the bank, contained more swallows in the same condition. In no case did I see one lying on another—they were all lying singly with their heads inwards, each head touching the tail of the bird before it How far these holes penetrated into the bank, or what number of swallows each contained I did not ascertain, but it is plain that the original entrance to these dormitories, must have been in the external face of the portion that had slipped, which as I have stated, was, in the middle, from ten to twelve feet thick The holes in the undisturbed portion may probably have been of equal or greater length, and if so the number of swallows hibernating there must have amounted to many hundreds."

Villa Poralto, Cannes, April 6

The Swallows and Cuckoo at Menton

THE swallow that arrived here on March 19 remained solitary until April 5. Early that morning a second arrived and entered the same room as the first. I saw them flying about together in the forenoon, and these two remain the only feathered occupants of that chamber In the afternoon of the same day, however, a party of ten arrived and distributed themselves, among the houses.

Madame Valetta, of whom I spoke in my previous letter (NATURE, vol xv., p 488), assures me that not during the last fifty years has one swallow preceded its fellows by so long an interval as this year; but perhaps it is only that her attention has not been drawn so much to the subject. It is certain, however, that unless more are yet to come, the swallows are this year fewer than ordinary by more than one-half. The opinion of the natives is that they have perished at sea.

I heard the cuckoo for the first time this year on April 1. But a lady had told me that she had heard it nearly a week before. DOUGLAS A. SPALDING

Cabrolles, près de Menton, France, April 13

Greenwich as a Meteorological Observatory

THE facts of observation appealed to by Mr. Eaton with the view of proving that Greenwich is, from artificial causes, more than half a degree warmer than the south-east of England generally, and is therefore not a suitable place for a meteorological observatory of the first order, evidently call for a closer critical examination than they have yet received. If from the sixteen stations within a radius of sixty miles from the metropolis given in the paper on "The Temperature of the British Islands," we omit those which are clearly inadmissible for the comparison with Greenwich owing to their position or to the short time during which observations were made, there remain the following eight stations as suitable for comparison:—Cardington, 52° 7′ lat. N.; Royston, 52° 2′; Colchester, 51° 53′; Hartwell, 51° 49; Oxford, 51° 46′; Great Berkhamstead, 51° 45′; Chatham, 51° 23′; and Aldershot, 51° 15′. The mean temperature of these eight stations, allowing for elevation, is 50°·6, and the mean temperature of Greenwich, 51°·1, results substantially agreeing with those given by Mr. Eaton

It is necessary, however, to observe that the mean position of these places does not agree with that of Greenwich. Thus while the latitude of Greenwich is 51° 28′ north, the mean latitude of the eight stations is 51° 45′, or 0° 17′ farther north, their true mean position being about two miles due north of St. Albans For this difference in latitude a correction of fully 0°·2 is required, judging from the position of the isothermal lines. The figures then stand thus: mean temperature of Greenwich, 51°·1; of the eight stations, 50° 8. On comparing the monthly means of the eight stations with those of Greenwich, it is seen that the residual excess of Greenwich is all but wholly occasioned by the high mean temperatures of June, July, August, and September, which are in each case 0°·9 higher than the means of the eight stations, these eight stations being nearly all outside or on the outskirts of the patch of high temperature around London during the summer months. It follows that the 0°·3 of excess of annual temperature at Greenwich over the eight stations is accounted for by the higher temperature of four out of the twelve months, and consequently cannot be due to artificial sources of heat in London, such as the consumption of fuel.

When drawing the isothermals of the British Islands seven years ago, no district of Great Britain occasioned so much trouble and uncertainty as the south-east of England, owing to the meagreness of the materials available for the purpose Since, however, immediately to westward, the mean temperature of Oxford was seen to be 50°·4, Aldershot 51°·2, and Osborne 51°·8, it was inferred as the most probable state of the case that the mean temperature increased southwards over the south-east of England in the manner indicated by the annual isothermals accompanying the paper. This supposition was confirmed by the temperatures at Colchester and Chatham, the only two stations furnishing satisfactory data on the point, for while at Colchester, for instance, the mean temperature was 0° 5 lower than that of Greenwich, no less than 0°·4 of this difference was due to the lower temperature of the east coast at Colchester as compared with Greenwich during the five months beginning with December, when the temperature in the south of England increases from east to west.

The coast stations of the Channel could not be considered as furnishing authoritative evidence on the question, owing to the irregular distribution of their temperature, which seemed to indicate certain obscure and ill-understood causes in operation modifying the climates of that coast. The force of this remark will be apparent from the following mean temperatures:—Helston, 53° 9; Truro, 52° 2; Torquay, 51° 6; Sidmouth, 51°·1; Bournemouth, 51°·5; Ventnor, 52°·4; and Worthing and Eastbourne, both 50°·7. It is perhaps scarcely necessary to remark that it would be a mistake to attempt to draw any conclusion from differences of mean temperatures of different stations amounting to 0°·3 and under, seeing that the English observations generally were made with thermometers in protecting-boxes quite open on one side, and therefore exposed in varying degrees to indirect radiation from walls and other objects.

While Mr. Eaton has thus failed to prove from past observations that the consumption of fuel and the massing together of living beings in London has raised the mean temperature at Greenwich Observatory to the extent of half a degree, or indeed to any appreciable extent, above that of the south-east of England generally, it might nevertheless be well, seeing the question has been raised, to do something towards definitely answering it, by instituting at Greenwich and at about a dozen stations distributed over the south-east of England, observations of the temperature of the air, strict uniformity being secured by employing the same pattern of thermometer-box and by placing it under the same conditions at each place as regards height above the ground, the vegetable covering of the soil, and openness of situation. ALEXANDER BUCHAN

Edinburgh, April 9

THERE is one consideration which your correspondents, the secretary of the Scottish, and the president of the British Meteorological Societies have equally overlooked, and which may seriously affect the conclusions at which they arrive as to the suitability of Greenwich for a first-class meteorological station. Since the year 1846 the temperature observations at Greenwich have been made under conditions of exposure of thermometers which, whatever their merits or demerits, are not those usually adopted. In a paper published in the *Quarterly Journal of the Meteorological Society* (October, 1873) I have shown from the average of five years' daily comparisons that the effect of the method adopted at Greenwich upon the mean annual temperature is to obtain a result 0°·475 warmer than is obtained by the usual method. This quantity is almost identical with the excess which Mr. Eaton attributes to the local consumption of fuel, an explanation surely most inadequate. Thus the discrepancy pointed out by Mr. Eaton only serves to establish his opponent's case. Mr. Buchan on the other hand must be unaware that it is the eye observations alone, made from the revolving stand, that are relied upon for temperature results at Greenwich, and though his conclusion would seem to be correct it does not seem possible to sustain the argument by which he has arrived at it.

Orwell Dene, Nacton JOHN I. PLUMMER

Cast-Iron

I HAVE been struck by the statement I found in several books on physics that cast-iron expands when it gets cool. As some of these books are used as text-books in schools in this country, and as this statement is contrary to the experience of all practical men with whom I have conversed upon the subject, I think the following translation of an article which appeared in *Der Civil Ingenieur*, edited by K. R. Bornemann, in Freiberg, 1863, ix. Band, iv. Heft, p. 219, may not be uninteresting, explaining, as it seems to me fully, at least one of the facts on which the statement mentioned above appears to be based, viz., the fact that cold iron swims in liquid iron :— H. M

"At a meeting of the Association of Saxon Engineers which took place in Freiberg in August last year (1862) Mr. H. Gruson, of Buckau, near Magdeburg, called the attention of the members to a phenomenon which had frequently been observed by him, but of which no proper explanation could be given at the time, viz., that pieces of cold cast-iron swim perfectly in molten iron. The question was raised, to what causes this may be due, and as from the physical point of view it was thought an interesting one, it was suggested that experiments should be made in order to obtain a proper explanation thereof.

"In consequence of this, M. Centner, Inspector of the Jacobi Iron-works, near Meisen, made such experiments, the result of which he communicated to the Association at a meeting on May 17, 1863. The following is an extract of Mr. Centner's report :— (Signed) W. TAUBERTH"

"Before anwering this question I made some experiments in order to ascertain whether this swimming is not caused by the specific weight of the body; by there I found confirmed that cold cast-iron weighs $\frac{1}{28}$ more than an equal volume of molten iron, for if a piece of cold cast-iron of 28 lbs. be used to form a mould, and if this mould be filled with molten iron, the new piece of metal thus obtained will only weigh 27 lbs. This weight, of course, is also that of the liquid metal which was required to fill the mould, formed from a piece weighing 28 lbs.

"For this reason, in making moulds for cast-iron, a measure is used which is $\frac{1}{28}$ longer than the ordinary measure, if the piece of iron to be formed is to have the full size of the ordinary measure.

"Repeated experiments with a mass of molten iron of 2,000 lbs. gave me further proofs that the causes of this swimming must be other than the specific weight.

"For my experiments I used four bodies of cast-iron of different shapes, but of the same volume, viz. a plate of 6" inches in the square and 1" thick, a cube of 3¼", a cylinder of 4" diameter, and 3" height, and a ball of 4" diameter. Each of these four bodies measured 36" cube and weighed 7 lbs.

"If the cause of the swimming were the specific weight, an equal part of the volume of all these bodies ought to remain above the surface of the liquid iron, but such is not the case at all. The volume above the surface of the liquid iron is different in each of the four bodies; it is greatest with the plate and smallest with the ball. Thus it is dependent on the shape and position of the surface which rests on the liquid iron.

"In order to come to the real causes of this swimming, I must first remind the reader that in every hot liquid in an open vessel, in consequence of the more rapid cooling at the surface, a continuous current is originated, the interior hottest parts ascending and the exterior colder ones descending; and thus a more or less visible movement or agitation is produced in the mass. Such currents occur in every mass of molten iron, and are there especially remarkable in consequence of a contemporaneous ascension and separation of slags, which, when they have arrived at the surface, are generally pushed towards the edges.

"If a solid piece of iron be put on the liquid mass the former gets at once heated at the expense of the latter; the portions of water and of air which are contained in the solid piece get expanded and expelled with considerable force, thus forming a current in opposition to the ascending one above mentioned.

"This expulsion of air and water may even cause dangerous explosions, if the usual precaution is neglected to warm the solid piece somewhat, before it is brought into contact with the liquid mass.

"Now there is no doubt that these opposite forces alone are able to raise the heavier solid piece more or less according to the more or less favourable surface it presents.

"But besides this there is to be taken into consideration that the overweight of the solid piece of iron is diminished by the previous heating which when the solid piece comes into contact with the liquid, is at once augmented and that the proportion of heat of the molten iron to that of the solid piece must to some extent have an influence on the more or less deep immersion of the latter.

"A further cause, although a slight one, of this swimming of the solid piece is the cohesion of the liquid iron; but at any rate this becomes of some importance in conjunction with the above-mentioned continuous ascending of slags which collect under the swimming body and retain partly the air expelled by the latter, helping in this way to keep it afloat.

"Solid cast-iron being $\frac{1}{28}$ heavier than an equal volume of molten iron, the overweight of each of the four bodies used for my experiments is consequently only ¼ lb., and in the present case it is therefore only this one *quarter of a pound* which the above-mentioned opposite forces have to lift within areas of 12" to 36" square in order to keep the body swimming.

"On increasing the size of the solid bodies, however, it will be easily understood that a limit to this swimming will soon be reached, and indeed I accidentally found this limit on my first trial in quadrupling the sizes of the four bodies so that each of them weighed 28 lbs.; for all the bodies with the exception of the plate which was 12" in the square and 1" thick went to the bottom. The plate on being put gently on the liquid mass was just kept afloat, but its surface was a little below the surface of the molten iron. 1 lb. overweight therefore with a surface of 12" in the square could scarcely be kept swimming.

"The behaviour of the other three bodies at the bottom was remarkable in consequence of a continuous vehement ebullition accompanied by the shooting out of long white brilliant flames, and these phenomena can only be attributed to the water and air expelled by the heat.

"These experiments with bodies of 28 lbs. weight show therefore that above this weight, without giving to the body a more favourable surface than 12" in the square, these bodies do not what is properly called swim in the sense that part of the solid body is kept above the level of the liquid. For if the bodies, for instance the ball, the cube, and the cylinder on being moved, rise and fall a little alternately, this can no longer be called swimming, for it is just the transition from overweight to equilibrium.

"That the greater or lesser degree of density of the different sorts of iron will also exercise an influence cannot be doubted.

"Less fortunate but still interesting was an experiment which I made with four pieces of zinc of the same shapes as the pieces of iron on 200 lbs. of liquid zinc, when with the pieces of 7 lbs. each the same thing took place as with the cast-iron pieces of 28 lbs. each on liquid iron, viz., the plate was just kept afloat and the three other bodies went to the bottom.

"With zinc, therefore, this phenomenon of swimming does not occur with such heavy bodies as with iron, and this may be explained by the fact that with zinc, in consequence of the much smaller difference of temperature between the liquid and the solid body, the currents mentioned above with reference to the iron must necessarily be far less strong.

"With similar modifications according to the temperature required for their liquefaction the swimming takes place with all other metals."

Tycho Brahe's Portrait

IN NATURE (vol. xv., p. 406) is published a copy of a portrait of Tycho Brahe in the possession of Dr. Crompton of Manchester. Although it seems, from the inscription in the corner, that the portrait is a contemporary one, there does not appear to me to be sufficient reason for preferring this portrait, of the origin of which nothing whatsoever is known, to others of the same date. Both Tycho's "Epistolæ" and "Mechanica" contain an engraving by J. D. Geyn from the year 1586, and if the newly-discovered portrait really (as conjectured by Dr. Crompton) should have been painted to be engraved for the "Mechanica," it can hardly have been considered a good likeness, as the engraving by Geyn was preferred. The latter is very like the portrait on Tycho's large wall-quadrant, of which an engraving in the "Mechanica" gives us an idea, and which Tycho himself mentions with the following words:—"Hanc effigiem magna solertia expressit Thobias Gemperlinus eximius artifex (quem mecum Augusta Vindelicorum in Daniam olim receperam) idque tam competenter, ut vix similior dari possit." This portrait is from 1587.

The Royal Gallery at Frederiksborg (about twenty English miles from Copenhagen) contained a fine portrait of Tycho Brahe, which unfortunately was burned in the great fire in 1859, when so much of that beautiful castle was destroyed. It agreed on the whole with the two above-mentioned portraits, while the long narrow face on the Manchester portrait shows hardly any resemblance to the features on the others. I may also add, that the fine monument erected by Tycho Brahe's heirs in the church in Prague (Teinkirche), where he was buried (of which I have seen a copy in Copenhagen), is very like Geyn's and Gemperlin's engravings.

The article which accompanies the portrait in NATURE contains several small mistakes, which perhaps also occur in Brewster's "Martyrs of Science." Tycho was not born in Sweden but in Denmark, as the province of Schonen (with the island of Hven) belonged to the latter country from ancient times and up to 1660, and he was of an ancient Danish noble family. His castle was called "Uraniborg" (Latin Uraniburgum, the Celestial Castle), the Observatory "Stjerneborg" (Stellæburgum). J. L. E. DREYER

Yellow Crocuses

CAN any of your readers elucidate this problem? When, a fortnight ago, the yellow crocuses flowered, the sparrows all at once made a terrible onslaught upon them. I found the gardener in Lincoln's Inn Gardens one day mourning over a fine line of crocus plants, every flower of which was in absolute ruins. All the work of the sparrows, he said. I have seen them, too, on the flower-boxes in my windows here frequently, tearing at the crocus blooms. Yet now, later, the blue and striped crocuses are blowing, and the sparrows leave them altogether untouched. What is there in the London bloom specially that attracts the London sparrow? The taste is, I think, peculiar to the town bird. In gardens at a distance from, and immediately around, London, I have watched plenty of yellow crocus blossoms, not one flower of which has been attacked.

Gray's Inn, April 6 ALFRED GEORGE RENSHAW

Tropical Forests of Hampshire

IN Mr. J. Starkie Gardner's lecture on The Tropical Forests of Hampshire (NATURE, vol. xv. p. 232), the following statement occurs which is open, I think, to considerable question:—"All the shipworms generally known to us live only in salt-water, and are so delicately organised that the slightest mixture of fresh-water instantly kills them." This sweeping assertion is partly qualified by allusion to the occurrence of a species described by Mr. George Jeffries as inhabiting fresh-water, and the fact of bored wood being found 300 miles up the Gambia River; still as Mr. Gardner speaks of these facts as a "theory" still in need of verification, I would point out that no waters are more infested with the shipworm than the deltas of tropical rivers wherein the water is often largely brackish if not potable.

My own experience is confined to the delta of the Irawadi, a tangled maze of creeks, the waters of which are brackish or salt for about a third of the year, and slightly so, and even potable, during the other months. The large canoes, however, which traverse these creeks are much injured by some species of shipworm, and so little does the easy remedy of exposing them to fresh-water answer, that the Birmese are in the habit of firing their bottoms from time to time; opportunity is taken of a high spring tide to get the boat well on shore. The ends are supported on blocks of wood, and a shallow saucer-shaped cavity is made underneath which is filled with straw or other combustible matter, which gives a fierce but short-lived flame. Fire is now applied and the bottom of the boat is for some minutes kept wrapt in flame, which steams the worms to death in their holes. I cannot recall any instances of bored wood well above the tideway, but wherever the water is occasionally brackish, thus far the worms seem capable of settling. What species occur in Pegu I cannot say. Percival Wright has described *Nausitora dunlopei* from the rivers of Eastern Bengal, and it may not improbably extend to the Irawadi delta, as *Novaculina gangetica* and a species of Scaphula closely allied to the Gangetic species do. The two Birmese species of Scaphula are both estuary forms, whereas the type of the genus in the Ganges is found a thousand miles from the sea, which suggests the plasticity of some species, which if met with fossil would be unhesitatingly regarded as marine. W. THEOBALD,

Hog Wallows or Prairie Mounds

IN NATURE (vol. xv., p. 274), Mr. Wallace quotes a letter from his brother in regard to the so-called Hog-wallows of California, in which their origin is ascribed to *débris* left at the broad foot of a retiring glacier modified by the erosion of innumerable issuing rills, and asks if this structure is known to occur elsewhere. As I have observed the same formation in many parts of the Pacific slope and have tried to explain it, I hope I may be allowed to say a few words on the subject.

The peculiar configuration of surface so well described by Mr. Wallace, is very widely diffused in America, and has been described under different names. In California the mounds are called *Hog-wallows*, but elsewhere they are known as *Prairie mounds*. This latter is the better name since they are found only in grassy, treeless, or nearly treeless regions. They occur over much of the Prairie region or "*plains*" east of the Rocky Mountains; also over portions of the *basin* region, *e.g.*, in Arizona; also over much of the bare grassy portions of California, *e.g.*, along the lower foothills of the Sierra and adjacent portions of the San Joaquin plains; also over enormous areas in Middle Oregon, on the eastern slope of the Cascade mountains, an undulating grassy region, also on the level grassy Prairies about the southern end of Pugit Sound, Washington territory.

They have been ascribed to the most diverse causes. In Texas, where they are very small, Prof. Hilgard thinks they are *ant-hills*. In Arizona, where they are also imperfectly developed, Mr. Gilbert thinks they are the ruined habitations of departed *Prairie dogs*. In some portions of California, also, where they are small, they have been popularly ascribed to *burrowing squirrels*. In the Prairies, about Pugit Sound, where they are splendidly developed, their great size and extreme regularity has suggested that they are *burial mounds*, and that the Prairies are veritable cities of the dead. It is possible that the cause may be different in different places, but I am sure that no one who has examined them in California, and especially in Oregon and Washington, can for a moment entertain any of these theories for the Pacific slope.

In a paper "On the Structure and Age of the Cascade Mountains," published in the *American Journal* for March and April, 1874, p. 167 and p. 259, among some miscellaneous points suggested by the main subject in hand, I discuss this one of Prairie mound. I there attribute them to *surface erosion under peculiar conditions*, these conditions being a *bare country* and a *drift-soil finer and more movable above* and coarser and *less movable below*. Erosion removes the finer top-soil, *leaving it only in spots*. The process once commenced, weeds and shrubs take possession of the mounds as the best soil, or sometimes as the driest spots, and hold them, preventing or retarding erosion by their roots. In some cases, perhaps in most cases, a *departing vegetation*, *i.e.*, a vegetation gradually destroyed by increasing dryness, seems to be an important condition. For my full reasons for holding this view I must refer the reader to my paper, but I may say in passing that in the bare hilly regions of Middle Oregon, on the east side of the Cascade Mountains, every stage of gradation may be traced from circular mounds, through elliptic, long elliptic, to ordinary erosion furrows and ridges.

Mr. Wallace asks in conclusion whether so extensive and uniform a deposit could be due to *glaciers* alone, or is it necessary to suppose *submergence?*

In answer I would say that nothing is to me more puzzling than the drift deposits on the Pacific slope, and I suppose the same is true everywhere. The prairies about Pugit Sound have evidently been submerged during the Champlain epoch, and I suppose the mound structure to have been formed after emergence, and the exceptional perfection of the mounds in that region may be due to this fact. But there is not the slightest evidence of submergence in the mound region of Oregon. All the high, bare, grassy, hilly, eastern slopes of the Cascade Mountains are covered evenly with a pebble and boulder drift, graduating upwards into a finer top soil. From this surface-soil are carved the mounds, which cover hill and dale so thickly that, viewed from an eminence the whole face of the country seems broken out with measles. This universal drift-covering, twenty to thirty feet thick over thousands of square miles, I know not what to call it, unless it be the *moraine profonde* of an ice-sheet.

OUR ASTRONOMICAL COLUMN

WINNECKE'S COMET, 1877, II.—In a note by Prof. Winnecke in M. Leverrier's *Bulletin* of April 13, it is remarked with respect to the elements of the comet discovered by him on April 5, "a great analogy exists between these elements and those of the comets 1827, II., and 1852, II., and it acquires a certain importance from the fact that the intervals are nearly equal."

The second comet of 1827 was discovered by Pons at Florence and Gambart at Marseilles, on June 20, and was observed at Florence until July 21; the original observations will be found in *Astron. Nach.*, No. 128. The best orbit is by Heiligenstein.

The second comet of 1852 was detected by M. Chacornac at Marseilles on May 15, and was observed at Vienna till June 8. On the suggestion of d'Arrest, the elements were calculated by Hartwig, without any assumption as to the eccentricity, and the resulting orbit proved to be a hyperbola, which, as d'Arrest remarked, rendered the identity of this comet with the second of 1827, which had been suspected by several astronomers very unlikely. Now, however, that a comet has made its appearance after a like interval with elements bearing a certain resemblance to those of the comets of 1827 and 1852, it may not be without interest to examine into the possibility of identity a little further. The elements of the three comets may be taken to be as follow:—

	1827, II.	1852, II	1877, II.
T	June 7·84	April 19·58	April 18·14
π	297° 31′·7	280° 0′·6	252° 0′·0
☊	318° 10′·5	317° 8′·4	317° 51′·3
i	43° 38′·8	48° 52′·9	56° 42′·7
q	0·8081	0·9050	0·9283

The motion is retrograde.

It is evident from a comparison of the three orbits that if they applied to the same comet, great perturbation must have taken place between the successive returns, the line of apsides in particular having considerably retrograded, and the inclination of the orbit increased by several degrees. This suggests an examination of the path of the comet near the nodes with respect to proximity to the orbits of the planets.

Assuming the mean of the two intervals for the period of revolution, we have 24·93 years, and for the semi-axis major 8·5338, and taking as sufficient for our present purpose the perihelion distance of 1852, the angle of eccentricity is 63° 22′·4. Hence it will be found that the radius-vector at the ascending node is 1·0008, which is less than 0·013 from the orbit of the earth; but to bring the two bodies together at this point the passage through perihelion must take place about September 3, which is not the case in any of the above years. At the opposite node the radius-vector is 5·966, not so very much greater than the radius-vector of Jupiter in the same longitude as to forbid the hope of finding a much closer approach. Accordingly on calculating the distances at different points of the orbit about the descending node, it appears on the assumption we have made with regard to the period of revolution, that in heliocentric longitude 139° the comet would be distant from the orbit of this powerful planet only 0·15 of the earth's mean distance from the sun, and it would arrive in this longitude about 480 days after perihelion passage, and therefore at the end of September, 1828, and the middle of August, 1853, but at these times the heliocentric longitude of Jupiter was about 232° and 265° respectively, and the planet was far removed from the comet in both years.

The case is a very curious one and possibly unique of its kind: similarity of elements at three epochs separated by very nearly equal intervals, and on the assumption of a corresponding period of revolution, a very near apparent approach to the planet which so greatly disturbs the cometary orbits, yet action to account for outstanding differences of elements, could not have taken place on either occasion of the comet's passage through the part of its orbit where great perturbation would be looked for.

A NEW COMET.—On Monday morning telegraphic intimation of the discovery of a new comet by M. Borrelly on the evening of the 14th reached England from Marseilles, and its position was determined the same night at Mr. Barclay's Observatory, Leyton. The place is thus given in M. Borrelly's telegram:—April 14, at 9h. 30m., R.A. 16° 31′, N.P.D. 34° 56′; daily motion in R.A. + 120′, in N.P.D. – 50′. On the 16th the comet was visible enough in a large-sized Berlin "Cometensucher," but was not a bright object in such an instrument.

OBSERVATIONS AT CORDOBA.—Dr. B. A. Gould, director of the National Observatory of the Argentine Republic at Cordoba, writes with respect to several objects to which allusion has been made in this column. Referring to μ Doradus—after remarking that it was noted as 5 m. by Lacaille, 6 m. by Rumker or Dunlop about 1825, and 8½ m. or 9 m. by Moesta, between February 1860 and January 1865, Dr Gould says: "Our observations of it here have been on the following dates:—1870, Dec. 27; 1871, Jan. 19, 30, March 16, April 13; 1873, March 7, on which days it was looked for in the work upon the Uranometry. Also it has been observed with the meridian circle 1874, Jan. 12, 26; 1875, Jan. 5, 9, 11, 20; 1876, Jan. 5, Feb. 12, 14. Some difficulty was experienced in recognising it on account of several other stars of the same order of brightness being situated in its immediate vicinity. The identification was confirmed, however, as soon as the equatorial telescope was mounted. The estimates of magnitude were from 8 to 8½, but I see no reason to believe that it has changed since December 1870. * * Mr. Thome estimated it as 8·3 m. last night" (March 3). Dr. Gould proceeds, "While writing, let me add a word regarding the red star in Sculptor, mentioned in the same number of NATURE. This is one of the most intensely red stars which I know in the sky. But I should neither call it 'orange-red' nor 'red purple,' nor 'couleur rose,' but a brilliant scarlet. In such cases, however, different eyes bear different witness, and different individuals express themselves very differently to communicate the same idea." Dr. Gould intends at the earliest opportunity, to obtain numerical values for this and some other stars, by means of a Zohlner's colorimeter. The star to which we are alluding is in R.A. 1h. 21m. 10s. N.P.D. 123° 11′ 48″ for 1874·0, according to observations at Cordoba.

The cluster γ Argus, respecting which Gillis reported changes since Sir John Herschel's observations, has been photographed several times, and Dr. Gould adds that he has similarly eight plates of η Argus and its surrounding stars—of which a very large number are secured upon the photograph by an exposure of eight or ten minutes.

TYPICAL LAWS OF HEREDITY[1]

III.

IF a graphic representation is desired, which will give the absolute number of survivors at each degree, we must shape the rampart which forms nature's target so as to be highest in the middle and to slope away at each side according to the law of deviation. Thus Fig. 6 represents the curved rampart before it has been aimed at; Fig. 7, afterwards.

I have taken a block of wood similar to Fig. 4, to represent the rampart; it is of equal height throughout. A cut has been made at right angles to its base with a fret-saw, to divide it in two portions—that which would remain after it had been breached, Fig. 5, and the cast of the breach. Then a second cut with the fret-saw has been made at right angles to its face, to cut out of the rampart an equivalent to the heap of pellets that represents the original population. The gap that would be made in the heap and the cast that would fill the gap are curved on two faces, as in the model. This is sufficiently represented in Fig. 7.

The operation of natural selection on a population already arranged according to the law of deviation is represented more completely in an apparatus, Fig. 8, which I will set to work immediately.

It is faced with a sheet of glass. The heap, as shown in the upper compartment of the apparatus, is three inches in thickness, and the pellets rest on slides. Directly below the slides, and running from side to side of the apparatus, is a curved partition, which will separate the pellets as they fall upon it, into two portions, one that runs to waste at the back, and another that falls to the front, and forms a new heap. The curve of the partition is a curve of deviation. The shape of this heap is identical with the cast of the gap in Fig. 7. It is highest and thickest in the middle, and it fines away towards either extremity. When the slide upon which it rests is removed, the pellets run down an inclined plane that directs them into a frame of uniform and shallow depth. The pellets from the deep central compartments (it has been impossible to represent in the diagram as many of these as there were in the apparatus) will stand very high from the bottom of the shallow frame, while those that came from the distant compartments will stand even lower than they did before. It follows that the selected pellets form, in the lower compartment, a heap of which the scale of deviation is much more contracted than that of the heap from which it was derived. It is perfectly normal in shape, owing to an interesting theoretical property of deviation (see formulæ at end of this memoir).

Productiveness follows the same general law as survival, being a percentage of possible production, though it is usual to look on it as a simple multiple, without dividing by the 100. In this case the front face of each compartment in the upper heap represents the number of the parents of the same class, and the depth of the partition below that compartment represents the average number that each individual of that class produces.

To sum up. We now see clearly the way in which the resemblance of a population is maintained. In the purely typical case, each of the processes of heredity and selection is subject to a well-defined and simple law, which I have formulated in the appendix. It follows that when we know the values of 1° in the several curves of family variability, productiveness, and survival, and when we know the co-efficient of reversion, we know absolutely all about the ways in which that characteristic will be distributed among the population at large.

I have confined myself in this explanation to purely typical cases, but it is easy to understand how the actions of the processes would be modified in those that were not typical. Reversion might not be directed towards the mean of the race, neither productiveness nor survival might be greatest in the medium classes, and none of their laws may be strictly of the typical character. However, in all cases the general principles would be the same. Again, the same actions that restrain variability would restrain the departure of average values beyond certain limits. The typical laws are those which most nearly express what takes place in nature generally; they may never be exactly correct in any one case, but at the same time they will always be approximately true and always serviceable for explanation. We estimate through their means the effects of the laws of sexual selection, of productiveness, and of survival, in aiding that of reversion in bridling the dispersive effect of family variability. They show us that natural selection does not act by carving out each new generation according to a definite pattern on a Procrustean bed, irrespective of waste. They also explain how small a contribution is made to future generations by those who deviate widely from the mean, either in excess or deficiency, and enable us to calculate whence the deficiency of exceptional types is supplied. We see by them that the ordinary genealogical course of a race consists in a constant outgrowth from its centre, a constant dying away at its margins, and a tendency of the scanty remnants of all exceptional stock to revert to that mediocrity, whence the majority of their ancestors originally sprang.

APPENDIX.

I will now proceed to formulate the typical laws. In what has been written, 1° of deviation has been taken equal to the "probable error" = C × 0·4769 in the well-known formula $y = \frac{1}{c\sqrt{\pi}} . e^{-\frac{x^2}{c^2}}$. According to this, if x = amount of deviation in feet, inches, or any other external unit of measurement, then the number of individuals in any sample who deviate between x and $x + \delta x$ will vary as $e^{-\frac{x^2}{c^2}} \delta x$ (it will be borne in mind that we are for the most part not concerned with the coefficient in the above formula).

Let the modulus of deviation (c) in the original population, after the process has been gone through, of converting the measurements of all its members (in respect to the characteristic in question), to the adult male standard, be written c_0.

1. Sexual selection has been taken as *nil*, therefore the population of "parentages" is a population of which each unit consists of the mean of a couple taken indiscriminately. This, as well known, will conform to the law of deviation, and its modulus which we will write c_1 has already been shown to be equal to $\frac{1}{\sqrt{2}} c_0$.

2. Reversion is expressed by a fractional coefficient of the deviation, which we will write r. In the "reverted" parentages (a phrase whose meaning and object have already been explained)

$$y = \frac{1}{rc\sqrt{\pi}} . e^{-\frac{x^2}{r^2c^2}}.$$

In short, the population, of which each unit is a reverted parentage, follows the law of deviation, and has its modulus, which we will write c_2, equal to rc_1.

3. Productiveness :—We saw that it followed the law of deviation; let its modulus be written f. Then the number of children to each parentage that differs by the amount of x from the mean of the parentages generally (*i.e.*, from the mean of the race), will vary as $e^{-\frac{x^2}{f^2}}$; but the number of such parentages varies as $e^{-\frac{x^2}{c_2^2}}$, therefore if each child

---

[1] Lecture delivered at the Royal Institution, Friday evening, February 9, by Francis Galton, F.R.S. Continued from p. 514.

absolutely resembled his parent, the number of children who deviated x would vary as $e^{-\frac{x^2}{f^2}} \times e^{-\frac{x^2}{c_2^2}}$, or as $e^{-x^2\left\{\frac{1}{f^2}+\frac{1}{c_2^2}\right\}}$. Hence the deviations of the children in their amount and frequency would conform to the law, and the modulus of the population of children in the supposed case of absolute resemblance to their parents, which we will write c_3, is such that—

$$\frac{1}{c_3} = \sqrt{\left(\frac{1}{f^2} + \frac{1}{c_2^2}\right)}.$$

We may, however, consider the parents to be multiplied and the productivity of each of them to be uniform. It is more convenient than the converse supposition and it comes to the same thing. So we will suppose the reverted parentages to be more numerous but equally prolific, in which case their modulus will be c_3, as above.

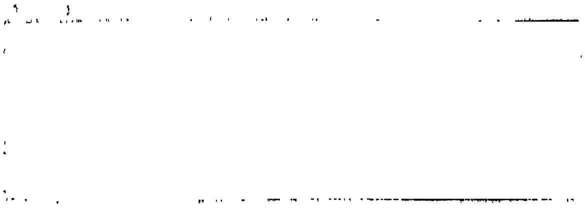

Fig. 6.

4. Family variability was shown by experiment to follow the law of deviation, its modulus, which we will write v, being the same for all classes. Therefore the amount of deviation of any one of the offspring from the mean of his race is due to the combination of two influences, the deviation of his "reverted" parentage and his own family variability; both of which follow the law of deviation. This is obviously an instance of the well-known law of the "sum of two fallible measures" (Airy, "Theory of Errors," § 43). Therefore the modulus of the population in the present stage, which we will write c_4, is equal to $\sqrt{(v^2 + c_3^2)}$.

5. Natural selection follows, as has been explained, the same general law as productiveness. Let its modulus be written s; then the percentage of survivals among children, who deviate x from the mean, varies as $e^{-\frac{x^2}{s^2}}$, and for the same reasons as those already given, its effect will be to leave the population still in conformity with the law of deviation, but with an altered modulus, which we will write c_5, and

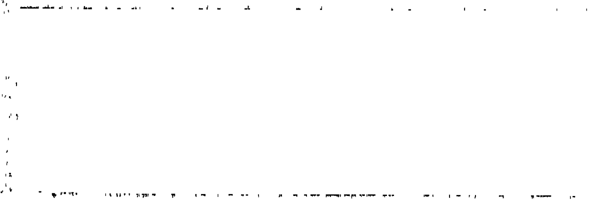

Fig 7.

$$\frac{1}{c_5} = \sqrt{\left(\frac{1}{s^2} + \frac{1}{c_4^2}\right)}.$$

Putting these together we have, starting with the original population having a modulus $= c_0$:—

1. $c_1 = \frac{1}{\sqrt{2}} c_0$.

2. $c_2 = r c_1$.

3. $c_3 = \sqrt{\left\{\frac{f^2 c_2^2}{f^2 + c_2^2}\right\}}$.

4. $c_4 = \sqrt{\left\{v^2 + c_3^2\right\}}$.

5. $c_5 = \sqrt{\left\{\frac{s^2 c_4^2}{s^2 + c_4^2}\right\}}$.

And lastly, as the condition of maintenance of statistical resemblance in consecutive generations:—

6. $c_5 = c_0$.

Hence, given the coefficient r and the moduli v, f, s, the value of c_0 (or c_5) can be easily calculated.

In the case of simple descent, which was the one first considered, we have nothing to do with c_0, but begin from c_1. Again, as both fertility and natural selection are in this case uniform, the values of f and s are infinite. Consequently our equations are reduced to—

Fig. 8

$$c_2 = r c_1;\ c_4 = \sqrt{\left\{v^2 + c_2^2\right\}};\ c_4 = c_1,$$

whence

$$c_1^2 = \frac{v^2}{1 - r^2}.$$

CARL FRIEDRICH GAUSS

Born April 30, 1777, Died February 23, 1855.[1]

De Morgan in his "Budget of Paradoxes" (p. 187), tells the following story:—The late Francis Baily wrote a singular book, "Account of the Rev. John Flamsteed, the first Astronomer-Royal:" it was published by the Admiralty for distribution, and the author drew up the distribution list.

---

[1] We adopt the date given by the Baron Sartorius von Waltershausen in his "Gauss. Zum Gedächtniss," Leipzig, 1856. Encyclopedias and other authorities are pretty equally divided between this date and April 23. All the English Cyclopedias we have consulted, with the exception of Chambers's (1874), give April 23. We may also mention that on the list of students at the Collegium Carolinum the name is Johann Friedrich Karl Gauss. We have followed Gauss himself in our heading.

Certain rumours led to a run upon the Admiralty for copies. "The Lords were in a difficulty; but on looking at the list they saw names, as they thought, which were so obscure, that they had a right to assume Mr. Baily had included persons who had no claim to such a compliment as presentation from the Admiralty. The secretary requested Mr. Baily to call upon him. 'Mr. Baily, my Lords are inclined to think that some of the persons in this list are perhaps not of that note which would justify their lordships in presenting this work.' 'To whom does your observation apply, Mr. Secretary.' 'Well, now let us examine the list; let me see; now—now—now—come!—here's Gauss—who's *Gauss*?' 'Gauss, Mr. Secretary, is the oldest mathematician now living, and is generally thought to be the greatest.'" Their Lordships ultimately expressed themselves perfectly satisfied with the list. Who then was Gauss? He was the son of a bricklayer at Brunswick, and it was the wish of his father that the boy should be a bricklayer too. The lad, however, was another Pascal,[1] and early showed a marvellous aptitude for calculation; indeed he might be said to have "lisped in numbers," for he used jokingly to say that he could reckon before he could talk. When scarcely three years old he pointed out the inaccuracy of an account, "Vater, die Rechnung ist falsch, es macht so viel," and the boy was right. At the public school of Buttner he soon attracted the attention of Bartels, subsequently Professor of Mathematics at Dorpat, and father-in-law of Struve, by whom he was brought under the notice of Charles William, the reigning Duke of Brunswick. The Duke became Gauss's good friend, and sent him in 1792[2] to the Collegium Carolinum, much against the father's wish. Having nothing more to learn from the professors here, he went in 1795[3] to Göttingen, as yet undecided whether to pursue philology or mathematics. Kaestner was at this time mathematical professor, of whom Gauss said: "He was the first of geometers among poets and first of poets among geometers."

Here, too, he was independent of his teachers, and having made several of his greatest discoveries in analysis (the Higher Arithmetic especially became his favourite study, and he called it a divine science, "Mathematics, the Queen of the Sciences, and Arithmetic, the Queen of Mathematics"[4]), henceforth he made mathematics the main study of his life.

Having finished his college course, he returned to Brunswick, and in 1798 repaired for a short time to Helmstadt to consult the library there. Again the next year we find him at Helmstadt, and he is now able to improve his acquaintance with Pfaff, having had only an hour or two of intercourse with him in the previous year, and the two mathematicians were much together, the probability being that Gauss communicated more than he received.[5]

In 1807, whilst a private teacher at Brunswick, the Emperor of Russia offered him a chair at the Academy of St. Petersburg, but by the advice of Olbers he declined the appointment.[6] On July 9 in this year he was appointed the first director of the new Göttingen Observatory and Professor of Astronomy in the University. His life henceforth was spent at Göttingen, in the midst of continuous work; in other respects it was quite uneventful. From the year 1828, when he was invited to Berlin by Humboldt to attend a meeting of natural philosophers in that city, he never left his university until 1854, in which year railway communication was opened up between Hanover and Göttingen.[1] His life was passed in a simple and regular manner, he enjoyed good sound health in spite of the fatigues of night observations, he seldom required a physician until a few months before his death, when he suffered much from asthma, which was subsequently complicated by the accession of dropsy. So passed away in his seventy-eighth year, Gauss, one of the greatest lights of the present age, a mathematician worthy to be placed on the same high platform as Archimedes and Newton.[2]

We are told that his tastes were simple (he never wore any of the numerous decorations which were showered down upon him), and that he had the full knowledge, which men of genius often have, of his superiority to the mass of mankind.[3] Though he looked upon mathematics as the principal means for developing human knowledge,[4] he yet fully recognised the beneficial influence of an acquaintance with classical literature. He had indeed a wonderful faculty for the acquisition of languages; he was acquainted with most of the European languages, and could speak many of them well.[5] At the age of sixty-two he commenced the study of the Russian language, and mastered it in two years. He took a great interest too in politics to within a few weeks of his death. His lectures, in which he adopted the analytic method, were exceedingly clear expositions; in them he liked to discuss the methods and the roads by which he had arrived at his great results. He required the closest attention, and objected to the taking of notes, lest his hearers should lose the thread of his argument. The students seated round the lecture-table listened with delight to the lucid and animated addresses of their master; addresses more resembling conversations than set lectures. The chief figure in this group stands before us with clear, bright eyes, the right eyebrow raised higher than the left (*more Astronomorum*), a forehead high and wide, overhung with grey locks, and a countenance whose variations were all expressive of the great mind within.[6] We can well understand how his pupils reverenced him and never forgot these meetings. Gauss was always ready to converse even with persons unacquainted with the subjects he had made his own, and his animation in doing so bore evidence to the delight he took in the contemplation of nature. It was this feeling that led him a short time before his death to have engraved at the foot of his portrait the following lines as expressing best the philosophy of his ideas and of his writings:—

> "Thou, Nature, art my Goddess to thy laws
> My services are bound!"

' Gauss. Z. Ged.,' p. 79. Shakspeare, King Lear, Act I Scene ii

The full list of Gauss's writings would fill many of our columns; there is a list on columns 854–857 of Poggendorff, Larrouse gives a very full list also, but the most complete list we know, not including the larger works, is given in the Royal Society's Catalogue of Scientific Papers. The titles are given of 124 papers

One of Gauss's earliest discoveries is the "method of least squares." This method, though first published by Legendre, was applied by Gauss as early as the year 1795.[7] It is somewhat remarkable that Gauss has devoted so few memoirs to subjects of an algebraic character. If we except a comparatively unimportant paper on Descartes' Rule of Signs, which appeared in *Crelle's Journal* (1828), his only algebraical memoirs relate to the theorem that every equation has a root. Of this he gave no less than three distinct demonstrations, one in 1799, one in 1815, and one in 1816. That in 1799 formed the subject of his first published paper: "Demonstratio nova theorematis omnem functionem algebraicam, rationalem integram unius variabilis in factores reales primi vel secundi gradus resolvi posse"—his inaugural dissertation as a candidate for the degree of Doctor of Philosophy in the University of Göttingen. This demonstration was repeated over again in 1849 with certain changes and simplifications. These demonstrations are prior to any other;[1] for various reasons those subsequently given by Cauchy have been justly preferred for insertion in modern text-books.

---

[1] cf. Prof. H J S. Smith's Presidential Address, *Proceedings* of London Mathematical Society, vol viii p 18, and Larrouse At the age of ten he was acquainted with the Binomial Theorem and the theory of infinite series, "Gauss Z Ged," p. 13

[2] "Gauss Zum Gedächtniss," p. 15. Roy. Ast Soc *Monthly Notices*, vol. xvi. pp 80–83. Larrouse, "Grande Dictionnaire," Paris, 1872, gives erroneously 1789.

[3] Larrouse and Michaud's "Biographie Universelle," Paris, 1856, both give this date 1794, see also Roy Ast Soc *Monthly Notices*.

[4] "Gauss. Z. Ged," pp 79, 86.

[5] Roy Ast Soc. *Notices* point out that the idea that Gauss studied under Pfaff is an erroneous one This error occurs in the "Encyclopædia Brit.," 1856 (8th edition) Laplace, when asked who was the greatest mathematician in Germany replied, Pfaff, his interrogator said he should have thought Gauss was. "Oh," replied Laplace, "Pfaff est bien le plus grand mathématicien de l'Allemagne, mais Gauss est le plus grand mathématicien de l'Europe." The statement that Gauss graduated at Helmstadt in 1799 (*Proceedings* of Roy. Soc., vol. vii p 598) is erroneous, see "Gauss Z. Ged.," p. 22. The degree was conferred upon him *in absentia*. No information upon this point is given either in Poggendorff, "Biog. Lit. Handwörterbuch," Leipzig, 1863, or in the *Göttingische gelehrte Anzeigen* (3rd vol. for 1855).

[6] Olbers, in a letter to Heeren, states that Gauss had a marked objection to a mathematical chair; his desire was to obtain the post of astronomer at an observatory, in order that he might spend all his time upon his observations and his profound studies for the advancement of science.

[1] He is said never to have slept from under the roof of his own observatory but on the one above-named occasion, and in the last-named year, i.e., the year before he died, to have seen for the first time a locomotive. During this visit to Berlin, Gauss made the acquaintance of Weber. "Z. Ged," p 61

[2] To use the words of Gauss's successor at Göttingen. A great living English mathematician says: "The mathematician lives long and lives young the wings of his soul do not early drop off, nor do its pores become clogged with the earthy particles blown from the dusty highways of vulgar life." (Dr Sylvester's address at the Exeter Meeting of the British Association, 1869) He cites Leibnitz 70, Euler 76, Lagrange 77, Laplace 78, Gauss 78, Plato 82, Newton 85, Archimedes 75 (then killed by a Roman soldier), Pythagoras 99.

[3] "Gauss Z Ged," p 93. He was a man of determined character, of strong will, and one who disdained all half-heartedness. (and p 102) His character showed a curious mixture of self-conscious dignity and childlike simplicity Larrouse says he was but little communicative and morose, not to say peevish

[4] A short time before his death he spoke to a celebrated psychologist on the possibility of putting psychology on a mathematical basis

[5] "Gauss. Z Ged.," p. 94, says he read Gibbon and Macaulay's histories with great interest. He was immensely amused (p. 93) with "The Moon rises broad in the north-west," which occurs in one of Sir W. Scott's novels He would not tell his friends what had set him laughing until after collecting a variety of editions of the novel in question he found that the passage was not a misprint.

[6] We are here indebted to M. Wagener the writer of the notice in the "Biographie Universelle (Michaud)," Paris, 1856.

[7] Theoria Motus, lib. ii. § iii. See Glaisher "On the Law of Facility of Errors of Observations, and On the Method of Least Squares," Roy. Ast. Soc. *Memoirs*, vol. xxxix (1872), in which is collected much information on the subject. Also Todhunter's "History of Theory of Probability," § 1,007 and elsewhere. Roy. Soc. *Proceedings*, p. 102.

A new epoch in certain branches of analysis dates from the publication of the "Disquisitiones Arithmeticæ" (Leipzig, 1801),[2] and from the researches with which some years later Gauss supplemented or further developed the theories contained in that work. We must bear in mind that he found the theory of numbers as Euler and Lagrange had left it. The former enriched it with a multitude of results, relating to Diophantine problems, to the theory of the residues of powers, and to binary quadratic forms; the latter had given the character of a general theory to some at least of these results by his discovery of the reduction of quadratic forms and of the true principles of the solution of indeterminate equations of the second degree. Legendre (with many additions of his own) had endeavoured to arrange as much as possible of these scattered fragments of the science into a systematic whole in his "Essai sur la Théorie des Nombres." But the "D. Ar." was in the press when this important treatise appeared, and what in it was new to others was already known to Gauss. This grand work merits an analysis at our hands, but lack of space compels us to pass on at once to the fourth section. The greater portion of it is occupied with a research, which of itself alone would have placed Gauss in the first rank of mathematicians. "If p and q are positive uneven prime numbers, p has the same quadratic character with regard to q that q has with regard to p; except when p and q are both of the form $4n+3$, in which case the two characters are always opposite, instead of identical." This is the celebrated Fundamental Theorem of Gauss, known also as the Law of Quadratic Reciprocity of Legendre. Gauss discovered it (by induction) in March, 1795, before he was eighteen; the proof given of it in this section he discovered in April of the year following.[3] He cannot at the earlier date have been aware that the theorem had been already enunciated (though in a somewhat complex form) by Euler, and that Legendre had attempted, though unsuccessfully, to prove it in the *Memoirs* of the Academy of Paris for 1784. The question of priority of enunciation or of demonstrating by induction in this case is a trifling one; any rigorous demonstration of it involved apparently insuperable difficulties. Gauss was not content with once vanquishing the difficulty, he returns to it again in the fifth section, and there obtains another demonstration reposing on entirely different, but perhaps still less elementary principles. In January, 1808, he submitted a third demonstration to the Royal Society of Göttingen; a fourth in August of the same year; a fifth and sixth in February, 1817. It is no wonder he should have felt a sort of personal attachment to a theorem which he had made so completely his own, and which he used to call the "gem" of the higher arithmetic. His six demonstrations remained for some time the only efforts in this direction, but the subject subsequently attracted the attention of other eminent mathematicians, and several proofs differing substantially from one another, and from those of Gauss, have been given.[4] It would be impossible to exaggerate the important influence which this theorem has had on the subsequent development of arithmetic, and the discovery of its demonstration by Gauss must be certainly regarded (it was so regarded by himself), as one of his greatest scientific achievements. The fifth section ("these marvellous pages") abounds with subjects, each of which has been the starting-point of long series of important researches by subsequent mathematicians. In the *Additamenta* to this section Gauss characteristically adds: "ex voto nobis sic successit ut nihil amplius desiderandum supersit Nov. 30—Dec. 3, 1800." It is remarkable that he should never have published the wonderful researches to which he here alludes. They first saw the light sixty-three years later in the second volume of the collected edition of his works.[1] Till the time of Jacobi, it is not too much to say, that the profound researches of the fourth and fifth sections were passed over with almost universal neglect, but the seventh section at once made the reputation of the "D. Ar." The well-known theory of the division of the circle, comprised in this section, was received with great and deserved enthusiasm as a memorable addition to the theory of equations and to the geometry of the circle. Gauss's note on § 365 ("circulum in 17 partes divisibilem esse geometrice, deteximus 1796, Mart 30")[2] is interesting because it shows that he was not yet nineteen when he made this great discovery. Even more remarkable, however, is a passage (§ 335), in which he observes that the principles of his method are applicable to many other functions beside the circular functions, and in particular to the transcendents dependent on the integral $\int\frac{dx}{\sqrt{1-x^4}}$. This almost casual remark shows (as Jacobi long since observed) that Gauss at the date of the publication of the "D. Ar." had already examined the nature and properties of the elliptic functions and had discovered their fundamental property, that of double periodicity. This observation of Jacobi's is amply confirmed by the papers on elliptic transcendents, now published in the third volume of Gauss's collected works.[3]

Carl Friedrich Gauss.

The "D. Ar." were to have included an eighth section; at first it was intended to contain a complete theory of congruences, but subsequently Gauss appears to have proposed to confine the work by a more complete discussion of the theory of the division of the circle. Manuscript drafts on each of these subjects were found among his papers; the first of them is especially interesting, as it treats of the general theory of congruences from a point of view closely allied to that subsequently taken by

---

[1] This dissertation (Helmstadt, 1799), so little known that Lagrange appears not to have been acquainted with it, and "Cauchy has received in France all the praise due to a first discoverer."—Larousse.

[2] For an amusing notice of this work see "Biographie nouvelle des Contemporains" (Paris, 1822): "Cet ouvrage a obtenu un succès d'après lequel on serait tenté de croire que le charlatanisme envahit quelquefois jusqu'au domaine des mathématiques" (see Roy. Soc. *Proceedings*, pp 590, 591, *ubi supra*). Twelve years later ("Biographie universelle et portative des Contemporains," Paris, 1834) we read, "Il suffit de dire qu'en général ses travaux sont estimés des mathématiciens les plus distingués et qu'ils se recommandent autant par leur exactitude que par la clarté, la précision et l'élégance du style." Laplace's saying, quoted above, also shows in what estimation Gauss was held at that date. Lalande speaks of his talent and zeal, "Histoire," p. 813 (1803).

[3] See Gauss's note (pp. 475, 476 of vol. i. of his "Werke," edited by Schering).

[4] By Jacobi and Eisenstein in Germany, M. Liouville in France; perhaps the simplest of all (one allied in its character to the third proof of Gauss) is one by M. Zeller (see *Messenger of Mathematics*, No. lviii., January, 1876 for an account by Prof. Paul Mansion)

[1] The theorem to which they refer had, in the interval, been rediscovered and demonstrated by Lejeune Dirichlet This demonstration has been to a certain extent simplified by M. Hermite, and the form of proof found in Gauss's papers after his death approaches very nearly to that adopted by M. Hermite.

[2] Schering's edition, *ubi supra*. M. Chasles passes by this discovery without any notice of it; in this case the language could not be the barrier: "Par suite de notre ignorance de la langue dans laquelle ils sont écrits," "Aperçu Historique," p 275. Delambre gives an account in his "Rapport Historique sur les progrès des Sciences," Paris, 1810. In the Roy. Ast. Soc. *Notice* are some pertinent remarks

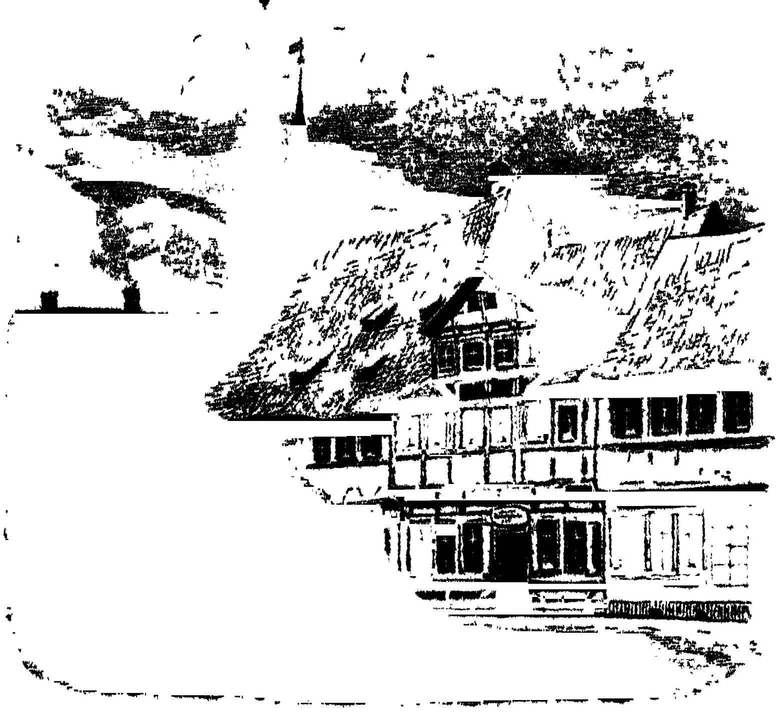
[3] On p. 593 Roy. Soc. Obituary Notice will be found the story of Gauss and Jacobi. For every theorem in the subject of elliptic integrals produced by the latter, Gauss could show its fellow among his manuscripts.

Evariste Galois and by MM. Serret and Dedekind. This draft appears to belong to the years 1797 and 1798.

To complete our hasty sketch of the arithmetical works we need only mention (1) the remarkable interpretation of the arithmetical theory of positive binary and ternary quadratic forms, which will be found in his review of the works of L. Seeber [1831] ("Werke," vol. ii. p. 188); and (2) the two important memoirs on the theory of biquadratic residues (1825 and 1831). In the second of these memoirs he gives a theorem of biquadratic reciprocity between any two prime numbers no less important than the quadratic law, viz., "If p_1 and p_2 are two primary prime numbers, the biquadratic character of p_1 with regard to p_2 is the same as that of p_2 with regard to p_1." This theorem itself and the introduction of imaginary integers upon which it depends, are memorable in the history of arithmetic for the number and variety of the researches to which they have given rise.[1]

A writer remarks each work of Gauss is an event in the history of science, a revolution, which, overturning the old theories and methods, replaces them by new ones and advances science to a height which no one had before dreamed of.[2] We have given proof of this in one branch of mathematics; we shall see that the witness is true as to other branches also.

The discovery of the planet Ceres at Palermo on the first day of the present century led to Gauss's taking up the subject of astronomy. He did not come into possession of the requisite data until the October following. In a few weeks he determined the elements of its orbit with sufficient accuracy so that the Baron de Zach was enabled to rediscover the planet at the first attempt he made for that purpose on December 7. This discovery was soon followed by that of three other small planets. These discoveries supplied Gauss with the means of further improving his solution of the problem, and in 1809 he brought out at Hamburg his "Theoria motus corporum cœlestium in sectionibus conicis solem ambientium." This contains an "elaborate discussion of the various problems which present themselves in the determination of the movements of planets and comets from observations made on them under any circumstances."[1] Gauss's other astronomical researches are chiefly contained in De Zach's *Monatliche Correspondenz*, the *Transactions* of the Royal Society of Gottingen, and the *Astronomische Nachrichten*; all are contributions of the highest order of excellence.



Gauss' Birthplace in Brunswick.

To astronomy Gauss joined geodesy, and the Hanoverian Government charged him with the triangulation and measurement of an arc of the meridian between Göttingen and Altona. This he accomplished between the years 1821 and 1824. For carrying out his purpose he invented many methods quite original.[3] It was his intention to publish an extensive work upon geodesy, but he did not accomplish his purpose. He contributed two memoirs on the subject to the Royal Society of Berlin (1844, 1847).

Mr. Todhunter in his "History of the Theories of Attraction," devotes §§ 1162-1175 to an analysis of a memoir by Gauss, "Theoria attractionis corporum sphæroidicorum ellipticorum homogeneorum methodo novâ tractata" (Royal Society of Göttingen, March 18, 1813). Mr. Todhunter says, "he completely succeeds in his design; his solution is both simple and elegant."[2] He further remarks, "Gauss's writings are distinguished for the combination of mathematical ability with power of expression; in his hands Latin and German rival French itself for clearness and precision."

In another of Mr. Todhunter's works ("Calculus of Variations," 1861) he discusses in his third chapter (pp. 37-52) a memoir by Gauss entitled "Principia generalia Theoriæ figuræ Fluidorum in statu æquilibrii" (Royal Society of Göttingen, 1833).[1] It relates to the theory of capillary attraction, and demonstrates in a new way some results which had already been obtained by Laplace. The part analysed by Mr. Todhunter is that devoted to the solution of a problem in the calculus of variations, "involving the variation of a certain double integral, *the limits of the integration being also variable*; it is the earliest example of the solution of such a problem." In 1831 we find Gauss commencing the study of crystallography; in a few weeks he had mastered the subject. We find that the question of the rationality or irrationality of the ratios of the crystallographic coefficients had attracted his attention.[2]

---

[1] In our account of Gauss's arithmetical work we have throughout freely referred to Prof H J S. Smith's presidential address (see above) and his two reports on the theory of numbers (Brit. Assoc. Reports, 1859, pp. 228–267; 1860, pp 120–172) But we are still more deeply indebted to him for references and criticisms most kindly given in the midst of the pressing claims of his other numerous engagements.

[2] Wagener, in Michaud's "Biographie Universelle." Prof. Cayley writes, "All that Gauss has written is first rate; the interesting thing would be to show the influence of his different memoirs in bringing to their present condition the subjects to which they relate, but this is to write a History of Mathematics from the year 1800."

[3] He invented the heliotrope to render angles visible at as great a distance as possible; this he did by reflecting the rays of the sun. He also devised a method for the correction of the errors which occur in an extensive system of triangulation.—"Gauss. Z. Ged.," pp. 51-53.

[1] Roy. Soc. *Proceedings*, v. 391; Roy. Ast. Soc. *Monthly Notices* (as above). A curious fact is recorded. The preface to this work is dated March 28, 1809, just two centuries after Kepler's "Præfatio de Stella Martis," March 28, 1609; "Gauss. Z. Ged.," p. 40. After the publication of this work Gauss became "a member of all the learned societies from the Polar Circle to the Tropics."

[2] Chasles (quoted by Todhunter) calls it "le beau mémoire de M. Gauss." Another celebrated memoir, "Allgemeine Lehrsätze . . . Anziehungs- und Abstossungskräfte" (Leipsic, 1840), is treated by Todhunter, § [illegible]. In this last Gauss uses the name *Potential* (apparently independent of Green) § 790. See also Maxwell's "Electricity," § 70.

We can only touch upon Gauss's further contributions to geometry.[3] To him are due many fundamental theorems in the theory of curve-surfaces; also on the development of surfaces; thus it was he who found the equation to developable surfaces. He was used to say "that he had laid aside several questions which he had treated analytically, and hoped to apply to them geometrical methods in a future state of existence, when his conceptions of space should have become amplified and extended."[4]

Those not acquainted with Gauss's writings would think we must have exhausted our account of them. In 1831, however, on Weber's arrival at Gottingen, physical questions took the first place in Gauss's thoughts, and separately and in conjunction many works were brought out by these two philosophers. There is so full an account of Gauss's achievements in this direction in the Royal Society's Obituary Notice, that we need only refer to it.[5] His contributions, we may briefly say, to the knowledge of electro-magnetism and terrestrial magnetism were perhaps the most considerable and important of his achievements. He invented the magnetometer, and was one of the first to point out the possibility of sending signals by galvanic currents, and so contributed to the invention of the electric telegraph.

[6] "If we except the great name of Newton (and the exception is one which Gauss himself would have been delighted to make) it is probable that no mathematician of any age or country has ever surpassed Gauss in the combination of an abundant fertility of invention with an absolute rigorousness in demonstration, which the ancient Greeks themselves might have envied. It may be admitted, without any disparagement to the eminence of such great mathematicians as Euler and Cauchy that they were so overwhelmed with the exuberant wealth of their own creations, and so fascinated by the interest attaching to the results at which they arrived, that they did not greatly care to expend their time in arranging their ideas in a strictly logical order, or even in establishing by irrefragable proof propositions which they instinctively felt, and could almost see to be true. With Gauss the case was otherwise. . . . . It may seem paradoxical, but it is probably nevertheless true that it is precisely the effort after a logical perfection of form which has rendered the writings of Gauss open to the charge of obscurity and unnecessary difficulty. The fact is that there is neither obscurity nor difficulty in his writings, as long as we read them in the submissive spirit in which an intelligent schoolboy is made to read his Euclid. Every assertion that is made is fully proved, and the assertions succeed one another in a perfectly just analogical order; there is nothing so far of which we can complain. But when we have finished the perusal, we soon begin to feel that our work is but begun, that we are still standing on the threshold of the temple, and that there is a secret which lies behind the veil and is as yet concealed from us . . . . no vestige appears of the process by which the result itself was obtained, perhaps not even a trace of the considerations which suggested the successive steps of the demonstration. Gauss says more than once that, for brevity, he only gives the synthesis, and suppresses the analysis of his propositions. '*Pauca sed matura*' were the words with which he delighted to describe the character which he endeavoured to impress upon his mathematical writings. . . . . If, on the other hand, we turn to a memoir of Euler's, there is a sort of free and luxuriant gracefulness about the whole performance, which tells of the quiet pleasure which Euler must have taken in each step of his work; but we are conscious nevertheless that we are at an immense distance from the severe grandeur of design which is characteristic of all Gauss's greater efforts. The preceding criticism, if just, ought not to appear wholly trivial; for though it is quite true that in any mathematical work the substance is immeasurably more important than the form, yet it cannot be doubted that many mathematical memoirs of our own time suffer greatly (if we may dare to say so) from a certain slovenliness in the mode of presentation; and that (whatever may be the value of their contents) they are stamped with a character of slightness and perishableness, which contrasts strongly with the adamantine solidity and clear hard modelling, which (we may be sure) will keep the writings of Gauss from being forgotten long after the chief results and methods contained in them have been incorporated in treatises more easily read, and have come to form a part of the common patrimony of all working mathematicians. And we must never forget (what in an age so fertile of new mathematical conceptions as our own, we are only too apt to forget), that it is the business of mathematical science not only to discover new truths and new methods, but also to establish them, at whatever cost of time and labour, upon a basis of irrefragable reasoning.

"The μαθηματικὸς πιθανολογῶν has no more right to be listened to now than he had in the days of Aristotle; but it must be owned that since the invention of the 'royal roads' of analysis, defective modes of reasoning and of proof have had a chance of obtaining currency which they never had before. It is not the greatest, but it is perhaps not the least, of Gauss's claims to the admiration of mathematicians, that, while fully penetrated with a sense of the vastness of the science, he exacted the utmost rigorousness in every part of it, never passed over a difficulty, as if it did not exist, and never accepted a theorem as true beyond the limits within which it could actually be demonstrated."

It will be evident to our readers that this notice has been drawn up with a purpose. The town of Brunswick proposes to celebrate the hundredth anniversary of Gauss's birthday, and the committee hope to have received before the 30th instant, sufficient subscriptions to enable them to lay the foundation stone of a memorial statue. We have endeavoured to present in a strong light[1] the claims which this great mathematician has upon mathematicians, not only in Germany, but on mathematicians in this country.[2]

Gauss might himself have considered his works his best monument ("exegi monumentum aere perennius,") and possibly if sufficient funds flow in, the committee might see their way to the bringing out a centenary edition of them. In this way they would confer a great boon upon mathematicians everywhere, for at present his writings are, as our great mathematical historian writes, "very costly."[3]

R. TUCKER

These are all we have seen The editor is Schering. The house in which Gauss was born bore the number 1550, and was situated on the west side of the Wendengraben. It now has a memorial tablet. The house was sold in 1804, and the family removed to another in the Mühlenstrasse, near St. Giles's Church. "Z. Ged.," p. 8.

METEOROLOGICAL NOTES

METEOROLOGICAL LUSTRUM OF 1871-75.—To the seventh Meteorological Report of the Grand Duchy of Baden, by H. Oscar Ruppel of Carlsruhe, just published, there is appended a paper giving the averages of the observations of pressure, temperature, humidity, rain, and snow, and thunderstorms made at the sixteen stations of the Grand Duchy during the Meteorological Lustrum ending with 1875. Considering the many physical and climatical inquiries of the highest importance which such averages, calculated for absolutely the same terms of years over considerable portions of the earth's surface, are certain greatly to elucidate, it is to be hoped that other meteorological institutes and societies will take the trouble to prepare and publish similar averages for their respective countries. In view of the more special inquiries which such averages are calculated to further, it will be necessary that anemometrical averages be included, and that all the averages be given for each of the different hours of observation.

DISTRIBUTION OF BAROMETERS IN FRANCE.—In virtue of the President's decree, signed by M. Thiers, for reorganising the French National Observatory, that establishment issues weather warnings for agricultural purposes. As it was impossible to send 40,000 telegrams daily (one to each parish) without gradually extending the institution, M. Leverrier decided that the daily telegrams should be sent only to those parishes which possessed an aneroid barometer and made arrangements for exposing it to public inspection at the same place where the official warnings were posted. Having obtained ready assistance from the Association Scientifique de France, of which he is the president, M. Leverrier was enabled to make the price of the aneroids as low as 20 francs (16s.). From the beginning of the year about 800 communes purchased the barometer, and now enjoy the free transmission of weather warnings. The number is increasing at the rate of about ten a day, and it is supposed that by the end of the present year 10,000 communes will be in constant communication with the national Observatory. The public barometer is to be used by local observers for interpreting, on their own responsibility, the weather-warnings issued by the Observatory. Special meteorological organisations have already issued general rules for this purpose partially based on Fitzroy's "Weather Manual," partly on special observations. The mean pressure for all these barometers, irrespective of the altitude of the stations is to be considered 760 mm., as it was supposed impossible to establish comparisons without thus displacing the variable. Isobaric curves are drawn daily on observatory maps after each observation has undergone correction by a constant number. M. Leverrier has established a rule for the determination of that constant. When he supposes the weather will be quite settled for a few days he sends to his correspondents a telegram stating *attention, réglage*. Each correspondent is ordered to observe the barometer at 6 P.M., and on the two following days at 9 A.M. and 6 P.M. The result of these three observations in millimetres is to be sent to the observatory for the determination of the value of the correction. When that number has been found it is sent to the station through the Minister of Public Instruction. The Mayor is informed officially how many divisions the indicating needle of his aneroid must be turned, left or right, in order that the correct reading may be read.

STORM IN THE SOUTHERN AND EASTERN COUNTIES.—A storm of unusual violence swept over this part of England on Wednesday last week, rising in Hertfordshire to a fearful hurricane. At Sacombe the whole of the farm buildings occupied by Mr. Mardell were destroyed, and one of his workmen killed. Large trees were broken across, hundreds of fruit-trees uprooted and carried away, and a large wall blown down. In a wood near Little Munden, one hundred fir trees were destroyed.

AURORAS IN CANADA DURING THE PAST WINTER.—We learn from a correspondent in Ontario that auroral phenomena have been unusually rare in that part of Canada during the four months preceding the middle of March. In that region, where auroras are usually very brilliant and frequent at that season of the year, only two have been noticed during these four months.

SOLAR RADIATION IN WINTER AND SUMMER.—M. A. Crova communicates to the *Bulletin International* of the Paris Observatory, March 20, a note on some observations he made near Montpellier on January 4 and July 11, 1876, with the view of ascertaining the calorific intensity of solar radiation received at the surface of the ground in winter and summer. These two days were selected as being characterised throughout by uninterrupted brilliant sunshine, and, there being no sea-breeze, uninterrupted calorific transparency of the air, and as being as near as possible to the winter and summer solstice respectively. The results arrived at are that the heat received normally on January 4 was 0·610 of that received on July 11, and the heat received over the surface of the ground on January 4 was 0·281 of that received on July 11. These results give a measure of the inequalities produced in winter and in summer by the obliquity of the sun's rays and by the duration of the sun above the horizon, between the absolute values of the intensity of solar radiation, and between the relations of the quantity of heat emitted directly to that which is received over the horizontal surface of the ground.

HAILSTONES IN INDIA.—Dr. Bonavia, of Lucknow, sends us the following:—On April 12, 1876, at 8.30 P.M., after a great deal of lightning and thunder in the north-west, a hailstorm occurred in Lucknow. We evidently only got the edge of the storm, as it was passing towards the north-east. The fall of hail was not plentiful, but the generality of the stones were enormous. The hailstones were of all sizes, from that of peas and marbles to that of oranges, two inches and more in diameter. The largest I measured, about half-an-hour after the fall, was a flat oval, resembling a paper-weight, with a depression in the centre above and below. Its circumference measured eight inches, its long diameter 2⅞ inches, its short diameter 2¼ inches, its thickness 1¼ inches. Two others I measured had a circumference of 7½ inches and 6¼ inches respectively. Some were of the above shape; others almost spherical; others might have readily served as models of the large flat China peach, with a depression above and below. Most of them had curious mammillary projections all over the surface, which strongly reminded one of some kind of Echinus. Their internal structure can best be described by stating that it resembled exactly that of agates. It consisted of concentric layers, with a more or less wavy outline, commencing from a small nucleus. The layers varied in thickness. Some were transparent; others opaque. One large oval stone, instead of having, like others, its nucleus in the centre of its oval, had it quite at one end. The nucleus was the size of a small marble; it was spherical, but the sphere was not complete. It appeared as if a small round hailstone had first been formed, then a bit of it chipped off, and afterwards a large oval hailstone agglomerated round it, leaving it at one end of the oval. I have been informed that one hailstone, weighed some time after it fell, was four ounces in weight; another weighed 2¼ ounces.

THE WEATHER OF EUROPE.—We have received the *Monthly Weather Reports* of the *Deutsche Seewarte* for March and April, 1876, in which the main features of the weather of Europe during these months are briefly detailed by various well-known meteorologists, particular attention being given to the remarkable storm of March 12 in its progress over the Continent. The tracks of all the storms of Europe during each month are shown by maps, and tables of figures are given of the means of the various meteorological elements for Germany and parts of the continent adjoining, from which the meteorology of a ge portion of Europe could be graphically presented. We are ich gratified to receive an intimation from the *Seewarte* that in ure the *Monthly Reports* will be published regularly at the d of the second month after the one to which the Report re- es. It would be a great boon if small maps accompanied the port, showing the mean pressure, temperature, rainfall, and ection of wind, in a manner similar to what is so well done the United States of America.

BALL LIGHTNING.—A very fine display of this interesting teor was witnessed at Vence, in the south-east of France, on night of March 21–22, by M. Ed. Blanc, of which an inter- ing detailed account has just appeared in the *Comptes Rendus* the French Academy, p. 666. Toward midnight there was served, about eleven miles north-east of Vence, a large black ndery cloud, in a state of extreme agitation, and continually sing and lowering its position. At the upper part of this ud three or four balls of fire issued every two minutes, as if m the invisible centre of the cloud, diverging in all directions, l after running a course of from six to eight degrees, broke ntly with effulgent brightness. Their apparent diameter, as n at a distance of eleven miles, was about a degree. They re mostly of a reddish colour, a few, however, being of a lowish tinge, but all of them assumed a white colour in the of bursting. Their course, which was horizontal and parallel the plane of the cloud, was relatively slow, not exceeding two grees per second, and they bore a strong resemblance to mense soap-bubbles, both as regards apparent lightness and eral appearance. From time to time a discharge of lightning sed through the cloud from above downwards, followed some onds after by a dull rumbling sound. The cloud, with its fine play of fire-balls, took a course from east to west, passing ut a league to the north of Vence. The glimmering of the tning with its low dull thunderous sound continued for more n an hour, after which the sky became darker and darker; n mixed with hailstones fell, and lightning, accompanied with nder, furrowed the sky in all directions.

NOTES

HE President of the Royal Astronomical Society has ounced that the Council of that Society have determined to ance the requisite funds to enable Mr. Gill to carry out his jected expedition to the island of Ascension to measure the allax of Mars at the approaching opposition, in the expecta- that they will be aided by Government or out of the Govern- nt grant to the Royal Society. At all events the Royal ronomical Society will not allow the opportunity of making important observation to be lost. Its duty in the matter was lent, and it has not hesitated for a moment in doing it. Mr. l will embark for the island of Ascension towards the end of t month.

IR ROBERT CHRISTISON, who has been in failing health some time, has resigned the Chair of Materia Medica he University of Edinburgh, which he has held with such inction since the year 1832. Sir Robert, before being ap- nted to the Chair he has now relinquished, had filled for ten rs that of Medical Jurisprudence.

AST Sunday evening the first of a course of eight lectures to king men on science and literature was delivered at the Alban's Schools, Holborn. The lecture was by Mr. R. wdler Sharpe, of the British Museum; the subject, "Birds of y and their Geographical Distribution." Mr. Mackonochie erves the hearty thanks of all interested in the welfare of the king classes for having undertaken so liberal an enterprise.

HE Annual Meeting of the Yorkshire College of Science held at Leeds on the 16th inst. A highly satisfactory report was presented, in which it was urged that the college should now apply for a charter of incorporation. The great desirability of establishing a classical side in the college was recognised in the report and by the president, Lord F. Cavendish, and other speakers, and there is every reason to hope that in no long time the Yorkshire College will be a flourishing rival of Owens College. The munificence of the Clothworkers' Company deserves all praise and imitation; its last gift to the College is one of 10,000*l.*

DR. JANSSEN has removed his photographic apparatus from the Boulevard Ornano to Meudon, where he is establishing, in barracks given by the French War Office, a permanent physical observatory at the expense of the Government.

ON April 23 next the Paris Academy of Sciences will hold its anniversary meeting for the distribution of prizes. M. Dumas will deliver a lecture on the two brothers Alexander and Adolphe Brogniard, both of them members of the Academy of Sciences. Admiral Paris will be in the chair.

THE Paris Physical Society held its anniversary meeting on April 5. Various apparatus were exhibited, including a number of radiometers, M. Bischoff's gas engine without refrigerator, and a Mouchat reflector for utilising the heat from the sun.

IT has been decided by the Committee of the French Sociétés Savants that special warnings should be sent to the coal pits when large depressions are foreseen, in order to suggest precautions against an escape of fire-damp. Many mining engineers believe that the system will be efficacious. Experience will soon settle the question.

THE U.S. Congress having appropriated 18,000 dollars for a Commission to report on the depredations of the Rocky Mountain locusts, the Secretary of the Interior has appointed as members of the Commission Prof. C. V. Riley, Dr. Cyrus Thomas, and Dr A. S. Packard. The Commissioners have already mapped out their work for the season, and will direct their attention to insect enemies and parasites, mechanical means for the destruction of the pests, geographical distribution, agricultural bearings of the subject, anatomy and embryology, remedial measures and migrations, &c. Bulletins giving the results of the Commission's inquiries will be issued at intervals.

THE opening meeting of the Yorkshire Naturalists' Union (formerly known as the West Riding Consolidated Naturalists' Society) was held at Pontefract on Easter Monday, April 2, and proved a great success in every way. The Union is a confederation of twenty-four Natural History and Scientific Societies in Yorkshire, banded together for the purpose of holding each summer a combined series of excursions and meetings, of investigating the fauna and flora of the country, and of publishing the results. The union is divided into five sections, viz., vertebrate zoology, conchology, entomology, botany, and geology, which work on the principle of the British Association. This plan was tried for the first time at Pontefract, and so far as it went proved a decided success. The towns represented in the Union are Huddersfield (three societies), Heckmondwike, Clayton West, Barnsley, Wakefield, Ovenden, Stainland, Ripponden, Holmfirth, Liversedge, Rastrick, Mirfield, Honley, Middlestown, Paddock, Bradford, Leeds (two societies), Goole, York, Selby, and Sheffield, numbering in the aggregate nearly 1,200 members. The next meeting will be held at Wetherly, on Whit Monday, May 21.

AT the last meeting of the French Anthropological Society, a long report was read which showed that Druidism was not quite extinct in Britanny, some country people still adhering to Pagan practices in spite of the priests' exertions. It was noticed that the clergy were anxious to destroy menhirs and other similar relics. A petition has been sent to the ministry to put a stop to this iconoclastic zeal.

A WORK has just appeared in Berlin from the pen of Friedrich von Barenbach, in which the author endeavours to show that the main features of the evolution theory were partially comprehended and advocated by Herder.

THE German Ornithological Society instituted, during the past year, an extensive series of observations by means of schedules, on the dates of nest-building, appearance of the young broods, movements of migratory birds, &c. The statistics resulting from the first year's observations are now being compiled and will shortly be issued in book form.

THE following College Lectures in the Natural Sciences will be given at Cambridge during Easter Term, 1877:—Gonville and Caius College: On Organic Analysis and Elementary Organic Chemistry, by Mr. Apjohn. Christ's College: On the Elements of Electricity and Magnetism, by Mr. Chrystal. St. John's College: On Chemistry, by Mr. Main. Instruction in Practical Chemistry will also be given. On Stratigraphical Geology, by Mr. Bonney; On Elementary Geology; On Palæontology, by Mr. Bonney. Trinity College: On Electricity (continued), by Mr. Trotter; Elementary Physics (Light, &c.), by Mr. Trotter; Vertebrate Embryology with Practical work, by Mr. Balfour; Practical Elementary Biology, by the Trinity Prælector in Physiology (Dr. Michael Foster). Sidney Sussex College: On the Morphology of Cryptogams, by Mr. Hicks. Downing College: On Chemistry, by Mr. Lewis; On Comparative Anatomy and Physiology, by Mr. Saunders.

THE Trieste papers describe an extensive stalactite cavern, consisting of several galleries, lately discovered in the neighbourhood of the city.

ANOTHER valuable addition has been made to the already enormous ethnographical treasures of the Berlin Museum by the purchase of the extensive collections of the African traveller, Piaggia. The explorer, Schweinfurth calls it the best collection of the kind in existence, and unrivalled in its special department. Although much larger sums were offered by speculators, Piaggia preferred to dispose of it for 75,000*l*. to the Berlin Museum, with the condition that it should be preserved in special apartments bearing his name.

FATHER SECCHI has invented a new electric seismograph with moving smoked paper, which indicates the direction, number, intensity, duration of the shocks, and many other details of great value in connection with seismography.

THE principal article in the April number of Petermann's *Mittheilungen* is on the condition of the bed of the Pacific Ocean, based on the researches of the *Tuscarora*, the *Challenger*, and the *Gazelle*. It is accompanied by a carefully prepared and unusually clear chart, showing by a variety of tints the results which have been obtained.

THE forthcoming number of the Italian geographical journal *Cosmos* will contain an article urging that Italy ought to take a part in Arctic exploration.

IT is stated that the Berlin gorilla, to which we have referred on more than one occasion, is to be brought to London during the present season.

THE annual session of the Congress of French Learned Societies took place at the Sorbonne on April 4, 5, 6, and 7. More than 1,000 *savants* from all parts of France, mostly professors in the several academies, were registered, 300 of whom belong to the scientific sections. M. Leverrier was the president of the scientific department. The question of weather warnings raised several interesting discussions. The final meeting took place as usual on the 7th, the minister for public instruction, M. Waddington, being in the chair. Gold medals were granted to M. Allnard, of the Puy de-Dôme Observatory; M. Tisserand, astronomer to the Observatory of Toulouse; Rollin, professor at Bordeaux for meteorology; Rouville, professor at Montpellier for geology; Grand-Eury, professor at the School of Mines at St. Etienne for geology. Nine silver medals were also granted to several provincial scientific men, and a number of similar distinctions to the members of the other sections.

THE Geographical Society of Paris held last week an extraordinary meeting for the purpose of procuring funds to build a large house for its own use to be ready by the time of the next International Exhibition. A sum of 300,000 francs is necessary, and will be raised by 1,000 bonds of 300 francs each.

M. LEVERRIER has been elected President of the Association Scientifique de France for the fifteenth time. The society spent about 1,200*l*. in scientific experiments last year.

WE have received from the United States Geological Survey a Hypsometric Map of the United States and a Drainage Map of Colorado.

NEWS has been again received at Munich after a long time, from the African traveller, Dr. Erwin v. Bary. He had safely returned to Ghât from his journey into the Valley Mihero. He is the first European who has visited the hot springs of Sebarbaret, and seen the crocodile-pond. Interesting geological and geognostic results, with a collection of many hitherto unknown plants have been gained from this journey. It was very dangerous owing to the war of the Asgar with the Hogar of Tuareg, and the traveller was in constant risk of attack. The sheikh of Tuareg, Jehenuchen, 102 years old, has lost two sons, so he is not easily propitiated. The murderer of the Dutch traveller, Alexandrine Tinne, whose unhappy fate excited European sympathy, goes about freely in Ghât. Dr. v Bary will endeavour, notwithstanding the danger, to penetrate further into the country of the Tuareg, in order to prosecute his geological and botanical inquiries.

IN a recent note in *Poggendorff's Annalen* on Maxwell's electromagnetic theory of light, Dr. Frohlich finds that the application of that theory to good electric conductors leads to results which are in direct contradiction with experience. It is not, however (he considers), to be therefore wholly rejected, as the researches of Boltzmann, Schiller, Silow, and Root show that its consequences agree with experience very well in the case of dielectrics (solid bodies, liquids, and gases). And the cause of its divergence in the case of metals may probably be found in the simplicity of the theory. The processes in the interior of metals are of course more complicated than those which occur in transparent or non-conducting dielectric media. And as little as the reflection of light on metallic surfaces can be deduced from the simple undulation theory, is it possible for Maxwell's theory to represent such complicated processes.

A CORRESPONDENCE has recently been going on in the *Journal of the Society of Arts* on the suitability of the leaves of the coffee plant as a substitute for tea. There is nothing new in this suggestion, for in Sumatra as well as in Jamaica coffee leaves are "cured" in a similar manner to those of tea in China for use in the production of a beverage. In some parts of India likewise the leaves are gathered, partially dried, fermented, and finally roasted in imitation of the commercial kinds of tea. Considering the composition of coffee leaves there can be no doubt that if properly and carefully cured they might in time become of some commercial value. Whether the husk which surrounds the coffee seed could also be so utilised is another question that has been raised. This coffee husk seems to be generally used in Arabia under the name of "kishr." In a letter on this subject in a recent number of the above journal a correspondent com pares the capabilities of Ceylon as a coffee-producing country with that of Arabia, he says: "Ceylon being a damp climate and the coffee fruit succulent it is gathered when at maturity, otherwise like cherries, it would mould on the trees. It is then placed in heaps for a day or two and the pulp allowed to ferment, in which state it is removed by washing. The pulp so washed off is only fit for manure. On the other hand, the climate of Arabia being dry the fruit is allowed to ripen and drop off of itself. In this case the pulp and other coverings dry on the berry and are often not removed for months after. It is from these husks that the *kishr* is made, or, to speak more correctly, this husk is the *kishr*, a decoction of which is used generally as a beverage throughout Arabia. The parchment and silver skin of the coffee amount to a mere nothing, but the dried husk of the Arabian berry amounts on an average to twenty per cent. The Arabs make their kishr coffee or a decoction of these husks by bruising about a handful, which is put into hot water in an earthen pan, and placed over a slow fire. A few bruised cardamoms and a little dry cinnamon or ginger is added, the whole being allowed to simmer for about half an hour, when it is ready for use, and is described as a most agreeable beverage. A handful of husks thus treated yields about ten Arab coffee cups, which are about the size of two of our ordinary tea cups. The price of the dried coffee husk at Aden is about two shillings for twenty-eight pounds.

The Italian Government have granted the sum of 6,000 francs for a special investigation of the natural history of Calabria. This part of Italy is only very imperfectly known; in fact its geognosy, its fauna and flora, both present and palæontological, are a *quasi terra ignota* to scientific research. The task has been confided to Messrs. Dr. Forsyth Mayor for the Palæontology and Zoology of Vertebrata, Dr. Cavanna for Zoology of Invertebrata, Dr. D. Stefani for Geology, and Dr. Arcangioli for Botany—all very earnest and able workers. We may, therefore, look forward with confidence and interest to the results of this expedition.

The Russian Geographical Society has undertaken the publication of a most important work, being a description of the upper parts of the Oxus, of the Hindu-Kush, and Western Himalayas. The object of the publication is to collect all existing information on the peoples inhabiting the above-named countries—the cradle of the Aryan family. The information will be collected from the works of Burns, Wood, Ferrier, Cunningham, Shaw, Hayward, Abramof, Grébenkin, Kuhn, Sobolef, and Fedchenko, and also that obtained from Chinese sources by Klaproth, Rémusat, St. Jullien, Sakinf, Palladiz, &c. This compendium will be accompanied by an ethnographical map and vocabularies of local dialects, as well as by bibliographical notices scattered in many papers, especially English. The Committee intrusted by the Society with the discussion of this scheme will add to the work a general geographical sketch of the country. The work will be under the direction of Prof. J. P. Minayeff.

The same Society is now preparing a scheme for the ethnographical and anthropological exploration of the Finnish tribes inhabiting the neighbourhoods of the Volga.

At the last meeting, March 14, of the Russian Geographical Society, Lieut. Onatsévich gave an account of his geographical work during 1874 to 1876 in North-eastern Siberia and the Sea of Okhotsk. The most interesting part of his account was that devoted to the attempt he made in the clipper *Vsadnik* to reach Wrangell Land through Behring Strait. Under lat. 67° the ship met, however, with a thick impenetrable barrier of ice, and was compelled to take a westerly course. In this direction, also, she soon met with ice and was forced to return. Lieut. Onatsévich then cruised about in the open parts of the ocean, making a series of very valuable measurements of depths, temperature of water, &c. He noticed thus the existence of a warm current which, after running through Behring Strait, takes a westerly direction. A great number of very valuable maps and of profiles of the sea-bottom were exhibited during the reading of the paper.

We have received the Annual Report of the Goole Scientific Society. Some very good papers have been read at the meetings and an attempt has been made to systematically work out the natural history of the neighbourhood.

The slab of sandstone, from Corncockle quarries, with the impression of footprints, which lately came into the possession of Mr. M'Meekan, Dumfries, has just been acquired by the Museum of Science and Art in Edinburgh. This slab is an unusually interesting one, as it has the impressions of two distinct footprints on it—*Chelichnus ambiguus* and *Herpetichnus sauroplesius*—Jardine ("Ichnology of Annandale"). On none of the slabs in the collection of the late Sir William Jardine, which is now in the Museum in Edinburgh, are to be found the footprints of two different animals, although both the above-mentioned footprints occur on separate slabs.

The additions to the Zoological Society's Gardens during the past week include a Bennett's Wallaby (*Halmaturus bennetti*) from King's Island, presented by Miss E. Woollatt; a Malabar Green Bulbul (*Phyllornis aurifrons*) from India, presented by Mrs. Arabin, F.Z.S.; two Smooth Newts (*Triton tæniatus*), European, presented by Master G. L. Sclater; eighteen Red-crested Whistling Ducks (*Fuligula rufina*), four Spotted-billed Ducks (*Anas pæcilorhyncha*), a Ring-necked Parrakeet (*Palæornis torquata*) from India, a Green Monkey (*Cercopithecus callitrichus*) from West Africa, a Brown Capuchin (*Cebus fatuellus*), two Scaly Doves (*Scardafella squamosa*), a Great American Egret (*Ardea egretta*) from South America, a White-fronted Guan (*Penelope jacucaca*), a White eye-browed Guan (*Penelope superciliaris*) from South East Brazil, deposited; an Impeyan Pheasant (*Lophophorus impeyanus*) from the Himalayas, two Siamese Pheasants (*Euplocamus prælatus*) from Siam, purchased; two Alpine Marmots (*Arctomys marmotta*), European, received in exchange; a Chinchilla (*Chinchilla lanigera*) born in the Gardens.

Zöllner.—On the determination of the principal and focal points of a lens-system, by M. Hoppe.—On thermo-electric determinations of temperature, by M. Rosenthal.—On the nature of gas-molecules, by M. Boltzmann.

Beiblätter zu den Annalen der Physik und Chemie, Band i. Stück 2.—We note here a useful paper on recent experiments with the radiometer and their explanation; also a doctorate-dissertation by M. Lorentz, on the theory of reflection and refraction of light.

FROM the *Naturforscher* (February) we note the following papers: On the most refrangible part of the solar spectrum, by T. L. Soret.—On the distribution of the electric current in conductors under decomposition, by R. Lenz.—On the southern shore of the northern diluvial sea, by Herr Credner.—On the mixed occurrence of different vegetations, by Oscar Drude.—On the nature of the substance which emits light in the flames of hydrocarbons, by Karl Heumann.—On a prehistoric steppe in the Prussian province of Saxony, by A. Nehring.—On the history of Tertiary deposits in South-eastern Europe, by M. Tournouer.—On the differences in the chemical structure and in the digestion of higher and lower animals, by F. Hoppe-Seyler.—On a relation of chemical structure to the power of polarising light, by G. J. W. Bremer.—On the conduction of heat by liquids of different densities, by E. Sacher.—On the behaviour of palladium in the alcohol flame, by F. Wohler.

THE *Archives des Sciences Physiques et Naturelles* (January), contains the following original papers:—On the tendrils of climbing plants, by Casimir de Candolle (see our note on this paper).—On the origin of the ancient alluvium, by Ernest Favre.—On static electricity, by E. Mascart.—Description of *Niphargus puteanus*, var. Forellii, by Alois Humbert (see our note on this paper).—Some researches made in the physiological laboratory of Geneva; on the formation of pepsine before and after death, by Prof. Schiff.—Note on the effect of the irritation of a nerve through which a constant electric current is passing, by Dr. B. F. Lautenbach.

THE *Journal of the Russian Chemical and Physical Societies* (vol. viii., part 9, December, 1876), contains the following papers:—On the action of bromine upon acetone, by N. Sokolowsky.—Synthesis of *a* oxybutyric acid, by S. Przibytek.—On the pinacoline of methylethyl acetone, by G. Lawrinowich.—On the synthesis and properties of diallyl-carbinol, by M. Saytzew.—On the action of the iodides of ethyl and allyl upon formiate of ethyl, by the same and J. Kanonnikow.—On the synthesis and the properties of dimethylallyl carbinol, by the same and M. Michail.—Theoretical researches concerning the distribution of static electricity on the surface of conductors constituted of heterogeneous parts, by D. Bobylew.—On electric rays, by O. Chwolson.

Reale Istituto Lombardo di Scienze e Lettere, Rendiconti, vol. x. fasc. 2.—On the co-ordinates of points and of lines in a plane, and of points and planes in space (continued), by M. Casorati.—Case of mammary hypertrophy, by M. Scarenzio.—Results of observations on the amplitude of the daily oscillations of the magnetic needle in 1875 and 1876, at the Observatory of Brera, in Milan, by M. Schiaparelli.—On some differential equations with algebraic integral, by M. Brioschi.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, March 8.—"Notes on Physical Geology," by the Rev. Samuel Haughton, M.D. Dublin, D.C.L. Oxon., F.R.S., Professor of Geology in the University of Dublin.

No. I.—*Preliminary Formulæ relating to the Internal Change of Position of the Earth's Axis, arising from Elevations and Depressions caused by Geological Changes.*

In this paper the author proves the following preliminary formulæ, necessary for the further discussion of his subject:—

$$-\tan 2\theta = 935{\cdot}6\,\rho \sin 2\lambda \quad . \quad . \quad . \quad . \quad (1)$$

where ρ is the ratio of the weight of an elevated mass to the weight of the whole earth;

λ is the latitude at which the elevation takes place, and
θ is the final displacement of the earth's axis of rotation.

$$-r\theta = 14{\cdot}11\,(\cos^3\lambda' - \cos^3\lambda) \quad . \quad . \quad . \quad (2)$$

where $r\theta$ is the displacement of the pole in English miles, caused by a continental slip of 5° longitude in breadth, and lying between the higher and lower latitudes of λ and λ'.

In proving the equations the author distinguishes between three level surfaces, viz.—

1. The surface of the sea.
2. The zero surface of the solid earth.
3. The zero surface, corrected for the weight of the ocean.

The zero plane, from which the elevations are measured, is the surface of the ellipsoid similar to the sea surface, and containing the same volume as the total solid matter of the globe. It is thus found, assuming the mean height of the continents above the sea-level at about 1,000 feet, and the mean depth of the ocean at about two miles, we have, in miles,

$$x = \frac{2{\cdot}2\,L}{W + L}.$$

where x is the height of the zero plane above the present mean sea-bottom, and L, W are the areas of land and water;

$L = 52$ millions of square miles.
$W = 145$,, ,,

Substituting we find—

$$x = 0{\cdot}58 \text{ mile}.$$

The zero plane, therefore, or original surface of the solid earth, before it became wrinkled by geological forces, lies at a depth of 1·42 mile below the sea-level. In using the equations we must therefore write—

Elevation = + 1·62 mile (continent).
Depression = − 0·58 ,, (ocean).

In calculating the motion of the pole caused by the ocean excavations, the weight of the sea water must be considered, and, by chance, it happens that the weight of the sea-water somewhat more than counter-balances the weight of the surface-rock excavated; so that the depression of the ocean-bottoms of the earth beneath the zero plane have had little or no effect in shifting the position of the pole.

Assuming 1·026 and 2·75 as the densities of sea-water and surface-rock, we have for the excess of weight of water added above that of rock excavated; expressed in depth of rock, in miles—

$$\frac{2 \times 1{\cdot}026 - 0{\cdot}58 \times 2{\cdot}75}{2{\cdot}75} = 0{\cdot}17 \text{ mile}.$$

The introduction of the weight of the sea will thus give us (raising the zero plane by 0·17 of a mile)—

Elevation = + 1·45 mile (continent),
Depression = 0·00 ,, (ocean).

No. II.—*On the Amount of Shifting of the Earth's Axis, already caused by the Elevation of the existing Continents.*

Having shown in the preceding note that the motion of the earth's axis caused by the geological wrinkling of the earth's surface depends (in consequence of the weight of the sea-water) only on the continents, it remains to calculate the numerical amount of change of axis produced by each of the existing continents.

For this purpose the author selects the following meridians for the co-ordinates Y and X of the motion:—

	°	
Greenwich	0	+ Y
Rangoon	90	− X
Behring's Strait	180	.. − Y
Yucatan	270	. + X

Reckoning the longitudes eastward, round the whole circumference of the earth, the equation (2) gives—

$$r\theta = -\,14{\cdot}11\,(\cos^3\lambda' - \cos^3\lambda),$$

in which the meridian of each 5° of longitude is used, λ' and λ being the lowest and highest degrees of latitude of the land on each meridian.

The expression $\cos^3\lambda' - \cos^3\lambda$ is found by observation on the globe, and resolved into its components X and Y, regarding the North Pole as the axis moved.

The equation (2) is then used (by quadratures) to determine the total effect of each continent taken separately. The tables of quadratures are given in the paper, and the final results are—

Displacement of North Pole caused by each continent.

	Towards Greenwich. Mile	Towards Behring's Strait. Mile.	Towards Yucatan. Mile	Towards Rangoon. Mile.
Europe and Asia	—	58·7	199·4	—
Africa	—	26·9	—	1·7
North America	15·2	—	—	105·5
South America	19·9	—	35·1	
Australia, &c.	—	30·2	—	30.2

The power of Europe and Asia in moving the pole is partly due to the extension of this continent along the parallel of 45°, which is the most effective latitude. The actual effect produced by Europe and Asia was not much less than that of our imaginary continent (Note I.), occupying one eighth part of the surface of the globe.

The foregoing results are positive, and the motions of the pole indicated must have actually occurred when the existing continents were formed. But simultaneously with these elevations depressions must have gone on elsewhere, continents disappearing beneath the sea and sinking to the zero plane, while other continents were rising. It is to be noticed that although the excavation of the sea-bottom to its present depth below the zero plane, corrected for the weight of the ocean, produces no motion in the pole, yet that the depression of a continent down to the zero plane produces a motion of pole equal and opposite to that produced by its elevation. I have calculated the hypothetical effects of the depression of imaginary continents occupying the sites of the present Pacific Ocean, with the following results:—

North Pacific Ocean (depressed).

Towards Yucatan . ... . . 3·4 miles.
Towards Behring's Straits . . 250·6 „

South Pacific Ocean (depressed).

Towards Rangoon . ... .. 156·2 miles.
Towards Greenwich ... . . . 238·2 „

The total effect of a continent equal to the North Pacific would be—

$$\sqrt{X^2 + Y^2} = 250{\cdot}6 \text{ miles.}$$

$$\frac{X}{Y} = \tan(\phi),\ \phi = 0^\circ\ 47' \text{ E. of } 180^\circ.$$

The total effect of a continent equal to the South Pacific Ocean would be—

$$\sqrt{X^2 + Y^2} = 201{\cdot}8 \text{ miles.}$$

$$\frac{X}{Y} = \tan(\phi),\ \phi = 23^\circ\ 17' \text{ E. of Greenwich.}$$

Geological Society, March 21.—Prof. P. Martin Duncan, F.R.S., president, in the chair.—William B. Coltman, William James Grimshaw, and Alexander Ross were elected Fellows of the Society.—The following communications were read:—On the strata and their fossil contents between the Borrowdale series of the North of England and the Coniston flags, by Prof. Robert Harkness, F.R.S., Cork, and H. Alleyne Nicholson, F.R.S.E., Professor in St. Andrew's. The object of this paper was the investigation of the strata between the great volcanic series of the Lake-district, the Borrowdale rocks, and the sedimentary rocks called Coniston Flags by Prof. Sedgwick. The Borrowdale series, the Green Slates and Porphyries of Sedgwick, are underlain by the Skiddaw Slates, forming the base of the Silurian series, and equivalent in age to the Arenig rocks of Wales, according to their fossil contents. The Borrowdale rocks consist of ashes and breccias, alternating with ancient lavas, and are partly subaerial, partly submarine. They contain no fossils except in a band of calcareous ashes near the summit of the group, which is followed by the Coniston Limestone, with or without the intervention of a bed of trap. The fossils are of Bala types. Sometimes this band is recognisable, with no traces of fossils except cavities filled with peroxide of iron. The authors regard this as proving the prevalence of volcanic activity in the Lake District up to the later portion of the Bala period. The deposits specially discussed in the paper sent lie, apparently quite conformably, upon the Borrowdale rocks, and are grouped by the authors as follows, in ascending order:—(1) Dufton Shales; (2) Coniston Limestones and Shales; (3) Graptolitic Mudstones or Skelgill beds; (4) Knock beds. The "Dufton Shales" are a well-marked but locally distributed group of muddy deposits, especially well developed in the Silurian area underlying the cross Fell range, where they are seen in four principal exposures, and their thickness probably exceeds 200 feet. They are richly fossiliferous. The "Coniston Limestone" has long been recognised as the best-defined division of the Lower Silurian rocks of the north of England. The "Graptolitic Mudstones" overlie the Coniston Limestone, wherever the summit of the latter is to be seen. Besides Graptolites, they contain many other fossils, including Corals, Brachiopods, Cephalopoda, and Crustaceans; and from the consideration of the whole fauna, the authors are led to believe that the position of these deposits must correspond either with the highest beds of the Bala series or with the lower portion of the Llandovery group. The Graptolitic Mudstones are succeeded by the "Knock beds," so called from their great development in Swindale Beck, near Knock. Wherever they occur they consist chiefly of pale green, fine-grained slates, very ashy in appearance, and presenting many dendrites, and frequently crystals of cubic pyrites. There is no evidence of unconformity between them and the underlying Mudstones.—On a new area of Upper Cambrian Rocks in South Shropshire, with the description of a new fauna, by C. Callaway, F.G.S. The purpose of the author was to prove that certain olive, micaceous, thin-bedded shales exposed at Shineton, near Cressage, and covering an area of eight miles in length by two in the greatest breadth, which had been mapped as Caradoc in the survey, were of Tremadoc age. They were seen clearly to underlie the Hoar Edge Grit, the lowest beds in the district, with Caradoc fossils; and no rock distinctly underlying the shales could be detected. The evidence for their age was chiefly palæontological. With the exception of *Asaphus homfrayi*, a Tremadoc form, the species are new. Genera such as *Olenus*, *Conocoryphe*, *Obolella*, and *Lingulella* suggested a very low horizon, but two Asaphoid forms (though not typical *Asaphi*) pointed in an opposite direction. Corroborative evidence was found in a correlation of the shales at Shineton with the *Dictyonema*-shales at Pedwardine and Malvern.

Anthropological Institute, April 10.—Mr. John Evans, F.R.S., president, in the chair.—The president exhibited two stone instruments from Sandoway District, North Burmah.—Some flint arrow-heads, scrapers, &c., from Ditchley, Oxon, were exhibited by Capt. Harold Dillon.—A paper on some rude stone monuments in North Wales was read by Mr. A. L. Lewis. The chief point of interest being the existence, hitherto, we believe, unnoticed, of single outlying stones on the north-east of the circle near Penmaunmawr which is thus shown to conform to and to lend further confirmation to the rule found by him to exist generally in British circles of a special reference to the north-east by outlying stones or otherwise.—The director read a paper by the Rev. W. Ross, F.S.A. Scotland, on some curious coincidences in Celtic and Maori vocabulary.—Papers were also read by the director, on Australian aboriginal languages, traditions, &c., by Messrs. Greenway, McDonald, Rowlay, Malone, and Dr. Creed, communicated by Mr. William Ridley, M.A., through the Colonial Office.—Col. A. Lane Fox, F.R.S., Messrs. Hyde Clarke, Walhouse, Moggridge, Park-Harrison, and the president, took part in the discussion.

Royal Microscopical Society, April 4.—H. C. Sorby, F.R.S., president, in the chair.—The following papers were read:—On the variability of the chlorophyll bands in the spectrum, by Mr. Thomas Palmer, in which he described the various effects produced by solutions in alcohol, &c., and by treatment with acids and alkalis.—On the mineralogical constitution and microscopical characters of the whetstones of Belgium, by M. l'Abbé Rénard, of Louvain.—On the microscopical character of Krupp's "silicate cotton," by Mr. H. J. Slack, and on the lower Silurian lavas of Cumberland, by Mr. Clifton Ward, in which it was shown that the difference between ancient and modern lavas was not so great as was usually supposed, their actual constituents being very nearly the same, though appaparently they differed owing to conditions which had produced metamorphosis in the earlier series.

Physical Society, March 17.—Prof. G. C. Foster, president, in the chair.—Mr. W. S. Seaton was elected a member of the society. Mr. Spottiswoode exhibited some experiments on the stratification of the electric discharge in vacuum tubes, and described his attempts to produce the effects as obtained by Mr. Gassiot and Mr. de la Rue, with batteries of several thousand cells, by means of the induction coil. An account of his experiments has already been given in our pages.—Capt. Abney, R.E., then read a paper on the photographic image, prefacing it by a brief account of the two theories, the chemical and the physical, which are held regarding it. On the former, a molecule of bromide of silver is split up into the latter of which is absorbed; and on the latter theory, light acts mechanically on the molecule, shifting the positions of the atoms. Poitevin has done much to confirm the former of these by placing a film of silver iodide in contact with a silver plate, when he succeeded in obtaining an image on the film of iodide and one on the silver plate produced by the liberated iodine. Capt. Abney has performed the following experiments: a portion of a dry plate which had been exposed, was wet with a sensitive collodion emulsion of bromide of silver, and developed by the alkaline method; the films were separated from the glass and from each other by means of gelatinised paper, and were found to bear images: and the same result was obtained when the emulsion was added after exposure, development, and fixing. These experiments entirely disprove the supposition that only those molecules acted on by light are reduced. If the two films be separated by a thick layer of albumen, the lower picture develops as a negative, and the upper as a positive. Capt. Abney is now engaged in an attempt to determine the attraction exercised by the sub-bromide, and this it is hoped, will do much towards the complete solution of the problem of the photographic image.—Mr. O. J. Lodge proposed a modification of Mance's method for determining the intensity of an electric current. This method, of which Wheatstone's Bridge is an application, depends upon the fact that if three conductors be united at a point *A*, and their extremities *B C* and *D* be united by three wires, *B C*, *C D*, *D B*, the resistance of *B C* will be independent of that of *A D* if *A B* is to *A C* as *B D* is to *C D*. In the arrangement proposed by Mr. Lodge, four wires are joined in the form of a square, and the circuit can be completed across one diagonal by means of a key, and in the other diagonal is included a condenser and a galvanometer, with a long fine wire. The greatest sensitiveness is obtained when the resistances in the four sides are equal. A great advantage of this method consists in the fact that it is equally applicable to the measurement of small and great resistances. Mr. Lodge then showed a modified form of Daniell's cell, capable of giving a constant current for a considerable period. A glass cell half filled with dilute sulphuric acid, contains two vertical glass tubes one of which, open at both ends, is traversed by a zinc rod, while the other is closed at its lower end, and contains cupric sulphate, from which rises a copper wire. The portion of the glass tube projecting above the acid is sufficiently moist to enable the current to traverse its surface while the zinc sulphate is prevented from reacting on the copper.

Victoria (Philosophical) Institute, April 18.—Rev. R. Thornton, D.D., vice-president, in the chair.—A paper on recent Assyrian research, and the light it threw on civilisation at the time of Abraham, was read by the Rev. H. G. Tomkins.

MANCHESTER

Literary and Philosophical Society, March 20.—Mr. E. W. Binney, F.R.S., president, in the chair.—On the action of sea-water upon lead and copper, by Mr. William H. Watson, F.C.S. Communicated by Dr. R. Angus Smith, F.R.S.—Note on the Upper Coal Measures of Canobie, Dumfriesshire, by Mr. E. W. Binney, president, F.R.S.—Losses and gains in the death-toll of England and Wales during the last thirty years, by Mr. Arthur Ransome, M.D.

PARIS

Academy of Sciences, April 9.—M. Peligot in the chair.—The following papers were read:—On the possibility of deducing from one only of the laws of Kepler the principle of attraction, by M. Bertrand.—Some of the fundamental data of thermo-chemistry, by M. Berthelot. He deals with the heat of formation of sulphurous acid and the compounds formed by bromine and iodine with hydrogen and oxygen.—On a theorem relative to the expansion of vapours without external work (continued), by M. Hirn.—Morphological relations between the antheridia and the sporules developed in the verticillate ramification of a particular form of *Batrachospermum moniliforme*, by M. Sirodot.—Substitution of chlorophyll for salts of copper ordinarily used in preparation and conservation of fruits and green vegetables, by M. Guillemare. This is based on three facts: (1) the chlorophyll of vegetables disappears in boiling; (2) vegetable fibre and its feculant matter put in contact, through washing, with dissolved chlorophyll, is saturated with it near 100;° (3) vegetables wholly or half saturated with chlorophyll, in washing, thenceforth retains, in boiling, this green matter.—On the presence of zinc in the bodies of animals and in plants, by MM. Lechartier and Bellamy. A man's liver weighing 1,780 grammes contained 2 centigrammes of oxide of zinc; 913 grammes muscular tissue of ox containe 3 centigrammes; 1,152 grammes of hens' eggs 2 centigrammes Zinc was found also in grains of wheat, American maize, barley winter vetches, and white beans; while beet, the stems of maize green clover and its seed did not contain it in perceptible quantity. These facts have an important bearing on toxicologica researches.—Discovery of a Gallo-Roman port and a Gaulish port, dated by a study of the layers of mud, in the neighbourhood of Saint Nazaire, by M. Bertrand. M. Gervais added some details.—Reconstitution of French wine-growing by sulphocarbonate of potassium, by M. Mouillefert.—Results obtained in the treatment of phylloxerised vines by alkaline sulphocarbonates applied by means of the distributing pale, by M. Gueyrand.—Note on a new mode of manufacture of sulphides, carbonates and alkaline sulphocarbonates, by M. Vincent. He utilises the reactions produced in making beet sugar to prepare sulphide of barium. This, mixed with sulphate of potash, gives by double decomposition sulphate of baryta and sulphide of potassium, and the latter, submitted to the action of carbonic acid gives carbonate of potassium. M. Vincent extends his method to manufacture of sulphocarbonate, which he can obtain at 50 franc the kilogramme instead of 120, which it has lately cost.—List of thirty new nebulæ discovered and observed at the observatory of Marseilles, by M. Stephan.—On a modification in the employment of electricity considered as agent of galvanic deposits and chemical decompositions, by M. Thenard. Instead of having only one bath with the two anodes, the conditions being those of small electric resistance and maximum effort, he has several, connecting their anodes like the elements of a battery connected for tension. The quantity of deposited copper increases with the number of baths.—New method for establishing the equivalent in volumes of vaporisable substances, by M. Troost. Given an inclosure filled with vapour of hydrate of chloral, then if the water is always combined, the atmosphere will behave as if it were dry in presence of a body capable of yielding water; if the water is simply in mixture the atmosphere will act as if saturated. Now the former occurs, and this confirms M. Dumas' hypothesis as against that of M. Naumann The method may have other applications.—On the oxidation of metallic sulphides, by M. De Clermont.—Decomposition of liqui organic substances by the electric-spark, with production of fundamental carburets of hydrogen, by M. Truchot.—On the existence of veins of bitumen in granite in the environs of Clermont Ferrand, by M. Julien.—New experiments on the toxical action attributed to copper and to substances containing copper in combination, by M Galippe. These confirm form conclusions.—Note on the first phenomena of the developme of sea-urchins (*Echinus miliaris*), by M. Giard.—M. Chasl presented (from M. Riccardi) the first part of a work called *Biblioteca matematica Italiana*, which is to be a bibliography all Italian works on mathematics from the earliest times to th beginning of the nineteenth century.

THE GEOLOGY OF THE LAKE COUNTRY

The Geology of the Northern Part of the English Lake District. Memoirs of the Geological Survey of England and Wales. By J. C. Ward, F.G.S. (London: Longmans, 1876.)

WHEN the staff of the Government Geological Survey first entered upon their labours, the Director, Sir H. de la Beche, saw very clearly that the work with which he was entrusted would be very imperfectly performed if he limited himself to the publication of geological maps and sections alone. He therefore gave orders that whenever from time to time sufficient portions of the country had been examined, descriptions of their geology should be issued, in which such details as could not be inserted on the maps should be recorded, and questions of theoretical and practical interest should be discussed. The Memoirs published in compliance with this regulation by Sir Henry himself and his coadjutors Phillips, Ramsay, Forbes, Hooker, Playfair, and others, are lasting witnesses both of the wisdom of the regulation itself and of the skill and energy with which the work of the Survey was carried on.

Then there came a time when the publication of explanatory memoirs was for a while dropped altogether, and so it happens that in many districts of the highest interest and importance, as for instance the Dorsetshire Coast, the Carboniferous Limestone country of Derbyshire, and the great coalfields of Derbyshire and North Staffordshire, we miss those descriptions which are elsewhere such a boon to the geological student, and the work of the Survey becomes shorn of half its usefulness.

When the publication of descriptive memoirs was resumed they took the form of small pamphlets, good as far as they went, but of the slenderest dimensions and almost niggardly in their details, in which for instance the geology of Charnwood Forest is dismissed in three pages, and eighteen pages are considered enough for the illustration of the important coalfield of Wigan and St. Helens. It is impossible to avoid contrasting these scanty bundles of notes with the exhaustive detail and broad scientific treatment that characterise the earlier publications of the Survey.

Of late years, however, there has been a welcome return to the old traditions which has resulted in the production of the admirable monographs on the Geology of Rutland, the Weald of Kent and Sussex, and the London Basin. The memoir now before us on the "Geology of the Northern Part of the English Lake District" is fully entitled to take rank with these latest productions of the Survey. It is curious, however, to find in it what looks like evidence of the existence in certain quarters of a sort of hankering after the vastly inferior class of memoirs which formed for a long time the staple of the Survey issues. In his Introductory Notice the Director, Mr. Bristow, thinks it necessary to apologise for the length to which the description has run, and to give a reason why the work "has been allowed to exceed the usual limits to which the explanations of such small areas as those comprised in quarter sheets have hitherto extended." We can assure the Director that he may make his mind easy on this point, for no one possessing even the most limited geological tastes and acquirements will find the book in any way too long; the only fear will be whether, from anxiety to cut down the memoir to regulation size, details and explanations that can be ill spared may not have been sacrificed. It will be an evil day for the Survey when it exchanges the scientific zeal which has hitherto so honourably distinguished its members, for a spirit in which devotion to official routine comes first and a desire for the spread of geological knowledge holds a subordinate place.

But *absit omen!* and a work like this furnishes good grounds for the hope that it never will be so. It might have been thought that the labours of Sedgwick and other eminent geologists had left little for their successors to do among the mountains and dells of Cumbria, but Mr. Ward has shown that there are many points yet remaining to be cleared up, and he has brought to bear on their elucidation the more refined methods and superior accuracy of the geology of the present day. He has investigated and admirably illustrated the microscopic character of many of the rocks; and though it is scarcely possible in the present state of our knowledge to determine exactly the geological bearing and value of some of his results, there are others whose great importance is even now obvious. In the case, for example, of some rocks which the naked eye cannot distinguish in hand specimens from flinty traps, microscopic examination confirms the conclusion arrived at on broad geological grounds that they are highly altered volcanic ashes. The descriptions of other altered rocks throw great light on the difficult question of metamorphism. The Skiddaw district is peculiarly interesting on account of the close parallel which its rocks present to the metamorphic beds of the Pyrenees so admirably worked out by Fuchs. We cannot but regret, however, that the papers which Mr. Ward has contributed on this subject to the Geological Society have not been more fully embodied in the present volume; a Survey memoir should aim at being a complete *vade mecum* for the local geologist, and it is not every one in the wilds of Cumberland who has access to the pages of the *Quarterly Journal* of the Society.

Perhaps the most generally interesting features in the work are the account of the volcanic products with the localisation of the vents from which they were discharged, and the description of the glacial phenomena of the district. The author has with great skill used his experience of modern volcanic countries to make the old ruined Cumbrian volcanoes tell the tale of their whereabouts and performances. The glacial phenomena are worked out with singular thoroughness, and strong evidence is brought forward in favour of the "great submergence" on which Mr. James Geikie has thrown such considerable doubt.

It is dangerous for an outsider to differ from an observer who has spent so much time and spent it so well in working out the geology of a particular district, but there are two points, and two points that to a certain extent hang together, on which we must confess we are not altogether satisfied. These are the absence of any unconformity between the Skiddaw slate and the overlying Volcanic Series, and the existence of the chain of faults which everywhere separates the two groups. Mr. Ward relies on the fact that beds of volcanic ash occur on the upper part of the Skiddaw slate. This shows that volcanic activity began before the deposition of the Skiddaw slate was completed, but it scarcely proves that no upheaval and denudation attended the commencement of the volcanic outbursts. Volcanic activity and elevation are so intimately connected that it may well be that the early discharges were the heralds of an upward movement of the rocks. The author indeed admits thus much, and believes that slow upheaval did attend the advent of volcanic activity, and that the bulk of the volcanic products are terrestrial. We should be inclined to go further, and to suggest that a long period may have followed the first volcanic outbreaks, during which the Skiddaw Slate was crumpled up and brought within the range of atmospheric denudation. Any volcanic deposits formed during this interval would of course be removed by denudation. By the time the volcanoes had reached their full growth, a land-surface, diversified by hill and valley, may have been produced, and when the volcanic products were showered down on this uneven floor, heaps of ash and sheets of lava would every here and there abut against banks of Skiddaw Slate, in a manner that produces to us a deceptive appearance of faulting. We give this hint merely for what it is worth, and have no wish to throw any doubt on the possibility of the boundary being such as the map represents it to be; indeed, instances about which there can be little doubt might be quoted, where two groups of rocks are parted by just such a jagged line of faults as that which Mr. Ward has drawn in the present case.

The book is liberally illustrated by maps and sections, and the bibliographical list of works relating to the geology of the district is a most welcome addition.

We cannot but feel that a great mistake has been made in the map which the memoir is intended to illustrate. As a typographical piece of work it is unsurpassed, but it is its excellence in this respect that makes it unsuited for geological purposes. The reliefs of the surface are admirably brought out by the hill shading, but in order to produce the desired effect, the hatching has been made so dark that in many places it is difficult, if not impossible, to distinguish the geological colouring and signs. The Ordnance Survey issue in the northern counties another set of one-inch maps, with contour-lines in the place of hill-shading, and had one of these been employed to receive the geological colouring, the very serious difficulty just mentioned would not have arisen. We have no hesitation in saying from actual experience in the use of both classes of maps, that had plain copies been used, the value of the map would have been well-nigh doubled.

Before concluding we would remonstrate with the author on his italics; the book bristles with them, till it reminds one of a school-girl's letter. This indiscriminate use of emphasis destroys that repose which is one of the chief charms of style, and in a very large number of cases there is no necessity for it, for the meaning would be perfectly clear without the adventitious aid of a variation in the type.

A. H. G.

VENNOR'S "ACCIPITRES OF CANADA"

Our Birds of Prey; or, The Eagles, Hawks, and Owls of Canada. By Henry G. Vennor, F.G.S. With Thirty Photographic Illustrations by W. Notman. 4to, pp. i.-viii., 1-154, plates i.-xxx. (Montreal: Dawson Brothers; London: Sampson Low and Co., 1876.)

SO little is really known respecting the ornithology of Canada that one cannot but welcome with great satisfaction such a substantial addition to our knowledge as has been given by Mr. Vennor in the present work. As a geologist employed on the survey of Canada the author has enjoyed unrivalled opportunities for studying many of the birds in the field, and although the fulfilment of his duties has prevented him from devoting his entire attention to ornithology, yet he has evidently kept his eyes open, and the work before us embodies the result of thirteen years' observation. It is to be regretted that at present Mr. Vennor has only written on the birds of prey, and it is to be hoped that he will continue his labours on the rest of the birds of Canada. The species themselves included in the present work are twenty-seven in number, and on all these very complete information seems to be given respecting their distribution in the Canadian dominion, including not only a *résumé* of the hitherto published facts, but giving also a large amount of new information. Excellent accounts of the habits of the birds are added, chiefly from the personal observations of the author himself, and each article concludes with the description of the species in which the colours of the soft parts are always given; this is a feature often omitted by Messrs. Baird, Brewer, and Ridgway in their recently-published "History of North American Birds." Mr. Vennor does not include among the species fully treated of, the Common Turkey Buzzard (*Rhinogryphus aurea*), which hardly extends to Canada in its northern range, though it is a regular summer visitant to "the extensive flats near Chatham and Lake St. Clair," while further to the westward it occurs frequently on the line of the forty-ninth parallel. Of the Barn Owl (*Strix flammea*), Mr. Vennor says that there is no authentic record of its occurrence in Canada, but we notice in Mr. Bowdler Sharpe's paper on the "Geographical Distribution of Barn Owls," published in Mr. Rowley's *Ornithological Miscellany*, that the British Museum contains a specimen from the neighbourhood of Toronto, collected near that city by Mr. James Whitely, who has resided there for some years, and has sent many interesting birds to this country. Other small points might also be alluded to in which we think further consideration on the author's part desirable, such as the relations between *Falco candicans* and *F. labradorus*, *Circus cinereus* and *C. hudsonius*, &c. We are not disposed to quarrel with the photographic illustrations to the book, which are excellent specimens of photography, although this mode of illustrating scientific works does not commend itself to our fancy. At any rate, however, a good photograph is better than a bad plate, especially in a work like the present, where the author's chief aim has been to give such a figure as may render the identification of the species more easy to the student, his object being, in his own words, "a work of practical utility, not a mere exhibition of pretty photographs." As a new worker in the vast field of ornithology we welcome Mr. Vennor, and only trust that many years will not elapse before he gives us a second instalment on the birds of Canada.

OUR BOOK SHELF

The Use of the Spectroscope in its Application to Scientific and Practical Medicine. By Emil Rosenberg, M.D. (New York: Putnam, 1876.)

THIS is an essay on the use of the spectroscope which obtained the Stevens triennial prize for 1876, awarded by the College of Physicians and Surgeons.

It treats mainly of the absorption spectra of blood in its normal state and after being acted upon by other substances. The first chapter gives a very short account of the optics of the spectroscope, which the author does not pretend to treat fully; then follows a short notice of the emission spectra of the metals. The absorption bands of oxyhæmoglobin (scarlet cruorine) and their change to the one reduction band of hæmoglobin (purple cruorine) by the abstraction of oxygen, discovered by Prof. Stokes, then comes in for recognition. The remainder of the book is chiefly on the absorption spectrum of blood with reference to forensic medicine and its spectrum after the introduction of foreign matters and gases.

It appears from the numerous references that the author has compiled this essay from books and papers rather than from observation, and the authors referred to are with few exceptions Germans. We think the book is well suited for the perusal and reference of the medical profession and others taking up this special subject.

Journey in the Caucasus, Persia, and Turkey-in-Asia. By Lieut. Baron Max von Thielmann. Translated by Charles Heneage, F.R.G.S. Two vols. Map and Woodcuts. (London, Murray).

BARON THIELMANN'S journey, which was made in the year 1872, embraced all the Caucasian region, much of the western shore of the Caspian Sea, with the long stretch of country between Tabrez, Hillah, and Beyrout. Though this is a region about which a good deal has been written, the Baron's narrative will be found to contain a considerable addition to our knowledge. His observations on the people and the antiquities of the countries traversed are especially valuable, while the work contains as well much interesting topographical and geographical information. The Baron is an exceedingly pleasant travelling companion, and as Mr. Heneage has made a thoroughly readable translation, the work will be found of value both to the stay-at-home reader and as a guide to the intending tourist.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.]

Structure and Origin of Meteorites

IN the abstract of Mr. H. C. Sorby's lecture "On the Structure and Origin of Meteorites," given in NATURE, vol. xv., p. 495, in reference to the subject of glass globules observed by the lecturer in certain meteorites, the condition in which glassy particles given off by terrestrial volcanoes occur, is contrasted with that produced artificially in furnace slag by the action of a strong blast of hot air or steam. In the furnace slag "pear-shaped globules, each having a long hair-like tail," are described as being formed, whereas in the case of volcanoes the glassy particles are said, when given off, to be immediately solidified on entering the atmosphere, [illegible] as mere fibres, as Pele's hair, or more or less [illegible] like pumice dust. In fact, the formations in the two instances are closely similar. In the crater of Kilauea, in the Island of Hawai, wherever the well known Pele's hair is in process of formation, long-tailed pear-shaped globules are formed in abundance, and a large proportion of the "hairs" are to be found with larger or smaller globules in connection with their ends.

I saw the formation of Pele's hair in two places in the crater.

In the one instance the formation occurred at the margin of one of the [illegible] of molten lava. The lake was inclosed by a range of low cliffs, against the bases of which the waves of the extraordinarily fluid lava were constantly surging, being kept in perpetual commotion by the violent discharge of gases from beneath. The waves splashed up against the cliffs and spray and large drops were thrown into the air, and on the leeward side of the lake were driven by the wind over the top of the cliff so as to fall on a level platform of rock which was even with its summit.

The platform appeared as if melted pitch had been splashed out all over it, and was covered with small masses of pitch-like looking lava. Those of the masses which had evidently completely solidified before reaching the platform in their fall were pear-shaped, whilst in other cases where hardening had not been complete, the elongate masses falling in the soft condition had become flattened into irregular shapes, which showed more or less evident traces of the coiling of the masses as they fell.

All the masses had tails, some short and spike-like, others long and hair-like, and there was every gradation between stiff fine rods of transparent lava and the perfectly elastic hair of which a handful could readily be raked together with the fingers on the platform in a very short time.

In the other instance, the Pele's hair was seen by me around one of the small hollow cones or lava fountains which are constantly formed in the crater. The cone was not active at the time I saw it. It was surrounded with the small lava masses thrown out by it and forming a deposit closely similar to that formed at the margin of the lake, except that numerous larger lumps occurred amongst the smaller ones.

Very striking objects in the crater are large bubbles which have been formed in the lava when molten by the escaping gases. The surfaces of the bubbles are composed of extremely thin transparent laminæ, which look just like thin green bottle glass. Such bubbles are encountered at almost every step on the floor of superficially solidified lava, on which the visitor walks in the crater.

A remarkable peculiarity of the Hawaian lava is its extreme fluidity when in the molten condition. This property has brought about the unusual form of the great mountains of the island composed of it, which have so gradual a slope that the observer can hardly credit their great height when viewing them from the sea.

On the Simplest Continuous Manifoldness of Two Dimensions and of Finite Extent

IT could hardly fail to be instructive if Mr. Frankland would explain the following obvious paradox in his theory (NATURE, vol. xv., p. 515). Let two "straight lines" XOX', LOL', make an angle XOL other than a right angle, and consider the shortest line PN from a moving point P in LL' to XX'; from the assumptions, this is a "straight line" perpendicular to XX'. As P moves from O along OL, it will by and by, according to the theory, be at L'; that is, on the other side of XX', if our "straight lines" are "of the same shape all along." Now, t put it algebraically, how does the perpendicular come to chang sign? It does not pass through infinity, for the manifoldness is o finite extent: it does not vanish except when P is at O; an though it is conceivable in itself that N should travel to a maximum distance along OX and come back again while P moves on yet this contradicts our principal assumption, for each perpendicular will then have two points in common with LL'. Is door of escape to be found through any interpretation of "continuous"? Or, while "there is nothing self-contradictory i the definition," is there something in it contradictory of th superposition-principle by means of which its consequences ar worked out?

The theory is partly exemplified upon the surface of revolutio got by bending a *hemisphere* till it closes up. Correspondenc is pretty close as to points in the equator and the simpler figure symmetrical to it.

Hadley, Barnet

Non-Amphibious Batrachians

ON calling the attention of the Rev. L Blomefield (formerly Jenyns) to the interesting article in NATURE (vol xv p 491) of a tree-frog which produced its young without their passing through the tadpole stage, he has been good enough to allow me to quote a MS note to his work, "Observations on Natural History," p 203, which may be useful to persons interested in the matter It refers to a colony of toads which lived in a cellar of Bottisham Hall, Cambs, and without access to water It runs as follows —

"See some remarks by Mr Lowe in *of Natural History* (No 64, April, 1853 p 341), tending to show that under certain circumstances where the parent animals have no access to water, the reproduction of the toad and frog takes place without the intermediate stage of tadpole. He mentions instances of their depositing spawn in cellars and young toads being afterwards observed Such was probably the case with the toads in the cellars of Bottisham Hall, though I never observed the spawn myself" "See further remarks by myself on this subject in *Annals of Natural History*, vol xi 2nd series, p. 482 See also NATURE, vol vii p 401, on 'The Adaptation of Animals to External Conditions'"

The following passage occurs in the Rev L Jenyn's "Manual of British Vertebrate Animals,' p 304 5, and bears upon the same phenomenon

"*Triton punctatus*, Common Eft

"This species is subject to considerable variation It is also found on land, a circumstance which tends in some degree to alter its characters In such specimens the skin loses its softness becoming opaque, and somewhat corrugated The membranes of the back and tail entirely disappear, causing this last to appear narrower and thicker in proportion to its depth The toes from being flattened become rounded, the colours are also everywhere more obscure In this state it is the *La* [illegible] of Sheppard and Turton, and considered as a distinct species by these and other authors. I am, however, perfectly satisfied that it is identical with the aquatic kind, and that all its peculiarities may be traced to the change of circumstances under which it is placed . I suspect that the period of time during which this species remains in the larva state is subject to much variation, and that if anything occur to oblige the young to exchange their native element for another before they would attain their perfect form, the gills are cast prematurely to enable the animal to accommodate itself to its new circumstances The fact of such small specimens as Sheppard has noticed being found on land is indisputable, but I think I have generally observed some traces of there having [illegible] gills at no very long period before"

GEORGE HENSLOW

Morphology of "Selaginella"

In consequence of my not having expressed myself sufficiently fully, Prof Thiselton Dyer somewhat misapprehends my remarks respecting Selaginella and Carex to which he is good enough to reply in NATURE (vol xv p 459), and I shall be glad of an opportunity of explaining the nature of the comparison that I drew between the reproductive organs in these two genera

I purposely avoided asserting that the spike of the one was the "homologue" of that of the other and I thought that my change of expression—"instead of regarding as the homologue we compare it" would sufficiently indicate that I was not raising the question of exact homology at all, but merely comparing the male and female structures of Selaginella (each as a whole) with those of a unisexual-flowering plant I regret that I did not state this in explicit terms.

Notwithstanding what has been written by Sachs and others, it appeared to me that the homology between the reproductive organs of Cryptogams and Phanerogams could not be regarded as yet so completely settled as to be past doubt, and I therefore wished to exclude, as not material to the line of argument I had in view, such questions as to homology as Prof Thiselton Dyer brings forward He considers that the ovule, and not the ovary, is the equivalent of the macrosporangium I did not wish, even by implication, either to assert or to deny this fact, and it does not affect my comparison in the least, for the female structure of Carex comprises of course an ovule He further considers that this leaves the ovary unaccounted for, and not only so, but the perigynium and seta also. The essential part of a female flower is the ovule, which may be naked as in Gymnosperms, and the surroundings, whether consisting of an open carpellary leaf, an ovary, hypogynous scales, corolla, calyx, perigynium, or seta are accessories, and any of them may be absent. A comparison may surely be made between the female flower of a conifer (as a whole) with the much more complex one of a diclinous polypetalous plant, without being vitiated by the fact that parts of the latter are unaccounted for, and I thought, and with due respect still venture to think, that the macrosporangium of Selaginella with its covering scale, and the female flower of Carex with its covering glume may properly be regarded as comparable.

Prof Thiselton Dyer had compared the sporangia of Selaginella with the male and female elements of a single hermaphrodite flower, reversing their relative position on the axis, and my object was to show that, as each sporangium had its own "lateral appendage," they might be equally compared with the male and female elements in the separate unisexual flowers of a diclinous plant, without reversing their position on the axis It was quite unnecessary for me to discuss which particular parts of the phanerogamic flower were the exact homologues of the macro or micro sporangia of the cryptogam, and I did not intend to express any opinion on that subject.

I thank Prof Thiselton Dyer for drawing my attention to his paper on C *pulicaris*, which, however I have already had the pleasure of perusing, for I read everything written by him to which I have access, and I can assure him that, as a non professional myself, I always receive his opinions with the respect that is their due, although in the present instance I cannot adopt his view as to the hermaphroditism of the primordial flower That subject is, I think, sufficiently important to be discussed by abler pens than mine, and it was in the hope that it would receive the attention that it deserves that I ventured to point out the diametrically opposite views that had been expressed by high authorities

THOMAS COMBER

Newton le Willows, April 11

The Rocks of Charnwood Forest

THE announcement by Messrs Bonney and Hill vol xv p 470) of their *discovery* of the *intrusive* character of the ridge of rock, stretching from Groby on the south east to Bardon Hill on the north west is a surprise to local geologists, they having recognised its *intrusive* character for the last quarter of a century

The rocks constituting the "ridge" are called by different names—sienite, syenitic greenstone, greenstone, &c, according to the greater or less degree of crystallisation of the components, and the abundance or scarcity, of some of them Its intrusive character is very obvious First we have Cambrian Rocks on both sides (east and west) of the "ridge," and at places near Groby these Cambrian rocks are less than half a mile apart Second, the *effect of the intrusion* in breaking up the formerly overlying beds, is well seen near Markfield, where there are several low hills called the "Altar Stones," these consist almost entirely of broken up fragments of unaltered Cambrian rocks embedded in a grey, coarse, felspathic base, the *fragments* forming more than two thirds of the mass, similar beds occur beyond Bardon Hill, but the quantity of embedded fragments is not so great, but pieces are found eight to ten inches square quite unaltered, and showing the "ribboned" structure, red, purple, and green bands, so characteristic of the Cambrian rock of this area Over other parts of this "igneous ridge" the broken and disturbed beds have long since been removed by denudation, but the *débris* is found in the "drift," which stretches far and wide for miles over the surrounding country I think both Mr Howell of the "Survey," who plotted this district, and Prof Hull who did the adjoining one, recognised the *intrusive* character of the igneous rocks on the west side of Charnwood Forest Many other facts bearing on this subject are known, but cannot be described in this short note Any *new* facts discovered by Messrs. Bonney and Hill, in illustration of this matter, will be gladly received by local geologists.

Leicester JAMES PLANT

Patenas of Ceylon

I do not think Mr Ablay's suggestion of a possible cause of the origin of the Ceylon patenas will be found to hold good to the extent he believes it will On the Dimbula patenas rock of any kind is very scarce, even if you go several feet down, and where it does occur, it is, to the best of my recollection, almost always gneiss On the patena on my property it is certainly — throughout. In part of the Ouvah patena district, mentioned by

Mr. Abbay, the rock is limestone, as is proved by its being largely quarried and burned. Moreover, the patena soil in Ouvah is not of the ordinary worthless quality, at any rate in the opinion of planters owning portions of it, as they frequently assert that it is as good as the jungle soil of Dimbula, and the neighbouring districts. What truth there is in this I cannot say.

Further, though cleared forest land when abandoned usually runs into "chena," I could show Mr. Abbay, if he were to return to Ceylon, as I wish he would, cases in which it has run into patena. The Dimbula cricket ground is a case in point.

Pendleton, Manchester, April 17 E. Heelis

Cumming's Electricity

In a passage from my "Introduction to the Theory of Electricity" which you quote in a review of the work in Nature, vol. xv. p. 526, occurs a very unfortunate misprint of the word *of* for the word *on*, which seems to have misled your reviewer, and I therefore beg a few lines to correct it. The passage in question is the statement of Prop. 8, p. 203, which ought to have been written: "In computing the potential on any closed circuit we may substitute for it any closed circuit which is obtained by projecting the given circuit by means of lines of force."

In defence of this phrase I may perhaps be allowed to point out that the definition of potential quoted by the reviewer as that of Sir William Thomson is not the definition of potential but of *electrostatic potential at a point*, which is given at p. 45 of my book. The phrase potential on an electrified body in a field of electrical force is, I hold, perfectly legitimate, denoting the work done against electrical forces in moving the body (supposing all electrification undisturbed by the movement) to an infinite distance out of the field.

The case in point, however, refers to electro-magnetic potential and the potential on the closed circuit really represents the work done in carrying the circuit against magnetic forces out of the magnetic field.

The phrase suggested in your review--induction through the circuit—I had purposely avoided as liable to be confused with ordinary "magnetic induction" in a mass of magnetic iron, or with the "self-induction" of the circuit, or even with the induced current produced by the movement of the circuit, while the phrase potential on the circuit is at once suggestive of its own meaning and clear from any ambiguity.

Rugby, April 19 L. Cumming

Remarkable Papuan Skull

I wish to call your attention to a remarkable Papuan skull which Prof. Mantegazza showed at the last meeting of the Anthropological Society of Italy. The upper jaw contained very distinctly no less than four molars and two canine teeth on each side, all the molars being well developed.

Unfortunately the lower jaw is missing, but if it corresponded with the upper jaw, as we may justly presume—the whole skull not showing any abnormality of structure—the total number of teeth would amount to *forty*. There are cases recorded of negro-skulls showing three, four, and five supernumerary teeth, but *eight* is certainly an *extremely rare* occurrence.

It would be interesting to know whether museums or collections in England contain any similar specimens. J. E. Z.

Meteor

About 10.50 p.m. on the night of Monday, the 16th inst., the sky being cloudless and the young moon just setting, I observed a remarkable meteor in the northern heavens. It originated near to the star γ Cephei, and travelled towards the eastern horizon, its path forming an angle of about 35° with the perpendicular. The head, two or three times as large and bright as Venus, was bluish, and left a trail of yellowish light. I took it at first for a falling rocket, whose ascent I had not noticed; but its transient existence, its sudden extinction without noise or sparks, and the straightness of its path, with only a slight zig-zag, but no curve, preclude that explanation I think.

Leicester, April 17 F. T. Mott

OUR ASTRONOMICAL COLUMN

The U.S. Naval Observatory, Washington.—Under the title "Instruments and Publications of the United States Naval Observatory," the superintendent has circulated a series of photographs of the instruments at present in use in that noble astronomical institution. They are taken by the heliotype process, and comprise (1) the mural circle, mounted in 1844, aperture [illegible] the transit instrument, 5·33 inch aperture, mounted in the same year, and placed in the same room beside the mural circle; the smaller equatorial, mounted in 1844, with which so much good work has been performed, aperture 9·62 inch; the transit-circle, by Pistor and Martins, Berlin, which was mounted in 1866, the aperture of the object-glass 8·52 inch, and the focal length 12 feet 1 inch; a general view of the grand 26-inch refractor, of 32 feet 5·8 inch focal length, mounted in 1873, and one of the most powerful telescopes in the world; the clock-work, &c., of this magnificent instrument is shown on a separate plate. Brief descriptions accompany these heliotypes, and in addition are drawings made with the 26-inch equatorial of the nebula in Orion, the omega nebula, the annular nebula in Lyra, and the planet Saturn. Some account of the foundation of the observatory and a list of its publications from 1845-76 precede the brief description of the instruments of which views are presented.

New Variable Star.—A recent number of M. Leverrier's *Bulletin International* contains a notice from MM. Henry respecting a variable star in Virgo, which they state has been under observation for some time. The period is about seven months, and the limits of variation 8m. to 14m.; at present it is near a maximum. The position for 1877·0 is in R.A. 12h. 27m. 32·2s., N.P.D. 93° 44′ 37″.

Early Observation of Solar Spots.—In our popular astronomical works the Chinese are not usually credited with the observation of spots upon the sun at a distant date. Gaubil, however, records from the Chinese annals that on May 7, 826 black spots were seen on the sun's disc, and again on April 21, 832. There are, indeed, few phenomena which are not noted by this observant people, or rather by their watchful astronomers; yet, strange to say, the zodiacal light is amongst them. And it is singular that while Kepler's star of 1604 is duly recorded, the Chinese annals have no reference to the similar object in 1572, with which the name of Tycho Brahe is commonly associated.

Comet 1877 III.—The comet discovered by M. Borelly at Marseilles, on April 14, appears to have been detected three or four nights earlier by Mr. Lewis Swift, of Rochester, New York, who is already the independent discoverer of more than one of these bodies. We say three or four nights earlier, for although the telegram forwarded to Europe through the Smithsonian Institution dates the observation on the night of April 11, the rough place there assigned agrees more nearly with the computed position for the previous midnight. In circular No. xxv. of the Imperial Academy of Sciences at Vienna, are elements by Dr. Holetschek, from the first three nights' observations, which it is remarked have "a [illegible] great resemblance to those of the comet of the year 1762." The following orbit has been calculated by Mr. Hind from the first complete observation at Marseilles, on April 14, one at Mannheim by Prof. Schonfeld, on the 16th, and a third at the observatory of Mr. J. Gurney Barclay, at Leyton, on the [illegible]. For the sake of comparison the elements of the comet of 1762, calculated by Burckhardt, after a new reduction of the Paris observations, are annexed.

	Comet 1877 III.	Comet 1762.
Perihelion Passage (G.M.T.) ...	April 26·9501	May 28·3345
	° ′ ″	° ′ ″
Long. of Perihelion	102 45 51	104 2 0
„ Ascending Node ...	345 53 18	348 33 5
Inclination	77 8 56	85 38 13
Perihelion Distance	1·01089	1·00905

The motion is direct. It will be remarked that the only material difference is in the inclination of the orbits to the ecliptic. The comet of 1762 was discovered in the Netherlands, by Klinkenburg, on May 17, and was observed by Messier and Maraldi at Paris until July 2. When first seen it was just visible to the naked eye. The interval between the perihelion passages is 114·91 years, and with such period of revolution, with the other elements of 1762, the descending node would fall about 0·27 from the orbit of Mars and the ascending node at a radius-vector of 3·35, or in the region occupied by the minor planets; thus the difference of inclination will not be easily explained on the supposition of identity of the comets, though it must be remarked that elements of the present comet founded upon the first few days' observations may be open to more sensible correction than is usually the case.

"THE OBSERVATORY, A MONTHLY REVIEW OF ASTRONOMY."—There is ample room for the new astronomical periodical, which has been launched by Mr. Christie, the First Assistant of the Royal Observatory, Greenwich, under the above title, during the last week. Its aim is to present in a popular form a general survey of the progress of astronomy and to afford early intimation of recent advances. Such a publication ought to be well supported in this country, where astronomical amateurs are in great force. The first number holds out good augury for the future; amongst the contents are a report of the proceedings at the last meeting of the Royal Astronomical Society, proceedings which are not detailed in the *Monthly Notices*, where the discussions following the reading of papers are, as a rule, ignored, but which, as everyone knows who has been in the habit of attending the meetings of our scientific societies, are frequently the most interesting feature in the evening's proceedings; and we hope this point will not be lost sight of in the new periodical. There is an article on the photographic spectra of stars, a subject known to have lately much occupied the attention of the president, by whom it is furnished; the first part of a contribution from Mr. Gill, on the determination of the solar parallax; remarks on the nebular hypothesis, by Mr. Darwin, being an account of an inquiry intended to suggest a cause which may fill up a hiatus in the theory, and an outline of the results of Dr. von Asten's researches on the motion of Encke's Comet, recently communicated to the St. Petersburg Academy; also, ephemerides for physical observations of the moon and of Jupiter, by Mr. Marth, whose assistance in this direction deserves the high appreciation of observers. We will further express the hope that accuracy of typography may characterise the future numbers of Mr. Christie's publication; it is most important that this should be the case if the confidence of the practical astronomer is to be secured for it, and we are induced to offer this suggestion from remarking one or two inaccuracies in the first number, as on p. 4, where the search for an intra-mercurial planet by the Rev. S. J. Perry is dated in April instead of in March, and on p. 27, where Mr. Swift's discovery of the comet subsequently found by M. Borrelly, is erroneously referred to April 5, which was the date of discovery of the previous comet.

THE NEBULÆ—WHAT ARE THEY?[1]

BEFORE the announcement of Mr. Huggins's discovery of the presence of bright lines in the spectra of nebulæ, it was generally, if not universally, accepted as a fact that nebulæ were merely stellar clusters irresolvable on account of their great distances from us. This view had become impressed on the minds of many of our greatest observing astronomers in the progress of their work, and is one therefore which should not lightly be abandoned.

It appears to me that Mr. Huggins's observations instead of being inconsistent with the view formerly held by astronomers, are rather confirmatory of the correctness of that view.

The sun is known to be surrounded by a gaseous envelope of very considerable extent. Similar envelopes must surround the stars generally. Conceive a close stellar cluster. Each star, if isolated, would be surrounded by its own gaseous envelope. These gaseous envelopes might, in the case of a cluster, form over the whole, or a part of the cluster, a continuous mass of gas. So long as such a cluster was within a certain distance from us the light from the stellar masses would predominate over that of the gaseous envelopes. The spectrum would therefore be an ordinary stellar spectrum. Suppose such a cluster to be removed further and further from us, the light from each star would be diminished in the proportion of the inverse square of the distance; but such would not be the case with the light from the enveloping surface formed by the gaseous envelopes. The light from this envelope received on a slit in the focus of an object-glass would be sensibly constant because the contributing area would be increased in the same proportion that the light received from each part is diminished. The result would be that at some definite distance, and all greater distances, the preponderating light received from such a cluster would be derived from the gaseous envelopes and not from the isolated stellar masses. The spectrum of the cluster would therefore become a linear one, like that from the gaseous surroundings of our own sun. The linear spectrum might, of course, under certain circumstances, be seen mixed up with a feeble continuous spectrum from the light of the stars themselves.

It should be noticed that, in this view of the subject, the linear spectrum can only appear when the resolvability of the cluster is at least injuriously affected by the light of the gaseous envelopes, becoming sensibly proportional to that from the stellar masses, and that in the great majority of such cases it would only be in the light from the irresolvable portions of the cluster that bright lines could be seen in the spectrum.

The changes in form which would be presented to us by such a nebula might be expected to be small. These changes would depend chiefly upon changes in the distribution of the stellar masses constituting the cluster. It has always appeared to me difficult to realise the conditions under which isolated irregular masses of gas, presenting to us sharp angular points, could exist uncontrolled by any central gravitational mass without showing larger changes in form than appear to have been the case with many of the nebulæ. In my view of the nature of nebulæ this difficulty no longer exists.

THE RACES AND TRIBES OF THE CHAD BASIN

ON this subject a most valuable paper has been contributed to the last number of the *Zeitschrift der Gesellschaft für Erdkunde* by Dr. G. Nachtigal, one of the few living writers entitled to speak with authority on the ethnography of Sudan. While the great problems now being rapidly solved in the portion of Africa lying south of the equator are almost exclusively of a strictly geographical nature, those still awaiting solution in the northern half of the Continent are on the contrary mainly of an ethnological character. The reason of this pointed difference is very obvious. Although there are vast regions south of the line still unexplored, enough is already known to warrant the conclusion that what remains to be there discovered is peopled by the same great race holding almost exclusive possession of the parts already opened up by the spirit of modern enterprise. With the sole exception of the extreme south-western corner, occupied by the Namaqua and Cape Hottentots, and of some districts also in the south still haunted by a few straggling Bushman tribes, the whole of Africa from the equator southwards would seem to be the domain of what is now conventionally known to philologists as the Bantu family. Whatever be their origin, all the countless tribes here settled are now at least linguistically united into one group, all of them, with the exceptions already specified, apparently speaking dialects of some one common mother tongue now extinct. Hence however interesting the questions that still remain to be settled relating to the physical geography of Africa south of the equator, its ethnography, so far as that can be determined by the test of language, presents little or no further difficulty.

---

[1] On a Cause for the Appearance of Bright Lines in the Spectra of Irresolvable Star Clusters. Paper read at the Royal Society by E. J. Stone, M.A., F.R.S., Her Majesty's Astronomer, Cape of Good Hope.

But north of the equator the case is completely reversed. Here there doubtless remain to be cleared up some few geographical points, such, for instance, as the water parting of the White Nile and Lake Chad, the course of the Upper Shari, and especially that of the Ogoway, so far as it may flow north of the line. But on the whole the main physical features of this half of the continent may be said to be at last fairly settled.

Its ethnology, on the contrary, only becomes all the more complicated in proportion as our knowledge of the land and its peoples increases.[1] No doubt we have here also one or two widespread linguistic groups, such as the Semitic, represented by two of its branches—the Arabic in the Barbary States and Egypt, and the Himyaritic (Lesana Gĕz, Tigré, and Amharic) in Abyssinia. There is also the great Hamitic family, with its three distinct branches—Egyptian, Libyan, and Ethiopic—occupying more than one half of the Sahara, from about the 15° E. long. to the Atlantic seaboard, large tracts in the south of the Barbary States, parts of Egypt and Nubia, and the whole of the Galla country and Somaliland as far south as the River Dana or Pocomo, where it is met by the Waswahili and other Bantu tribes of the eastern seaboard.

But there still remains the pure negro race, properly so-called, occupying nearly the whole of the Sudan in its widest sense, the banks of the White Nile, and all its head streams, from Khartum to the Victoria Nile, and in all probability the still unexplored regions of the Ogoway, and of Central equatorial Africa generally, from Cape Lopez inland, to the Blue Mountains west of the Albert Nyanza, and from Lake Chad southwards to the equator. Here we find innumerable negro tribes, dwelling more especially in three great centres of population—the region between the Niger and the West Coast, the Basin of the Chad, and the Upper Nile, with all its head streams[2]—tribes generally speaking differing as much in speech as they would seem on the whole to resemble each other in their main physical features. Here live the Wolofs, the Veis, the numerous Mandenga and Haussa peoples, the Fulahs (who, however, are not Negroes), the Masa family, the Bagirmi, Babir, Nyamnyam, Shilluk, and many other Niger, Gambia, Chad, and Nilotic races, all speaking idioms seemingly in no way related to each other, and in fact possessing nothing in common with any known forms of speech beyond the general and somewhat vague feature of agglutination characteristic of most, if not of all, of them. Here, therefore, we have many linguistic and ethnological puzzles still awaiting solution, and forming, as stated, the counterpart of the topographical mysteries now being so successfully unveiled in the southern half of the continent.

The Basin of Lake Chad, situated in the very heart of this vast region, is peopled by such a bewildering number of races, as to have hitherto baffled all attempts at analysis, or any general classification based on recognised scientific principles. Here we find dwelling either separately or toge[illegible]ches of the Semite, Hamite, Fulah, and Hauss[illegible] none of them, except the Semite Arabs, in any considerable numbers. Here is further repres[illegible] of the mysterious Tibu people, who [illegible] the Great Desert with the Twareg (Tu[illegible] Teda and Dasa, that is, northern and southern [illegible] Tibus, pure and mixed, nomad and settled. Here [illegible] the Kanembu,[1] or people of Kanem, who are Tibus, one degree removed, and the Kanuri or Magomi, the ruling race in Bornu, who may be described as Tibus, or rather Kanembu, in the third and fourth degree, in other words, half-caste descendants of Kanembu and the Aboriginal Negro inhabitants of the land. Here are, moreover, the Margi, Mandara, Makari, Logon, and other members of the Masa or Mosgu family, in all probability akin to, if not the collateral descendants of, the So or Sou people, now either extinct or absorbed in the Tara, Manga, Ngalmaduko, Dalatoa, and other Kanuri tribes. Here, too, are the Bede, Babir, and some other independent or unclassified Negro peoples, fragments of the Kuka and Bulala from Lake Fittri, and lastly, the Bagirmi from the neighbourhood of the Middle Shari, and apparently connected with the Jur and Dor tribes on the western head waters of the White Nile, thus forming a sort of connecting link between the Nilotic Negro tribes, and those of Central Sudan.

All or most of these data were doubtless previously known, at least in a vague or general way; but thanks to Dr. Nachtigal's careful investigations on the spot, we are now for the first time enabled to form a clear idea of the various geographical, political, social, and linguistic relations of these different peoples, one to the other. Unfortunately in his elaborate monograph he treats the whole subject under the threefold division of races in Kanem, Bornu, and the lake islands, a political rather than an ethnographic distribution, which is all the more confusing that several Kanembu tribes, such as the Sugurti and Tomagheri, are now settled also in Bornu, while on the other hand several Bornu or Kanuri people, such as the Magomi of Fuli on the east coast, the Bulua, Malemia, and Ngalma Dukko, have found their way back to Kanem, whence their forefathers originally migrated westwards.

The inconvenience, however, arising out of this arrangement of the subject matter is largely obviated by the excellent coloured map accompanying the paper, without which it would in fact be scarcely intelligible to the ordinary reader. It will therefore be necessary in the subjoined *résumé* of Nachtigal's conclusions to depart somewhat from his triple division, and give a general classification of all the Chad races, based rather on their permanent linguistic and physical affinities than on their accidental political relations, while in all other respects closely adhering to the data supplied by him.

The map above referred to is shaded in ten different colours, corresponding to so many distinct peoples. But one of these colours comprises four not yet classified Negro tribes on the west and south-west frontier of Bornu, between that state and the adjoining Haussa states further west. On the other hand, the Bagirmi are not represented at all by any of these colours, so that four more shades would really be needed to embrace all the Chad races, while even then excluding such more remote peoples as the Adamawa on the south-west and the Fulahs on the west.

It thus appears that all the peoples dwelling either round about the Chad or on its numerous islands may be grouped under the subjoined fourteen main divisions:—(1) Tibus (Teda, Dasa, and Kojam); (2) Kanembu;

---

[1] A striking proof of this is afforded by the recent expedition of Dr. W. Junker along the Lower Sobat from its junction with the White Nile to Nasser, the most advanced Egyptian military station in that direction. He informs us that between these two points are spoken no less than five distinct idioms, some of which are now heard of for the first time. These would seem to be the Nuer, along the right bank of the Sobat, and the Shilluk, Janghey, Fallangh, and Nuak on the left. And beyond Nasser he reports the existence of many other independent tribes on the Middle and Upper Sobat, such as the Bonjak, Jibbe, Kunkung, Nikuar, and Chai, all apparently speaking different languages.

[2] Reporting last year to the E[illegible] on the White Nile between Dufli and Magungo, G[illegible]marks: "Le pays est très peuplé; beaucoup plus qu'[illegible]Afrique."

[1] The suffix *bu* is simply the plural of the personal suffix *ma*: *Kanemma* = a native of Kanem; *Kanembu* = the people of Kanem.

(3) Kanuri or Magomi; (4) Masa or Mosgu; (5) Yedina or Buduma and Kuri; (6) Bulala and Kuka; (7) Dana or Danawa; (8) Bede; (9) Ngisem; (10) Kerrikerri; (11) Babir; (12) Bagirmi; (13) Haussa; (14) Arabs.

1. TIBUS, of whom, as already stated, every variety is represented. They occupy the greater part of Kanem proper and are found on both banks of the Komodugu Yoobe in Bornu, between the 12° and 13° E. long. Principal pure nomad Tibu tribes: Gunda, Atereta, Worda, Juroa, or Osumma, Mada, Wandala, Dogorda, with a total population of 13,000. Principal pure settled Tibu tribes: Salemea, Beggaroa, Aborda, Nawarma, Oreddo, and Billea, numbering altogether 4,400. Mixed and doubtful Tibu tribes: Gadawa, Kumosoalla, Hawalla, or Famalla, Medolea, Jinoa or Mallemin, say 10,500, giving a total of 27,900 Tibus in the Chad district.

2. KANEMBU, dwell principally round the eastern, northern, and western shores of the lake, therefore, as already remarked, both in Kanem and Bornu. Their principal tribes are the Sugurti and the Tomaghera or Tomagheri, both in Kanem and Bornu; the Konku, Gallabu, Kuburi, Kunkinna, &c., with a total population of over 18,000.

3. KANURI, the ruling people of Bornu, and by far the most important nation in the Chad basin. Nachtigal proposes two derivations of the name: first from the Arabic نور = nūr = light, and the Kanuri prefix *Ka*, implying the concrete idea of "the people of light," as the first heralds of Islam in the Pagan lands occupied by them. But this mixture of elements from two radically distinct languages, though perhaps interesting to Mr. J. C. Clough and other advocates of mixed languages, can scarcely be meant seriously. It is as if the first English settlers in the Fiji Archipelago were to announce themselves as the "lumen-bearers," as the first messengers of the "lumen evangelii," or "light of the Gospel," to the natives of those islands. Second, and much more probably, a corruption of *Kanemri*, implying their Kanem origin, already referred to. Principal Kanuri tribes in Kanem: Bulua, Anjalibu, Rogodobu, Biradull, Biriwa, Melemia, Forebu, Ngalma Dukko, the Magomi of Fuli, and Dalatoa. These last, though claiming to be considered a Kanuri people, being really descended from slaves of other races subject to them. Principal tribes in Bornu: The Magomi or Kanuri proper, the Tura, Manga, Nguma, Kai, Ngallaga, Ngalmaduko, Ngomatibu, Ngasir, &c., with a total population of about 1,500,000.

4. MOSGU or MASA family occupies the region south of the Chad as far as Adamawa, and seems to belong to the same race as the extinct So and other autochthonous peoples of Bornu either extirpated by, or absorbed in, the Kanembu invaders of that region. Principal tribes: Margi, Mandara, Mekari or Kotoko, Logon, Gamergu, the unsettled Keribina, and the Mosgu or Masa proper. Masa is the name by which they call themselves. They may number altogether about one million.

5. YEDINA, or BUDUMA and KURI, are the two native lake tribes, the former dwelling on the great central group of islands, the latter on the Kaika, or smaller South-eastern Archipelago. Yedina is the proper name of the first, Buduma being the name by which they are known to the Kanuri, from *Budu* = *hay*, and the suffix *ma* singular (for the plural *bu*), meaning the "hay-people." They are fierce and daring pirates; the terror of the surrounding nations. The Kuri, so called by the Arabs and others, call themselves *Kalea* or *Kaleama*, and are undoubtedly akin to the Yedina, though the two languages vary not a little. Principal Yedina tribes: Maijoja, Maibulua, Buja, Guria, Margauna, Jillna; numbering from 15,000 to 20,000 altogether. Principal Kuri tribes: Arigna, Media, Kadiwa, Toshea, Karawa, Kalea.

6. BULALA and KUKA, kindred tribes, originally from Lake Fittri, whither most of them seem to have returned. Some of the Bulala have withdrawn to a few of the islands in the lake, but the four following tribes are still in Kanem: Ngijem, Bedde, Sarabu, and Tirra, all off the south-east shore of the lake. The Kuka are now found only in Gujer, in the same neighbourhood. They jointly number about 5,800.

7. DANA or DANAWA, called by the Arabs *Haddad*, and by the Dasa or Southern Tibus *Azoa*, both terms meaning "Smiths," occupy a compact territory at the south-east corner of the lake opposite the Korio group of islands inhabited by the Kanembu. According to their tradition, the Danawa are half-caste Manga Tibus and Bulalas, but they now speak a Kanuri dialect.

8. BEDE, about 12° 30′ N. lat., 11° E. long.

9. NGISEM, 12° N. lat., 11° E. long.

10. KERRIKERRI, 11° 30′ N. lat., 11° E. long.

11. BABIR, 11° N. lat., 12° E. long.

Unclassified aboriginal Negro tribes on the west and south-west frontier of Bornu, confining westwards on the Haussa States, and southwards on Adamawa

12. BAGIRMI, along the eastern or right bank of the Lower Shari, with undefined southern limits, and extending north-eastwards in the direction of Lake Fittri and Waday. Are closely related to the Sara tribes of the Middle Shari, and are also connected with the Jur and Dor dwelling on some of the head waters of the White Nile. Some of the Bagirmi are settled in Bornu, where they are called Karde, possibly through some confusion with their northern neighbours, the Kredas of the Bahr-el-Ghazal, who are Dasa or Southern Tibus akin to the Sakerda further up the bed of that now dried-up stream.

13. HAUSSA communities exist in one place only in Bornu, the district round about Gummel, on the 13° parallel and the 10° E. long. north-east of Kano.

14. ARAB TRIBES are found both in Kanem and Bornu. The principal Kanem tribes are the Tunjer, Uledsoliman (Wassili), and Mgharba, about 80,000 altogether. The principal Bornu tribes are the Auladhamed and Salamat, numbering perhaps 100,000. Many of them have become in some respects assimilated to the surrounding Kanuri people, but still hold tenaciously to their Semite speech. "I have met with Arabs settled in Bornu for a series of generations, near the centre of the kingdom, and who were still so little acquainted with the Kanuri language that I was obliged to act as their interpreter" (Nachtigal). These Bornu Arabs are called Shoa by the Kanuri, and are carefully to be distinguished from those Arabs who occasionally make their appearance in these regions, either as marauders or traders from the Barbary States.

Though mainly ethnological, Dr. Nachtigal's paper is introduced with a few geographical notes, which, however, present little or no novelty. The lake is described as about 27,000 square kilometres in superficial area, of a triangular shape, open and navigable in its western section, but along its eastern shores crowded by a large number of islands in many places separated only by narrow channels one from the other. The upper course of its one great affluent, the Shari, still remains to be determined, the writer merely remarking on that point that it flows "in two main streams apparently rising in the heathen lands to the south and south-east of Waday, receives a small portion of the rivers flowing down the western slopes of the Marra range, and throughout the whole year discharges a considerable volume of water into the lake." The Bahr-el-Ghazal, its former north-easterly outflow, has long been dried up, so that the Chad has now no outlet of any sort, its waters being kept by evaporation alone at their present variable levels.

But nothing could possibly be more thorough and satisfactory than Nachtigal's elucidation of the complicate ethnography of this region, which he has disentangled as successfully as Stanley has just solved the geographical problems connected with Lake Tanganyika.

THE "LOST ATLANTIS" AND THE "CHALLENGER" SOUNDINGS[1]

IT may perhaps not be at first apparent what is the connection between those tubes and masses of metal and other apparatus on the right and these fossil leaves in the cases on the left. Those are some of the sounding apparatus used on board the *Challenger* in her four years' voyage. They have been brought from the galleries of the Loan Collection of Scientific Apparatus, where they are deposited by the Admiralty, into this theatre, in order to illustrate the method by which deep-sea soundings and temperatures are ascertained. It is the results obtained from soundings in the Atlantic Ocean alone that we shall consider this evening. While the working out of these results, as shown in the diagram, has been accomplished by the staff of the *Challenger*, there are some few other ships to which passing allusion will have to be made. These fossil leaves, deposited by Mr. J. Starkie Gardner, F.G.S., are also brought in from the Loan Collection. It is not these particular leaves we have to consider; these are all English: but we shall have to consider the teachings of collections of leaves similar as regards their manner of preservation, obtained from different parts of Europe and America. There are no specimens at present in the collection besides these, though until recently there was the small typical collection of the Baron von Ettingshausen. These English specimens will, however, serve our purpose very well as illustrations to convey an idea of what Tertiary fossil leaves look like.

The connection between these two subjects is here. We are going to consider certain past vegetations which are made known to us by their fossil remains. The study of some of them led Prof. Unger by a process of reasoning that will be presently indicated, to the belief that there existed in Tertiary times land between Europe and America by which the ancestors of the plants gradually travelled from America to Europe. It is *now* seventeen years ago that Prof. Unger proposed to call this hypothetical land the Island of Atlantis;—the sunken island or lost island of Atlantis. It was, no doubt, what our American cousins would call "a big thing" for a botanist to do, to "create" a former land in mid-ocean simply because he wanted it to account for the migration of the ancestors of fossil plants he had studied, and to do so without a particle of physical evidence. It was the first time in the history of geological science that so bold a step had been taken. The arguments by which Unger arrived at his conclusions were criticised at the time and another route for migration by the Pacific was suggested.[2] Whatever may be opinions as to the value of the evidence on which Prof. Unger based his "lost *Atlantis*," we now know from the *Challenger* working out of soundings that not only a "sunken island," but a ridge does lie in mid-Atlantic between the Old and New World.

Our subject groups itself into three divisions:—(1) Tertiary fossil plants; (2) Deep-sea soundings; (3) the "Atlantis ridge."

[The lecturer then turned to the fossil leaves, and described their manner of preservation and the conditions under which they are met with, and referring to diagrams and tables explained the meaning of the word Tertiary.]

No one now doubts these are really the remains of plants that grew and are not *lapides sui generis*. In comparing them with living plants and determining their affinities there are many difficulties to be encountered. The remains themselves are often fragmentary. Even when they are tolerably perfect the comparisons have to be made for the most part with specimens in herbaria, and the variations seen in the few leaves of a specimen often suggest that variations from different parts of the tree may be considerable. With fruits and with ferns preserving the fructification, the determination is safer, but with leaves alone, while in some well-marked cases there can be hardly a doubt; in a large proportion of cases the doubt is great. When the lecturer first paid attention to the Lower Bagshot flora, fourteen years ago, he thought, as many unacquainted with the subject might think, that with such herbaria as at Kew and the [illegible] Museum the work of comparison would be simple. The riches of these places will soon show, however, that a wide experience and a trained eye are needed to refer to all the species, frequently of orders and genera widely separated in the natural classification, whose leaves resemble a fossil leaf under consideration. Those who may try the work will more readily understand how it was that a few years ago not a single English botanist of note was willing to attach any importance to the determinations based on fossil leaves alone.

Matters are looking more hopeful now, partly because more perfect and well-marked specimens are being frequently added to museums and private collections, and partly because the writers of monographs on any living order are now beginning to adopt the plan of adding what is known about its fossil forms. There can hardly be a doubt that the solid reliable progress in the determination of fossil leaves is to be made alone by botanists who select a particular group of plants for exhaustive study, and include such fossil forms as they find no hesitation in admitting. General botanists of even great experience may make good guesses, but nothing short of the determination of a specialist can be regarded as absolutely safe, even if that may be considered so.

While the feeling of English botanists a few years ago was as described, there were on the Continent some few whose hesitation with regard to fossil leaves did not prevent them from trying what could and what could not be done in the way of identification. [The lecturer then referred to the work of continental botanists, especially of Heer and Unger, and alluded to the confirmatory evidence which in some cases had occurred of fruits being found subsequently from the same locality as leaves, whose determination had been attempted.] Unger compared the Tertiary flora of America with that of Europe, and in 1860, in a lecture called "Die versunkene Insel Atlantis," made a comparison between the two, and detailed the steps by which, after twenty years' study, he had been led to the conclusion that the European Tertiary flora had a North American character. There have been two theories respecting the origin of plants in particular areas. One is that the plants of that area have been created there as fully developed as met with; another is that they have been partly the result of evolution in the same district, and partly or entirely the result of immigration from other districts. [Starting with familiar illustrations of the effects of climate on plants, the lecturer proceeded to show how plants retreated before climatal conditions that were hostile to them and spread where the conditions were favourable, in [illegible] cases changing the elevation at which they grew, in others changing their area.] It was the consideration of the migration of the plants that led Prof. Unger to believe that a high proportion of the European Tertiary forms had come from North America.

It would occupy too much time and would fulfil no useful purpose in a popular lecture like this, to give in detail the data on which he based his conclusions. A *résumé* of them in a form convenient for reference may be found in a translation of his lecture in the *Journal of Botany* of January, 1865. Believing the evidence was sufficiently strong that the Tertiary plants he studied had come from North America, he proposed a hypothetical land between the two as the route by which they had travelled.

He took the name of his hypothetical land from a legend met with in the "Timæus" of Plato. In a conversation between a priest of Saïs and Solon, when in Egypt, mention is made of a great island of Atlantis, situated beyond the pillars of Hercules, where lived a powerful nation that ruled over Libya as far as Egypt, and over Europe as far as Tyrrhenia. They tried to subjugate the Hellenes, but that heroic people defeated them. At a later period, during severe earthquakes and great floods, the island of Atlantis sank into the ocean. Such in brief outline is the legend. [The lecturer, alluding to the translations of Jowett and Whewell, referred to the puzzle this passage had been to students to know where an Egyptian priest could have known such a legend, or why (possibly) Plato had invented it, and alluded to one explanation that it was probably an exaggeration of some local phenomenon. In the *Journal of Botany* for January, 1865, a list of the literature of the subject is given.] This is as much as time will allow to be said to indicate the nature of the reasoning by which Unger, on the evidence of plant remains in Europe and America, conjectured former intervening land between the two, and why that hypothetical land was called "the sunken" or "the lost island of Atlantis."

We now turn to the *Challenger* soundings, and with these must be mentioned those of the United States ship *Dolphin*, the German frigate *Gazelle*, and the British ships *Hydra* and *Porcupine*. The generalisations of the soundings taken by these vessels, with inferences drawn from bottom temperatures, have been worked out by the staff of the *Challenger*, and a contour map has been prepared, of which the features which bear on our subject are reproduced in the diagram. Some of the most important soundings were taken from the *Challenger* herself, and as the working out of the whole results have been performed by the staff of that ship it is not unfair, at any rate in a short title for a popular lecture to mention only "*Challenger* soundings." That there was no feeling of international jealousy on the part of the *Challenger* staff is fully evidenced by the fact that the northern portion of the ridge has been named after the *Dolphin*.

Before referring to the results it may be of interest, as we have some of the *Challenger* apparatus here, to speak of the method of deep-sea soundings.

[The lecturer then briefly sketched the history of deep-sea soundings, alluded to the impulse given by the laying of cables, and mentioned how the improvement in mechanical appliances made possible now what was impossible a few years ago.]

The line used is about one inch in diameter; on this the twenty-five and seventy-five fathom distances are marked with white thread, interwoven, the fifty by red, and the 100 fathoms in blue. By this means the amount of line paid out can be easily ascertained. The weights to sink the line are so arranged, that when they touch the bottom they release themselves. There are several modifications of this apparatus, but the principle of those used on board the *Challenger* is that round flat weights with holes through them are placed one above another with a rod or tube running through them, the number of weights depending on the expected depth. To the bottom of the lowermost weight a wire ring is fastened, and a wire passes up and is fastened to a spring at the top of the tube. The tube is then attached to the line. So long as the strain of the weights is on this spring it remains closed. Directly the weights rest on the bottom the strain is removed, the spring opens, the wire is released, and when the line is hauled in it brings up the tube only, leaving the weights below. For taking temperatures a cup lead is generally used to sink the line, to which self-registering thermometers specially arranged to withstand great pressures are attached at every 100, and sometimes at every ten fathoms. It is not necessary here to speak of dredging, nor of the means for bringing up water or samples of mud from the sea bottom. We have now only to speak of soundings and taking temperatures. In both operations the line is passed through a pulley-block, which is attached to a group of elastic "accumulators," the object of this being to break the shock of the roll of the ship.

Dr. Spry, writing about the *Challenger* voyage, has said:—

"It has been found that in all deep soundings it is necessary to use steam power. No trustworthy results can be obtained from a ship under sail, as even in the calmest weather the heave of the sea or the surface current is sufficient to drift the ship in a very short time a considerable distance from the place where the lead was originally let go. . . . The first thing therefore to be done is to shorten and furl all sail and bring the ship head to wind, regulating the speed in such a manner as to avoid forcing her through the water."

The soundings and temperatures obtained by the *Challenger* have been from time to time issued in special reports, of which there have been seven. In the seventh is given a map on which the soundings have been marked, together with those of the other ships already mentioned. On this map the ridges and deep basins have been contoured, and where soundings have been wanting the bottom temperatures have been taken as a guide of the probable position of the separating ridges. For the *Challenger* ridge there are plenty of soundings and nearly as many for the *Dolphin* ridge. The connecting ridge is, however, assumed from bottom temperatures.

It is on this map our diagram is based.

Having now obtained approximately the contour of this ridge, which throughout the greater part of its range is known as a FACT from actual soundings, there are some few speculations concerning it which naturally present themselves for consideration. In the first place it will be noticed that along the ridge itself there are four places where it rises to dry land, at the Azores, at St. Paul's rocks, at Ascension, and at Tristan d'Acunha. In the deeper basins there is land rising above the sea-level at Fernando de Noronha, at Trinidad, and at St. Helena. In the deeper basins too there are five soundings which show a depth of more than 3,000 fathoms. These are given on our diagram. The greatest depth recorded is 3,450 fathoms. A glance at the *Challenger* map on which the soundings are marked in figures is sufficient to show that if the contour lines were drawn at every 250 fathoms the Atlantic would be found to be diversified by hills and valleys. Geologists are familiarised with invoking former rises and falls in land to account for some of the facts they study. Indeed in some cases it seems almost as if it were believed that the axis of the earth may be shifted and its ice-caps, its soil-caps, and its continents moved about with impunity to suit any particular theory. At any rate it would not be received as a startling idea that the whole area of what is now the Atlantic has been dry land. True we know that deposits are now being formed on the floor of the ocean, and at different rates, and consequently producing different thicknesses; rivers carry material which is spread out according to conditions over large or small areas, and so produce variations in the thickness of their deposits; and perhaps allowance must also be made for currents. These circumstances may to some extent modify the relative levels of parts of the ocean bottom. But they could hardly account for such extent of variations in the hills and valleys as are met with. Some of the ridges may be the result of submarine elevation analogous to that which has raised high mountain ridges elsewhere, and in this case has never brought the ridge above the sea except in a few peaks. It must too be remarked that if we admit the ridge through its whole length to have been dry land, it does not necessarily follow it was so all at the same time. There is not, however, any readily apparent argument against the theory that it has been all dry land and at one and the same time. Let us for a while assume that it was, and let us then see what facts about climate we may infer with regard to it.

There are no doubt many other places besides these already known where the depth exceeds 3,000 fathoms. Let us, however, take the group of the known [illegible] which run in a line north-east and south-west, and are respectively 3,450, 3,200, 3,250, and we may assume that they represent a valley line. Let us suppose that the area is raised till this valley is dry land; what then will be the height of our ridge, and what will be the highest peaks of the country? To the north-west of the valley, distant about as far as from here to the Grampians, would tower the peaks, now the islands of St. Paul's Rocks, and Fernando de Noronha, rising some 30,000 feet; and to the south-east would rise Ascension to a similar height. The "ridge" itself would be about 15,000 feet. There is no reason whatever for supposing that the ridge is a table land. On the contrary, it seems more probable, judging from the variations in the soundings, that it was diversified with hills and valleys. Now a ridge of this elevation would, in all probability, have a snow capping even at the equator. Astronomers tell us that in "former" times the earth's atmosphere was higher and its pressure greater than now, but that was in a very remote past, and we may fairly assume that at the time of this ridge being land the atmospheric conditions were much as now. We should thus have a mountain ridge with hot valleys and every variation in temperature according to height; so that so far as temperature is concerned botanists would have no difficulty in accounting for the migration across the equator of plants that would be killed by great heat. With regard to the part of the ridge between Europe and America, answering to Unger's "Atlantis," the soundings are more numerous. The undulations seem to have been many, and the general elevation was probably not more than 9,000 feet, unless the original depths are masked considerably by a deposit of globigerina-ooze. Some peaks—now the Azores—still remain above water. When the ridge sank is a question on which we have at present no evidence. The whole subject is still young, and we have much yet to learn.

In conclusion the lecturer said: I hope I have given sufficient prominence to the distinction that must be drawn between fact and inferences from those facts.

I should be very sorry for anyone to go away from this place and say that they heard a lecture at South Kensington in which they were told that there formerly was a continent running down the middle of the Atlantic, and that there was a lofty mountain ridge along it, capped with snow even at the equator.

I wish carefully to point out to you I have made no statement of the kind. I have simply told you the fact that a ridge less than [illegible] fathoms beneath the ocean runs down mid Atlantic in a sinuous course, whose contour is roughly indicated by the diagram. That on each side of it are ocean depths twice and in some cases thrice the distance it is below the sea-level. That *if* these depths were once land valleys, as geologists have no difficulty in believing possible, then there would be a ridge running north and south along the area of what is now the deep Atlantic, ranging from 9,000 to 15,000 feet above the sea-level, and that *if* the atmospheric conditions were the same then as now, judging from what we know of the Andes under the equator at the present time, there was probably a snow-capping.

Such a land-connection between Europe and America, if it existed as late as Tertiary times, would meet the requirements of Unger's hypothesis, varying in height as it sank, and the whole ridge would afford a solution of any difficulty botanists may have on the score of temperature in accounting for the migration of cold-loving and heat-shunning plants across the torrid zone.

The remarks at the conclusion of the lecture, in reference to its being the last of the series, we have already reported at p. 490.

REMARKS ON THE INVESTIGATION OF CLIMATES

TO Prof. Balfour Stewart we are indebted for the separation of meteorology into its two great divisions of *physical* and *climatic*. The latter I have proposed to separate into two sub-divisions, viz., *normal* and *abnormal*. The first of these subordinate branches includes the investigation of the usual states of the atmosphere in different parts of the earth's surface, as ascertained by periodic data derived from the averages of observations continued for a series of years. The second subordinate branch has for its object the investigation of unusual temporary disturbances of the equilibrium of the atmosphere—such, for example, as storms of wind, by means of the comparison of individual observations, extending over only a few hours or a few days.

We need hardly wonder at the disfavour with which meteorology is regarded by some men of the highest standing in physical science, from whom valuable assistance might have been expected; for we know that there is a great want of agreement among meteorologists themselves as to the means of determining even the most important fundamental data. For example, it will hardly, one would think, be disputed that the essential condition in all meteorological inquiries is *uniformity in instrumental observation*. But towards the establishment of a uniform international system no progress has as yet been made. Points of subordinate importance may have been adjusted at the Congress meetings at Leipzic and Vienna, but this all-important question remains just where it was. To Mr. Glaisher is due the adoption among his observers of the uniform height of 4 feet above the ground for thermometers, and one invariable form of screen for protecting them. The Scottish Meteorological Society, when establishing their stations in 1855, followed the example of Mr. Glaisher by adopting the 4-feet standard height, and they ultimately selected the form of double-louvre boarded protecting box, which I proposed in 1864. The Meteorological Society of England have also adopted the same uniform system as that in Scotland of boxes, and their exposure, and hours of observation. But other observers follow different methods, and on the Continent it is believed there is still less approximation to uniformity than among ourselves. The very first matter which should be taken up by home and foreign meteorologists is the settlement once for all of the questions how, when, and with what position and exposure of instruments are observations to be made. Until this is done it is impossible to arrive at useful results, because the observations which are now being obtained at different stations are not comparable the one with the other. Unless there be some such general Council as that lately proposed in NATURE by Prof. Balfour Stewart for carrying out this and other important objects, I shall certainly despair of the future of this new science.

But let us now see in what way the mode of instrumental observation bears on the subject of climate. Climates may be defined as states of the atmosphere due to the joint operation of geographical, geological, and other conditions more or less local, and they are judged of by their effects on animal and vegetable life. They do not, therefore, depend simply on the geographical position on the earth's surface of the district where the observations are made, but are largely affected by various conditions, such as the distribution of land and water, the nature of the soil and its covering, and the elevation or land at, and adjacent to, the place. Climates are, therefore, frequently of a local nature, by which I mean of small superficial extent. Thus many varieties of climate may coexist about the same parallel of latitude, and even over a very limited portion of that zone. Instead of saying, then, that a whole country such as Britain has a certain mean temperature, as ascertained by lumping together observations made at places of widely different character, level, and exposure, we should rather say that there are in that island mountainous districts with a certain mean temperature, districts of open plain, having another, and sheltered districts and valleys having another; while parts near the sea-shore, have their own peculiar characteristics. To take a familiar case, we may refer to the Isle of Wight, all parts of which, small though the island be, can hardly have the same climate as Bonchurch and Ventnor, which are the favourite retreats of invalids in pursuit of health. That such local atmospheric distinctions do really exist may at once be shown by a reference to the varied distribution of plant life which, though no doubt largely affected by the nature of the soil, is nevertheless to a considerable extent dependent on the existence of certain atmospheric conditions.

If meteorological stations were to be established in some place situate in a low latitude—such, for example, as the Island of Java, we should be told, as I have more than once been in similar cases, that though 4 feet above the ground may be suitable for thermometers in Britain, it would be quite preposterous for so hot a climate as Java. Now if what were wanted was to ascertain the amount of heat emitted directly by the sun, such a statement might be correct; for then the instruments should be kept as clear of terrestrial influence as possible, and by taking proper precautions we might perhaps make our observations indifferently at sea or on land. But these would not be observations of climate. Now, as in the case we have supposed, it is the *climates* of Java and Britain that are to be compared by ascertaining the amount of heat communicated to thermometers by conduction and convection of the air which has been heated by solar, and cooled by terrestrial radiation, the observations must be made on the islands themselves and not on the sea which surrounds them, and by instruments placed at the same level above the surface of the ground. It has been farther objected that in very hot countries there are large districts where canes or other kinds of jungle vegetation rise much *above* the level of the thermometers, while in Britain there is generally a grassy sward nearly 4 feet *below* them. These differing kinds of vegetation nevertheless largely influence the character of climates, and their effects ought not to be eliminated even although it could be done. The results which have been obtained in a jungle should not, however, as I have already said, be mixed up with those of other places which have a free exposure. The truth is that by adopting different kinds of protecting boxes, and by varying sufficiently their levels above the ground, we may so far depress the temperature of a hot country and exalt that of a colder, as *instrumentally* to equalise them.

There is but one mode of getting results which shall be comparable, and that is by adopting the same standard height and the same standard form of protecting box. The results may, however, be vitiated in another way by placing the instruments near or under shelter of buildings, or still more, by the monstrous system of fixing them to the walls of houses; for masses of masonry or other building materials prevent either extreme from being recorded by the instruments. It must also be kept in view that however valuable continuous registrations may be, in showing intermediate variations of temperature, no photographic self-registering thermometer hitherto constructed gives any result which can be regarded as correct because it does not record the temperature of the air of the locality and is not comparable with those of common thermometers, nor even, perhaps, is ever comparable with those of other similar self-recording instruments. The house or framework with which the instruments are necessarily connected cannot fail variously to affect the mercury in the bulb and thus to veil the results. The only mode of counteracting this influence is to have common thermometers in the neighbourhood placed and protected in the usual way and to record their indications eight or twelve times in the course of the twenty-four hours.

It must be kept in view that I have been speaking only of local climates, or those which are subordinate to the *normal climate* due to geographical position. That such great climatic zones due to latitude exist and vary as we recede from the equator towards the poles is abundantly evident, both from the animal and the vegetable world. The best mode of investigating these climatic zones would be to select stations as little affected as possible by surrounding vegetation, the instruments being exposed as freely as possible all round and placed at the same level above the ground, and as nearly as possible at the same level above the sea, so as to avoid confusion with what have been termed the climatic zones of altitude. For this purpose I venture to suggest the use of an instrument which I proposed in 1870,[1] the indications of which depend on the heating up of a *large quantity of water* or other fluid contained in a thin glass globe which is freely exposed to the sun's rays. When the water expands under the influence of heat, the surplus fluid escapes into an adjoining vessel in which it can be afterwards weighed. On the other hand when the fluid is contracted by cold, the deficiency is continuously supplied from a connecting cistern kept always at the same, or sensibly the same, level. By this automatic arrangement the whole of the heat given out, however irregularly, by the sun, is constantly treasured up. The readings of maximum and minimum thermometers would also serve to correct errors due to the proximity of the tubes and cisterns of the instrument to which I have referred. The difference between the results of this and the common thermometer is the continuous registration of the alterations in bulk produced by the variations of temperature; whereas the common thermometer fails to record the many changes that take place between the maximum and minimum readings, and which are due to sudden obscurations and revelations of the sun caused by passing clouds during the day, while the terrestrial radiation at night is similarly affected. Even where this instrument is not used it would I think be an improvement on the present system were maximum and minimum thermometers kept constantly immersed in a large globe of thin glass filled with water.

THOMAS STEVENSON

VOLCANIC PHENOMENA DURING 1875

DR. GUSTAV TSCHERMAK'S *Mineralogische Mittheilungen* (1876, 2) contain a most interesting account of the volcanic occurrences during the year 1875, computed by Prof. C. W. C. Fuchs. In the short introduction Dr. Fuchs expresses his regret that the scientific academies and societies do not give more general attention to this most important branch of geological research, and points out that through the numerous and universal relations of the institutions in question the statistics of volcanic eruptions and earthquakes would become far more correct in details and numbers, than it is in his own power to make them. The publication of the valuable information now given by Prof. Fuchs therefore all the more deserves the highest praise and attention. Dr. Fuchs divides the events into two classes, viz., eruptions and earthquakes. The first volcano treated of is—

Ætna.—After the short eruption of August 29, 1874, which lasted until the beginning of September, the mountain was perfectly at rest. Early in January, 1875, there were signs of new activity in the shape of repeated shocks, which, on the 8th, caused considerable damage near Acireale. But the shocks decreased again both in frequency and intensity, and a new period of rest ensued until the beginning of October. At that time a small crater on the south-side of the mountain became slightly active. From December 19, smoke mixed with reddish vapours was seen to rise, and the reflection of subterraneous fire could be seen from Acireale.

---

[1] *Journ. Scott. Met. Soc.*, vol. iii. p. 114

Vesuvius.—With the exception of a small eruption on July 18, 1874, this mountain had only given off clouds of smoke, and had come to complete inactivity by the end of [illegible] from [illegible] slight earth[illegible] noises [illegible]ces. Only in December the in[illegible] to return. In the interior of the large [illegible] considerable changes took place, a great [illegible], towards the south[illegible], fell in, and thick clouds of black smoke rose at this spot. [illegible] the 20th the glow of fire was seen in the crater, and all other phenomena increased in intensity, however, without it coming to an eruption by the close of the year

Iceland.—The eruptions which occurred in this country during 1875 are the most important ones of all. They were numerous and followed each other in quick succession, some of them with extreme intensity The first one was a side-eruption of the Vatna, which began with vehement earthquakes on January 2. A broad stream of red-hot lava broke forth on the following day and continued to flow until the third week of February. About this time a second eruption began in another locality. This was preceded by a copious fall of ashes spreading over Kelduverfet. The crater of this second eruption lies within one of the largest prehistoric lava fields, called Odarhaun A third eruption took place on March 10 to the north of the latter, no less than sixteen small craters ejected masses of red-hot slakes, and more to the west a broad stream of incandescent lava flowed for several days to a distance of 600 yards The fourth eruption was perceived on the whole of the island It occurred on March 29 on the Vatna, and was accompanied by loud reports and subterraneous noise. The most remarkable phenomenon in this eruption was an enormous fall of ashes, which was so dense in Oesterland that the sun was darkened and lights had to be lit. The ferry on the Yokul river could not penetrate for several days the enormous masses of floating pumice stone The fall lasted five hours in the Yokul Valley, three in the Fljotr Valley, and two at Seydisfjord A strong west wind carried particles of these ashes to enormous distances, *i.e.*, to Norway and Sweden. (We have repeatedly reported on the ashes found in those countries at that time, and upon their origin.) Another prolonged eruption took place on April 4. The active crater this time lay to the south of Burfell, and the phenomenon was accompanied by violent explosions and the ejection of high garbs of incandescent slakes. It lasted about twelve days. The next eruption happened between April 20 and 24 in the so-called Oster Mountains Matter was ejected to an enormous height and streams of lava overflowed the environs to a distance of fifteen miles at a breadth of from 800 to 2,000 metres Towards the end of June another new crater formed and several lava streams broke forth near Thingo, between Vivatn and the Yokulsan. The last eruption, another very violent one, occurred on August 15 at the same place as the last. Twenty different columns of smoke were ejected, and on the next day slakes and red-hot lava followed.

Klot.—This volcano, one of the less known mountains of Java, had a great eruption early in 1875, according to news dated February 3 An enormous stream of lava completely destroyed the settlement of Blikar, besides causing great damage in other localities.

[illegible] Mexican mountain (situated at lat. 21° 25′ N.), which rises to a height of [illegible] metres (1,525 metres above sea-level) was believed extinct since the discovery of America, its first historical eruption taking place in 1870. Another great eruption followed on February 11, 1875, together with violent earthquakes, which particularly damaged St. Cristobal and Guadalaxara. On the evening of February 10 a fall of ashes occurred, and a high garb of fire rose in the night.

Mauna Loa.—A crater on the summit of the Mauna Loa, called Mukunweoweo, had an eruption of lava on August 11, 1875, but more detailed accounts have not reached Dr. Fuchs. This is the same crater which sometimes causes the whole island of Hawaii to be covered with the so-called "hair of the Goddess Pele," a fine thread-like obsidian, resembling fine threads of cotton.

Tongariro.—This volcano, situated in New Zealand, was active in the second half of 1875, and from time to time ejected lava and slakes. At intervals great geyser eruptions occurred, [illegible] one time more than fifty jets of hot water, surrounded by vast columns of steam, were counted.

Santorin.—Since the last eruption the fumaroles on the island of Santorin were extremely active. On October 10, 1875, M. Fouqué observed numerous openings ejecting gases, not differing much from air in a chemical sense. During the night they [illegible] the reflection of fire, and the stones surrounding the [illegible] were red-hot. A second group of fumaroles yielded [illegible]us, carbonic, and hydrochloric acids, their temperature varying from 110° to 310° C. Yet another group ejected sulphuretted hydrogen, carbonic acid, and water-vapour, at a temperature of 90°-99° C

Speaking of earthquakes, Dr Fuchs gives a complete list of all the earthquakes and terrestrial shocks which were felt in different parts of the globe during 1875, and they amounted to no less than ninety-seven in number, occurring on 100 different days. We regret that our space does not permit us to enumerate them, but compels us to confine ourselves to an account of the distribution of their number over the different months. Thus we have in January, 15; February, 7; March, 12; April, 7; May, 9; June, 10; July, 6; August, 5; September, 3; October, 2; November, 9; December, 12. Of fifty-two of which exact details could be obtained, thirty-six occurred in the night. On ten days earthquakes occurred simultaneously in different localities, and fourteen distinct places were repeatedly visited by them during the year. The most lamentable of all—real catastrophes—were those of Cucuta, on May 16-18, destroying several towns and numerous villages, and of St. Cristobal and Guadalaxara (February 11), which reached from the Pacific Ocean to Leon. Very severe were the earthquakes of the Lifu Island (March 28), of Uschak (May 3-5 and 12), of Lahore (December 12), and of Porto Rico (December 21). Altogether Dr. Fuchs estimates the number of lives lost in these earthquakes at 20,000, not to speak of the great damage to property. In conclusion the author gives an account of those earthquakes which were in evident connection with the eruptions of neighbouring volcanoes; and also mentions a few whose causes were undoubtedly not volcanic but mechanical phenomena. In a short appendix Dr. Fuchs gives some details of an eruption which occurred between September 7, 1873, and January 22, 1874, on the Island of Vulcano (one of the Lipari Isles), in continuation of his Report for 1874

BIOLOGICAL NOTES

Broca's Stereograph.—A very ingenious instrument for taking mathematically accurate drawings of human crania and other objects of natural history, known as Broca's stereograph, has been lately presented to the College of Surgeons by the President, Mr. Prescott Hewett, which will prove a useful adjunct to the systematic study of the important anthropological collection now contained in the museum. It was exhibited and its use demonstrated by Prof. Flower at his concluding lecture on the Comparative Anatomy of Man.} Among recent additions to this department of the collection are the valuable series of skulls of natives of New Guinea, collected by Dr. Comrie, Staff-Surgeon R.N. of H.M.S. *Basilisk*, described in the last number of the *Journal* of the Anthropological Institute; also four of natives of the Navigation or Samoan Islands, presented by Dr. Pye Smith On several occasions during the course, Prof. Flower pointed out the necessity of far larger series of human skeletons and skulls than are at present contained in our museums, before our knowledge of physical anthropology can be placed on a satisfactory basis, as the individual variations are so great that it is only when a considerable series of any race are brought together that their true characteristics can be determined.

Tendrils of Climbing Plants.—M. Casimir de Candolle publishes some interesting observations on the tendrils of climbing plants in the *Archives des Sciences Physiques et [illegible]* (January). The experiments the author made were suggested to him by reading Mr. Darwin's work on the movements and habits of these plants. With regard to the manner [illegible] composed of two segments which are curved in opposite directions. The curvatures increase gradually in both segments, and ittle by little transform themselves into two screws, of which he upper one is turned from left to right. The primitive sinuous urve very often spreads over nearly the whole of the tendril, nd in this case only two screws are produced, wound, of course, n opposite directions. In all cases, with very few exceptions, he number of screws thus produced in the tendrils is an even ne, and M. de Candolle demonstrates that the cause of this henomenon is a simple mechanical law.

EYELESS CRUSTACEANS.—A valuable paper on the eyeless, ave, and deep-water crustaceans, by M. Alois Humbert, is ublished in the same periodical. It is principally a minute decription of *Niphargus puteanus*, which M. Humbert believes to e an ancient genus, descended from a form which is now exinct, thus corresponding entirely with *Proteus*, *Leptoderus*, *Anohthalmus*, and others. With regard to the question whether e *Niphargus* found in the Swiss lakes are merely colonies from he other animals of the same genus, which inhabit subterraneous aters, or whether the reverse is the case, the author expresses imself as follows:—If we suppose that the genus *Niphargus* ppeared before the ice period, it is impossible to say anything ith regard to its place of origin. But, if we do not suppose it date so far back, and only look at the present fauna, I incline the belief that the *Niphargus* of our Swiss lakes originate om those inhabiting subterraneous waters. When they reached e lakes they acclimatised themselves at depths where they und the darkness sufficiently intense, and in such a zone, all ut completely dark, where they found the necessary conditions for eir existence. In a more illuminated zone they could not have scaped from their enemies so easily and could not sustain the cometition with their fellow-inhabitants, which possessed better visual rgans. If we consider the greater dimensions attained by the rms inhabiting caves, it seems that the lake species, although ving in vaster bodies of water, yet find themselves in conditions hich are less favourable to their development and are suffering, it were, from atrophy.

ORIGIN OF THE FLYING-POWER OF BEES.—The following teresting experiments made with bees, by Herr Donhoff, are corded in the *Archiv fur Anatomie und Physiologie*. He took me bees from the hive, just as they came out of the entrance ole, and placed them under a glass bell at a temperature of 9° C. (66° F.). First they ran hastily up and down the sides of e glass and flew about in the jar. Later on their movements ecame less hasty, and after forty-five minutes they all sat quietly gether, moved slowly and clumsily. They were no longer able fly about. He let a few crawl upon a pencil, and by giving a jerk threw them into the air; they fell down perpendicularly ithout giving a humming sound, *i.e.*, without moving their ings. He killed and opened one or two and found their oney-bags empty. To the others he then gave a solution of gar, and after they had fed for about 3½ or 4 minutes he again rew some into the air. They no longer fell down perpendicularly ut a little further off, and also moved their wings. A minute terwards they did not fall down at all but flew to the window; ey had become the same lively insects as before. If the temerature is under 19° C. they lose the power of flying even sooner, d a longer period elapses before it returns after they are fed sugar-water. In higher temperatures the power returns oner. Herr Donhoff thinks it probable "that the bee loses e power of flying because it does not possess the necessary rength to be converted into muscular action, and that this rength returns to its system because in sugar it finds the necesry vital support."

THE BIRDS OF CELEBES.—In the March session of the German rnithological Society Dr. Reichenow gave a detailed account of the birds of the Island of Celebes. Although this island is classed geographically with Borneo, Java, and Sumatra in the Sunda group, yet its fauna is almost entirely distinct from that of the other islands mentioned, approaching very closely to the Australian fauna. Late investigations show that this is peculiarly true of the ornithology of Celebes, and that in the geographical distribution of animals, the island must be classed with Australia, New Guinea, &c., and not with the other members of the Sunda group. The speaker exhibited six new varieties of Australian Colibris lately found in Celebes.

ITALIAN PLIOCENE EQUIDÆ.—Dr. Forsyth Major (Florence) will shortly publish a work embodying the results of his long and diligent researches on the Italian Pliocene Equidæ which will form a very valuable contribution to the evolutional history of the *Horse*. The publication of the book—illustrated with numerous finely executed plates—is being prepared by the Swiss Palæontological Society, under the supervision of Prof. Rutimeyer. A short *résumé* of some parts of the work appeared some time since in the *Rivista Scientifico-Industriale*.

DEVELOPMENT OF MOLLUSCA.—Dr. Packard, of Salem, Mass., writes with reference to Prof. Lankester's review of his work entitled "Life Histories of Animals, including Man" (NATURE, vol. xv., p. 271), to the effect that on p. 112 of the work in question, and also on p. 110, Prof. Lankester's name is cited by him as the authority for the use of the word "trochosphere." The paper in which Prof. Lankester proposes the term "veliger" is quoted on p. 113. This he considers sufficient reply to the reviewer's statement that he (Dr. Packard) does not ascribe, either the terms "veliger" or "trochosphere," or the views connected with them, of which he makes use, to their author.

PARTHENOGENESIS IN A PHANEROGAM.—Prof. Kerner, of Innsbruck reprints from the "Sitzb. der k. Akad. der Wissensch. zu Wien" an account of a remarkable instance of parthenogenesis in a flowering plant. The instance is a small Alpine Composite, *Antennaria alpina*, a native of the high Alps and Arctic region. Like some other allied species it is diœcious, and the male plants are extremely scarce. Prof. Kerner has never seen the male plant, and in 1874 cultivated the female plant with very great care in the botanic garden at Innsbruck, excluding apparently all possibility of foreign impregnation either by this or any allied species. The plants produced, notwithstanding, a number of seeds, which were sown the following spring. Six of these seedlings germinated, but four out of these shortly perished. The two remaining ones reached maturity, growing as luxuriantly as the mother plant, and showing no signs of hybridisation. It is not stated, however, whether they also flowered and produced seed. From the extreme scarcity of the male plant, Kerner believes that the seeds are ordinarily matured without impregnation.

RESPIRATION OF ROOTS.—From recent experiments on the respiration of roots (the plants employed being ivy and veronica) MM. Deherain and Vesque conclude (1) That oxygen is necessary for all organs of plants, and that for the life of a plant it is not sufficient that its air-parts be in air; the roots must also find oxygen in the atmosphere of the ground in which they grow; (2) That the absorption of oxygen which takes place through the roots is accompanied with only a slight development of carbonic acid, so that the roots produce a partial vacuum in vessels in which they are contained; (3) That this development of carbonic acid takes place just as well in an atmosphere without oxygen as in one which contains it; whence may be inferred that the excreted carbonic acid does not come from superficial oxidation of some self-decomposing organs, but from a regular circulation of gases in the plant.

NOTES

FIFTY-SEVEN candidates for the Fellowship of the Royal Society have offered themselves during the present session. From these the Council have selected the following fifteen to be recommended to the Society for election at the annual meeting on June 7 next:—Prof. James Dewar, M.A.; Sir Joseph Fayrer, M.D., K.C.S.I.; Rev. Norman Macleod Ferrers, M.A.; Thomas Richard Fraser, M.D.; Brian Houghton Hodgson, F.L.S.; John W. Judd, F.G.S.; William Carmichael M'Intosh, M.D.; Robert M'Lachlan, F.L.S.; Prof. John William Mallet, Ph.D.; Henry B. Medlicott, M.A.; Henry Nottidge Moseley, M.A.; Prof. Osborne Reynolds, M.A.; William Roberts, M.D.; Prof. James Thomson, LL.D.; Prof. William Turner, M.B.

THE scientific men selected this year by the Universities of Edinburgh and Glasgow for the degree of LL.D. are well deserving of the honour. Among those on whom Edinburgh has conferred it are Mr. George Gore, F.R.S., Mr. J. B. Lawes, the well-known scientific agriculturist, Dr. Reinhold Rost, principal librarian to the India Office, and Mr. John Westlake, Q.C. Glasgow has given her degree to Prof. Andrews, F.R.S., president, and Prof. Allan Thomson, president-elect of the British Association.

THE Council of the Royal Microscopical Society have resolved to institute a lecture in memory of the late Prof. John Quekett, to be delivered from time to time by eminent microscopists, to whom will be presented the Quekett Medal provided out of the Medal Fund collected some years since. The first of these lectures will be delivered in the theatre of King's College on May 2, at 8 P.M., by Sir John Lubbock, Bart., M.P., F.R.S., the subject being "On Some Points in the Anatomy of Ants."

MR. WARD HUNT stated in the House of Commons last week that the deductions of the Astronomer-Royal with respect to the late transit of Venus will be ready in about six weeks, but that some months must elapse before the photographic records will be completed, without which the report would be imperfect.

THE Paris Academy of Sciences held its anniversary on the 23rd inst., Vice-Admiral Paris being in the chair. Only one national prize was awarded this year to M. Darboux for a memoir on "Singular Integrals," obtained in the solution of the differential equations of the first order. This work, of exceptional excellence, will be published in "Recueil des Savants Étrangers" at the expense of the Academy. A number of minor prizes were awarded for memoirs in botany, chemistry, medicine, &c. But the largest number of rewards were distributed amongst authors of works already published and not specially written for competition; this is a laudable innovation. The following are some of the awards:—The prize for the progress of the application of steam to the military navy to M. Ledieu, as author of an elementary treatise on "Marine Engines." The Poncelet Prize to M. Kretz, an engineer in the French Civil Service, for his publication of Poncelet's works on "Mechanics." The Delmont Prize to M. Ribaucourt, engineer of Ponts et Chaussées, for his geometrical disquisitions on the tri-orthogonal system. M. Violle was rewarded by a donation of 80*l.* for his researches on the heat generated by the sun; MM. Vicaire by a donation of 40*l.* each for similar researches. The Monthyon Medal to M. Melsens for his method of working mercury ores, as practised at Ydria, where working men have been effectually protected against toxical emanations. M. André took one prize for his experiments on the causes of the "black drop" seen by some observers of the transit of Venus last century. M. Gaugain obtained a similar reward for his long continued observations on tourmaline and other electrical disquisitions. The Cuvier prize was awarded to M. Fouqué, the celebrated Santorin and Etna explorer. MM. Filhol and Velaine obtained one prize each for the excellent zoological preparations collected at St. Paul and at Campbell Islands on the occasion of the last transit of Venus. M. Palisa, director of the Pola Observatory, obtained the Lalande Medal for the discovery of nine small planets and the rediscovery of Maia, lost from 1861 to 1876. The usual number of prizes have been proposed for 1877 and following years. A programme stating the conditions will be sent to any person writing to the secretary of the Academy of Sciences. No limitation of nationality is imposed, and the necessity of writing in French or Latin is practically abolished, at least for several of the prizes. A sum of about 4,000*l.* is to be distributed amongst thirty-eight different competitors, exclusive of the Breant prize. M. Dumas read the *éloge* of MM. Brogniard, two naturalists who were influential members of the Academy of Sciences, and whose lives were long associated in kindred work. The eminent perpetual secretary obtained one of the greatest successes of his whole academical career. The address was a masterpiece, most carefully written and admirably delivered.

A LECTURE delivered in Washington in the beginning of April, at the opening of the summer course of the National Medical College, by Dr. Elliott Coues, the well-known ornithologist, has attracted some attention in America not only by contrast with similar addresses, but for its mode of treatment and advanced views in discussing the bearings of anatomical science on the question of the origin of species and man's place in nature.

A VERY extensive Etruscan necropolis has been discovered at Montelparo, near Ascoli Piceno (Umbria). An enormous quantity of bronze, iron, and terra-cotta objects have been and are being found in the grounds, chiefly consisting of helmets, armillas, collars, buckles, nails, spurs, bows, rings, lances, spears, swords, and thousands of perforated bronze grains or beads, besides numerous objects of amber, glass, shells, and pottery, all of which are likely to be secured by the Italian Government for the Florentine Museums.

THE Bradford Scientific Association *conversazione*, we are glad to hear, has been a great success, over 1,600 persons having visited it. It was held for two days—Wednesday and Thursday, April 11 and 12—and the members were so encouraged by the support received, that they continued the exhibition until the Saturday. Over 100 microscopes were shown nightly, and the collective display of physical and chemical apparatus has, we believe, not been equalled in the north. The society introduced a novel feature in the management of the affair—admitting those engaged in teaching at a reduced charge, while demonstrations on various subjects took place each evening, according to a printed time table, given to each person on entrance. They endeavoured to take as their model the Loan Collection at South Kensington. This enterprising society have demonstrated the immense educational value which a collection of scientific instruments must have, if accompanied by proper explanation. They are so satisfied with the success, that they will attempt things on a much larger scale in the future.

IT was announced at the last meeting of the Paris Geographical Society that the expedition organised to investigate the possibility of cutting a channel through the Isthmus of Darien has proved a failure.

TWO Prussian officers have arrived in Paris for the purpose of determining telegraphically the longitude of Berlin. Two French officers have been despatched to Berlin in order to carry out similar operations. The apparatus to be used in Paris have been located at Montsouris under the superintendence of M. Mouchez and [illegible]. The ultimate aim of he operation is to connect the French trigonometrical triangulation with the system of the Geodesical International Association, which is covering almost the whole of Europe.

We recently announced that Mr. Siddal, of the Chester Society of Natural Science, had detected Radiolarians in Carboniferous imestone. At a meeting of the Society lately it was announced hat another member of the Society (Mr. Shrubsole, F.G.S.) had disovered both Foraminifera and Radiolarians in the chalk of the North Wales border.

Mr. George Cross, of Chester, a member of the Chester Natural Science Society, and conductor and teacher of the classes formed in that city under the auspices of the Government Science and Art Department, died on the 16th inst. at the early age of forty. As an able scientific man of genial disposition and kindly feeling his loss is deplored by a large circle of friends.

The Agricultural Society of France is building a large hotel n the Rue de Bellechasse at Paris, which will be fitted with every convenience for meetings and lectures, including museum and libraries. The expenses are defrayed by a benefactor who has taken effectual measures to conceal his name. The cost will be more than 20,000*l.*

The Society of Arts are prepared to offer prizes of 5*l.*, 3*l.*, and 2*l.* respectively, and certificates, for proficiency in qualitative blowpipe analysis. The competition is open to any person, but as it is intended principally for those interested in the mining ndustries of Devon and Cornwall, the examination will be held n the centre of the mining districts. The arrangements will be n the hands of the committee of the Miners' Association, and ntending candidates should apply to the honorary secretary of the Association, Mr. J. H. Collins, Lemon Street, Truro. The examination will be held at Redruth, from 5 to 9 P.M., on Tuesday, June 5, 1877.

The subject of the Rhind Lectures on Archæology in connection with the Society of Antiquaries of Scotland this year is:—"Do we possess the means of determining scientifically the condition of primeval man and his age on the earth?" The lectures, six in number, commenced yesterday, the lecturer being Dr. Arthur Mitchell.

At four o'clock on Monday morning a sharp shock of an arthquake was felt at Oban. The motion was undulatory, accompanied by a rumbling noise, and terminating in a sort of jerk. The motion did not last above six seconds. Furniture and articles of household use were jerked upwards, and pieces of crockery were thrown from the shelves. A lighter shock was felt in the Island of Kerrera last week, and a short time ago a shock was felt in Tobermory, Island of Mull.

At the first meeting for the year of the West Riding Geological and Polytechnic Society held at Ripon on April 4, the Marquis of Ripon gave an address on scientific pursuits and their results. He advocated thoroughness in all such work, and urged his hearers not to accept facts without complete investigation, nor yet stubbornly to reject facts because they did not accord with heir own preconceived ideas.

Under the title of "Giuseppe de Notaris, sua Vita e sue Opere," an interesting sketch of the life of this eminent botanist, who died in January last, is published, reprinted from the olumns of the Roman journal, the *Opinione*. De Notaris was a member of a noble but poor Italian family, and was born at Milan in 1805. Brought up to the medical profession, he early devoted himself to the study of botany, and filled botanical chairs successively at Milan, Turin, Genoa, and Rome. His labours were directed mainly to the description and the principles of the classification of cryptogams, especially of mosses, in which his services to science are very great and his publications very numerous. Until the last few years his labours received but little recognition by the State, and the publication of their results was frequently interrupted by his poverty; but the Municipality of Genoa did itself immortal honour by publishing at its expense his important "Epilogo della Briologia italiana." In 1872 de Notaris was elected a foreign member of the Linnean Society of London.

The Mathematical and Physical Sections of the Russian Geographical Society discussed at a recent meeting a scheme for the thorough exploration of the Lower Angara outflow of Lake Baikal, the pecuniary means for the purpose being offered by M. Sibiryakof. The navigability of this important water-communication would be the principal problem to be solved by the explorers. At the same meeting M. Vojeikoff described the results of his meteorological travels to British India.

Some striking experiments have been lately made by M. Daubrée, on the physical and mechanical action of strongly-compressed incandescent gas arising from combustion of powder. In one case a thin steel plate (23 sq. ctm. surface), rolled up, was inclosed in the chamber along with 12 grm. of powder, which was fired by electricity. The steel was completely fused, and transformed into an ingot curiously twisted and swollen, resembling the ferruginous skeleton of some meteoric irons. A good deal of the iron had passed into the state of sulphuret, found as a fine powder. These remarkable changes must have occurred in a fraction of a second. In another series of experiments the gases formed had opportunity of escape by a small orifice in the side of a hollow cylindrical cock (with conical top) adapted and screwed into the chamber. Here the hot particles of gas fused and carried off the steel in the state of fine powder, which was sulphurised immediately. The cock was put considerably out of shape, deep sinuous furrows being made in its surface, and in one case reaching the central cavity so as to make a second orifice, while the terminal cone wholly disappeared. An abundant metallic dust, incandescent, was projected into the atmosphere. Analogous phenomena probably occur in volcanoes, meteorites, &c.

Our readers will remember the announcement made by us some time ago of the shipment of a consignment of white-fish eggs, furnished by the United States Fish Commission, to Wellington, New Zealand. We are happy to state that, as the result of this action, a report has been received of the safe arrival of these eggs at Wellington in good condition. The young fish at the end of five days from the time of hatching, were three-quarters of an inch long, very transparent, with bright yellow eyes, and very lively, apparently doing well.

According to a recent Austrian census it appears that the percentage of cretinism ranges from a small figure up to as high as forty in the different districts of the Alpine parts of the empire. The proportion to every ten thousand inhabitants is, in the Salzburg district, 40; in Upper Austria, 18·3; in Styria, 17; in Silesia, 10; in Tyrol, 4·6, &c.

The last number of the *Isvestia* of the Russian Geographical Society contains some extracts from the journal kept by Dr. Miklucho Maclay during his cruise in Western Micronesia, from March to June, 1876. In the early part of March, after visiting the Island of Geby, lying under the equator, Dr. Maclay, about the end of March, passed by Auropic Island, the inhabitants of which he describes as not very dark, with thick curly hair. Thence he proceeded to Mogemos, or Mackenzie Island, Woap Island, and others, on his way to the Pelew Archipelago, where he stayed about two weeks, studying very interesting specimens of the "picture-writing" and folk-lore. The shameful exportation of the inhabitants by whites, which he had opportunity of witnessing during his cruise, will be the subject of a special report. From the Pelew Islands the indefatigable traveller proceeded to the southern and then to the northern shore of Admiralty Island, noticing the remarkable prognathous development of the Melanesian natives of this island, as well as those of the island Agomes, of the Hermite Archipelago. After a short visit to the Ninigo Islands, Dr. Maclay returned to the shore bearing his name, the natives of which received him very kindly. He built a house for [illegible], where he intended to remain, pursuing his anthropological researches.

THE *Journal of Forestry and Estates Management* is the title of a new shilling monthly, which will appear on May, 1 published by Messrs. J. and W. Rider, of Bartholomew Close, E.C. It will be devoted to the interests of Arboriculture in its scientific, practical, and economic aspects, and will give a large portion of its space to matters appertaining to the general management of estates.

WE have received through Mr. Tucker, from Mr. J. M. Wilson, Rugby, two guineas towards the Gauss Memorial Fund.

THE inventor of the new electric seismograph referred to last week is not Father Secchi, but Father Cecchi, of the Scuole pié at Florence.

THE additions to the Zoological Society's Gardens during the past week include a Rusa Deer (*Cervus rusa*) from Java, presented by Mr. A. A. Frazer, F.Z.S.; a Bay Bamboo Rat (*Rhizomys badius*) from India, presented by Mr. J. Wood Mason; a Horned Lizard (*Phrynosoma cornutum*) from Texas, presented by Mr. T. Clover; a Brown Monkey (*Macacus brunneus*) from Assam, deposited; a Demeraran Cock of the Rock (*Rupicola crocea*) from Demerara, purchased; two Chinchillas (*Chinchilla lanigera*), born in the Gardens.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, March 15.—"On the Tides of the Arctic Seas.—Part VII. Tides of Port Kennedy, in Bellot Strait." (Final Discussion.) By the Rev. Samuel Haughton, M.D. Dublin, D.C.L. Oxon., F.R.S., Fellow of Trinity College, Dublin.

The tidal observations at Port Kennedy were made hourly for twenty-three days; and in my former discussion of these tides (Part VI.) I used only the observations made in the neighbourhood of H. W. and L. W., obtaining the following results for the tidal coefficients :—

Diurnal Tide.	*Semidiurnal Tide.*
$S = 23{\cdot}4$ inches.	$S = 7{\cdot}0$ inches.
$i_s = 5^h\ 12^m$.	i_s = ,,
$M = 20{\cdot}9$ inches.	$M = 17{\cdot}0$ inches.
$i_m = 0^h\ 33^m{\cdot}8$.	$i_m = -\ 0^h\ 12^m$.

In the present discussion I have employed all the hourly observations made during the twenty-three days, and have obtained the following results :—

Diurnal Tide.	*Semidiurnal Tide.*
$S = 36{\cdot}4$ inches.	$S = 5{\cdot}9$ inches.
$i_s = 3^h\ 2^m$.	$i_s = 2^h\ 48^m$.
$M = 18{\cdot}5$ inches.	$M = 15{\cdot}5$ inches.
$i_m = -\ 2^h\ 48^m$.	$i_m = 6^h\ 2\frac{1}{2}^m$.

The present more complete discussion fully confirms the result before obtained by me, respecting the great magnitude of the solar diurnal tide at this station, and also shows a satisfactory agreement in the other coefficients obtained from H. W. and L. W. observations only.

The method employed in the present paper is based on Fourier's Theorem, by which the height of tide is expressed as follows :—

$$F = A_0 \begin{array}{l} + A_1 \cos s + A_2 \cos 2s + \&c., \\ + B_1 \sin s + B_2 \cos 2s + \&c., \end{array}$$

where

F = height of water.
s = hour-angle of sun.

The coefficients A_0, A_1, A_2, B_1, B_2, &c., being found by wel known formulæ, they are again expressed, by Fourier's Theoren as follows :—

$$A_n = a_0 \begin{array}{l} + a_1 \cos u + a_2 \cos 2u + \&c. \\ + b_1 \sin u + b_2 \sin 2u, \end{array}$$

where u passes through all its changes in a fortnight, and tl coefficients are calculated in a similar manner.

The known theoretical formulæ for the diurnal and sem diurnal tides, expressed in terms of parallax, declination, lun and solar, hour-angles, are now converted into functions of tl true and mean anomaly, and of the sun's hour-angle, and final into simple functions of s and u. These expansions are no compared, term by term, with the terms of the tidal expansio found by means of Fourier's Theorem, and the final lunar ar solar tidal coefficients calculated out with ease.

Although the short period of observation at Port Kenne (23 days) renders this method of discussion not much mo valuable than the usual method of H. W. and L. W. observ tions, I have developed it at length in the hope of applying tl method to more complete series of Arctic tides, which I ho shortly to lay before the Royal Society.

March 22.—"On Friction between Surfaces moving at Lo Speeds," by Fleeming Jenkin, F.R.SS. L. and E., Professor Engineering in the University of Edinburgh, and J. A. Ewing

The common belief regarding friction, which is based on tl researches of Coulomb and Morin, is that between surfaces motion the friction is independent of the velocity, but that tl force required to start the sliding is (in some cases at leas greater than the force required to overcome friction durir motion; in other words, the static coefficient is usually co sidered to be greater than the kinetic. It occurred to tl authors that there might possibly be continuity between the tw kinds of friction, instead of an abrupt change at the insta in which motion begins. We should thus expect that when tl relative motion of the surfaces is very slow there will be a gr dual increase of friction as the velocity diminishes. Whether a such increase takes place at very low speed is left an open questi by the experiments of Coulomb and Morin, whose methods d not enable definite measurements of the friction to be made wh the velocity was exceedingly small. The authors have succeed in measuring the friction between surfaces moving with as low velocity as one five-thousandth of a foot per second, and ha found that in certain cases there is decided increase in the c efficient of friction as the velocity diminishes.

The surfaces examined were steel on steel, steel on brass, ste on agate, steel on beech, and steel on greenheart—in each ca under the three conditions, dry, oiled, and wet with water. I the cases steel on beech oiled or wet with water, and steel c greenheart oiled or wet with water, the coefficient of frictio increased as the velocity diminished between the two limi given above, the increase amounting to about twenty per cen of the lower value. It appeared that at the higher limit velocity there was little further tendency to change in the c efficient, but it is impossible to say how much additional chan might take place between the lower limit of the velocity and tl higher. In the case of steel on agate wet with water there was similar but much less marked increase of friction as the veloci decreased. And in the case of steel on steel oiled there was slight and somewhat uncertain change of the opposite characte that is, a decrease of the friction as the velocity decrease This case, however, would require further examination. In other cases the friction seemed to be perfectly constant and ind pendent of the velocity. Out of all the sets of circumstanc investigated, the only ones in which there was a large differen between the static and kinetic values of the coefficient of frictio were those in which a decided increase was observed in tl kinetic value on the speed decreased. This result renders exceedingly probable that there is continuity between the tw kinds of friction.

Linnean Society, April 5.—Prof. Allman, F.R.S., pr sident, in the chair.—Capt. Chimmo, R.N., the Rev. J. Co stable, and Prof. Liversidge, of Sydney, N.S.W., were elect Fellows of the Society.—In a[illegible] a donation from t author (Mr. [illegible], of the [illegible]), "Monograph the Genus [illegible] the Society the issue of this handsome work by the private energy of one of its members.—Sir Chas. Strickland exhibited a specimen of *Crinum aquaticum* obtained from Grahamstown, South Africa, but which showy plant hitherto has rarely been seen in flower in Britain.—A paper on ferns collected by Miss Gilpin in the interior of Madagascar, was read by Mr. J. G. Baker. Some seventeen are new out of 150 species, a fair proportion, and evidence of an unsuspected richness in this department of the Madagascar flora.—The Secretary announced a paper on the fresh-water algæ of the Cape of Good Hope, by Prof. Reinsch: this being of a technical character, and in Latin, was taken as read.—Mr. R. Collett, of Christiania, then read a communication on *Myodes lemmus* in Norway. His observations on the habits and economy of the Lemming had extended over several years, and in 1876 he had published these in *Nyt. Mag. f. Naturvsk.* But his attention had lately been called to Mr. Crotch's contributions in the Linnean *Journal*, and as in many particulars he differed from that author, the present notice resulted. The number of young at a birth vary from three to eight, and two sets are annually produced. Mr. Collett regards their wandering as a necessary consequence of their temporarily strong vitality, together with an inherent migratory instinct. The tendency at intervals to appear in unusually large numbers is not confined to the genus, but is common to all the species of the sub-family Arvicolinæ. The majority of the wanderers are young, and in one instance observed, by himself, were chiefly males. The migration closes with the death of the individuals, generally brought about by an epizootic disease, the result of over population; the denser the masses the higher the rate of mortality. The bare patch on the rump considered by Mr. Crotch to be due to the habit of protecting themselves against stones in resisting attack, Mr. Collett states is due to a skin disease. He however, supports Mr. Crotch's statement as to the number of winged and four-footed enemies which devour the Lemming, and also that domestic cattle and reindeer destroy them. Their occasional enormous increase in numbers he holds to be owing to periodic prolific years, the facility of rearing their young, and the early procreative faculty of the latter. Parallel instances among other groups of animals, for instance unusual swarms of butterflies and locusts are well known, though as to the true reason of such departures in number, &c., much is only conjectural. Coincidently with the notable years of the Lemming migrations, the increase above the normal number of rats, mice, shrews, and even the grouse tribe, have been recorded. Mr. Collett affirms that the Lemmings travel chiefly in the direction of the valleys, and not constantly due west as has been asserted; their great movements are chiefly nocturnal. He is inclined to question Mr. Crotch's notion of hereditary search for a "Miocene Atlantis," and rather is of opinion that in accounting for the periodical excess of multiplication and migratory impulse a physiological necessity impels them; the nature of this is at present beyond our power to explain rationally.—A further contribution to the natural history of swine, by Prof. Rolleston, was read in abstract, this paper forming an appendix to that previously brought under the notice of the Society. The additional information is in the main confirmatory of the views already expressed, but several important facts relative to the striping of the young of *Sus celebensis* and *S. verrucosus* according to Dr. A. B. Meyer, with information from others, necessarily causes a modification in former conclusions.—On South African Hepaticæ (Liverworts), by Mr. W. Mitten, and on new Irish Lichens, by the Rev. W. A. Leighton, were two technical papers the titles only of which were read by the Secretary.

Royal Astronomical Society, April 13, Dr. Huggins, F.R.S., president, in the chair.—Lord Lindsay read a paper on the diurnal parallax of Juno observed at Mauritius in 1874 with the heliometer, which (rejecting one discordant observation) gave a value of 8″·82 for the solar parallax.—Mr. Gill read a paper on the proposed expedition to observe the approaching opposition of Mars. Observations can be made during six weeks. At the Island of Ascension the geometrical conditions are about as favourable as possible; and what is of great importance, the meteorological conditions are no less so, the range of temperature between 6 P.M. and 6 A.M being only two or three degrees. None of the stars of comparison are of less than the eighth magnitude, and they are selected so as to determine the position of the planet in right ascension as accurately as possible. Mr. Gill proposes also to observe the oppositions of the minor planets Ariadne, Iris, and Melpomene. That of Ariadne occurs ten days earlier than Mars. Its declination will be 15° south. Melpomene has 4° north declination.—Mr. Christie explained the principle of his new form of spectroscope. It depends on the fact that the half of an isosceles prism, cut perpendicular to the base, magnifies the angle between two incident pencils, by virtue of the oblique emergence. By using a compound prism composed of a half prism of flint with a prism of crown cemented to the oblique face, to correct the deviation, the magnifying effect might be increased to ten or fifteen times. By turning the half-prism about its centre different parts of the spectrum would be brought into the field without any movement of the viewing telescope. With two half-prisms the dispersion of ten ordinary compound prisms has been obtained, and with better definition; for with ten prisms the errors of forty surfaces are accumulated. When the breadth of the lines is diminished by narrowing the slit, the spectrum is still far brighter than in the other form, for the loss by absorption is enormous, amounting to 50 per cent. for three or four inches of glass, and in the large Greenwich spectroscope only $\frac{1}{30}$th part of the incident light reaches the eye. Mr. Bidder, Lord Lindsay, and Mr. Gill offered some criticisms, and Mr. Christie replied, showing that he had anticipated all the objections offered.—Prof. Pritchard read a paper on the comets of '1877. The recent dearth of comets he attributed to the probable sleepiness of seekers. Two had been observed at Oxford, and the elements and an ephemeris of Winnecke's calculated. They had made observations on April 7 and 11, which were combined with Prof. Winnecke's of the 5h. in making the calculations.—Prof. Pritchard also read a paper on a mechanical solution of Kepler's problem.—Mr. J. W. L. Glaisher read a paper on an elliptic-function solution of Kepler's problem.—The Rev. S. J. Perry described how neither he nor his assistants could see Vulcan.—Lord Lindsay stated that M. Leverrier thought it would be useless to look for Vulcan for the next six years.

Mathematical Society, April 12.—Lord Rayleigh, F.R.S., president, in the chair.—Mr. C. Pendlebury was elected a member.—The following communications were made:—On Hesse's ternary operator and applications, by Mr. J. J. Walker.—Geometrical illustration of a theorem relating to an irrational function of an imaginary variable, and on the general differential equation $\frac{dx}{\sqrt{X}} + \frac{dy}{\sqrt{Y}} = 0$, where X, Y are the same quartic functions of x, y, respectively, by Prof. Cayley, F.R.S. (Profs. Smith and Henrici took part in a discussion on these papers, the former making remarks on the question whether infinity is a point or a straight line).—Mr. Merrifield, F.R.S., vice-president, having taken the chair, Mr. Harry Hart deduced some cases of parallel motion from the consideration that the contra parallelogram represents the motion of two equal ellipses rolling upon each other, and that of these (*i.e.*, parallel motions) two especially were very simple, inasmuch as the motion was obtained in either case by the use of five bars only and was moreover perfectly continuous.—Mr. Tucker, hon. sec., read an abstract of a paper by Prof. H. W. Lloyd Tanner, on a method of solving partial differential equations which have a general first integral, applied to equations of the third order with two independent variables.

Chemical Society, April 19.—Dr. Gladstone in the chair.—The following papers were read:—On the estimation of manganese in spiegeleisen, and of manganese and iron in manganiferous iron ores, by E. Riley. For estimating manganese in spiegeleisen the author recommends the indirect method, *i.e.*, estimating the iron, adding five per cent. for impurities, and taking the difference as manganese, for accuracy and rapidity; for the estimation of manganese in its ores the author prefers to separate the iron as basic peracetate with carbonate and acetate of ammonia, and to precipitate the manganese with bromine and ammonia, taking care that the ignited precipitate contains no baryta, zinc, or lime. For the determination of the iron a standard solution of bichromate of potash yields the best results, the iron being reduced with pure sulphite of soda.—On a method of detecting small quantities of bismuth, by M. M. Pattison Muir. The author proposes Schneider's reagent, consisting of a clear solution of 12 grm. of tartaric acid and 4 grm. stannous chloride in caustic potash; one part of bismuth in 210,000, if warmed to 60°–70° C. with this reagent, gives a brownish colour.—On certain bismuth compounds, by M. M. Pattison Muir. This paper gives an account of the properties and reactions of bismuth ferricyanide.—Notes on madder colouring matters, by E. Schunck and H. Roemer. Munjistin: this substance resembles purpuroxanthic acid in its physical properties. Purpurin: a pure specimen was examined, and its properties are given. Alcoholic lead acetate gives with purpurin dissolved in alcohol a precipitate soluble in excess, with alizarin a precipitate insoluble in excess. Triacetyl-purpurin and brom-purpurin were prepared and analysed by the authors. By heating pure purpurin in sealed tubes to 300° C. it was found to be partially converted into quinizarin.

Physical Society, April 14.—Prof. G. C. Foster, president, in the chair.—The secretary described a new form of colorimeter, devised by Dr. Mills. It consists of two vertical glass tubes about ten centimetres in length and two centimetres in diameter, and contracted at their lower ends, which are graduated in millimetres and fixed in a frame. In each tube a loosely-fitting disc of white or black glass (as occasion may require) can be raised or lowered from below by means of a glass rod fitting water-tight, and the meniscus of the liquid is concealed by a wooden screen. The two liquids under examination are introduced into the tubes to the same level, and the discs adjusted until rendered invisible.—Mr. Christie gave an account of a new form of spectroscope, in which "half-prisms" are used to magnify the dispersion (see Astronomical Society).

GENEVA

Society of Physics and Natural History, March 1.—Prof. Zahn presents preparations of the human costal cartilage, showing a fragmentary infiltration of the cellules. This infiltration is very frequent; it is observed in half of the men over forty, and especially in such as have any touch of lung disease.—Dr. Prevost described a case of aphasia observed at the Cantonal Hospital, in a young girl attacked with a right *hemiplegia*, in whom the aphasia subsisted after the cure of the hemiplegia. Though she cannot speak she has recovered the power of articulating words when she sings, and her intellect is untouched.

March 15.—M. Alph. de Candolle announced the conclusion of his work on the family of the *Smilaceæ* for the work which he will publish under the name of "Monographs of the Phanerogameæ." This family includes three principal species, *Heterosmilax*, *Smilax*, and *Riphogonum*, and is found in the division of the globe between India, Japan, and the Sandwich Islands. The first of these species is probably the most ancient.

PARIS

Academy of Sciences, April 16.—M. Peligot in the chair.—The following papers were read:—Note on a problem of mechanics, by M. Bertrand. Knowing that the planets describe conic sections, and without supposing more, to find the expression for the components of the force soliciting them, in function of co-ordinates of its point of application.—On a solar spot which appeared on April 15, by M. Janssen. While the disc had been wholly without spots on the 14th, it had, next day, a space near the centre some 2′ diameter, covered with them. This is of the order of things that occurs at a maximum; and the old idea seems incorrect that the rarity of spots at the minimum is due to an absence of activity of the photosphere. There is a tendency to prompt extinction of the phenomena.—Researches on iodic acid, by M. Berthelot.—On the theory of plane elastic plates, by M. Kirchhoff.—Determination of the differences in longitude between Paris and Marseilles, and between Algiers and Marseilles, by MM. Loewy and Stephan. The apparatus comprised a meridian instrument and pendulum, a Hipp's chronograph, a very sensitive Siemens' relay, a galvanometer, and a rheostat. The difference of longitude observed between the Paris and Marseilles instruments was 12m. 13·430s. ± 0·009s.; that between the Algiers and Marseilles instruments 9m. 23·219s. ± 0·009s. The difference of these, viz., 2m. 50·211s. expresses the difference of longitude between Paris and Algiers; which closely agrees with that got by MM. Loewy and Perrier by direct measurement (viz., 2m. 50·217s.). The velocity of transmission of the signals the authors state to be 30,000 km. per second in the aërial line and 4,000 km. in the cable.—New experiments on the origin and nature of typhoid fever, by M. Guerin. Experimenting with vomited bilious matters, bile, and fecal matters proper from the larger intestine (of typhoid subjects) introduced into rabbits by injection, he found that they rarely caused death—once in twelve experiments; while the special diarrhœic matter from the small intestine caused death almost constantly in a few hours or days. Experiments distinguishing the periods of the disease also pointed to the special toxical matter being almost entirely contained in the smaller intestine. M. Guerin offers some interpretation of these facts.—Divisibility of the electric light, by MM. Denayrouze and Jablochkoff. Using alternating currents and induction coils with interrupter and condenser suppressed, and a kaoln plate between the wires, a steady light is obtained. There is a central artery of the series of interior wires, and as many distinct conductors branch off as there are coils in the circuit. Each luminous centre is thus quite independent, and each may be extinguished or lit separately.—Discovery of a Gallo-Roman port and a Gaulish port near St. Nazaire; determination of the age of the layers at different heights (second note), by M. Bertrand.—The Phylloxera in the department of the Gironde (continued), by M. Azam. At the end of 1873 97 communes were attacked; at the end of 1876, 268.—On ozœna, by M. Brame.—Investigation of the law which must be obeyed by a central force, so that the trajectory it produces may be always a conic, by M. Darboux.—On the laws of reciprocity in the theory of the residues of powers, by M. Pepin.—On the radii of curvature of the successive podaries of a plane curve, by M. Niewenglowski.—On the rolling of ships in calm water, by M. Bourgoin.—On the state of salts in solution, by M. Gernez. His experiments contradict M. Tscherbatschew's view that saturated solutions of sulphate of soda, made under 33°, contain the hydrate with 10HO, those heated to a higher temperature the hydrate with 7HO.—On a new series of acid salts, by M. Villiers.—Transformation of ordinary pyrotartaric acid with tribromic bromhydrate of ethylene, by M. Bourgoin.—On the properties of resorcine, by M. Calderon.—Male flowers of Cordaites, by M. Renault.—Note on the calcifugal flora of the Albe of Wurtemberg, by M. Contejean.—Researches on the cardiac disorders which produce the intermittences of the arterial pulse, called *false intermittences*, by M. François Franck.—Experiments proving that the septicity of putrefied blood is not due to a soluble ferment, by M. Feltz.—On the winter of 1877 in Paris, by M. Renou. It is very rare that the minimum of the cold season falls in November or March (which show the lowest in the present case), or that March should present the lowest monthly average.—On the thunderstorm of April 4, 1877, by M. Godefroy. Figures of the hailstones are given, the form being that of a solid of revolution from a spherical pyramid.—On poisoning with salts of copper, by M. Decaisne.—On the precautions taken by tortoises against cold, and the indications they may furnish to farmers, by M. Bouchard.
